As a subsidiary aspect of the study, Zou notes that "the extract of *H. fusiforme* has an immunomodulating activity on humans and this ability might be used for clinical application to treat several diseases such as tumors (Suetsuna, 1998; Shan *et al.*, 1999)." He also reports that the alga "has been used as a food delicacy and an herbal ingredient in China, Japan and Korea." In fact, he says that it "is now becoming one of the most important species for seaweed mariculture in China, owing to its high commercial value and increasing market demand." The ongoing rise in the air's CO<sub>2</sub> content bodes well for all of these applications. In addition, Zou notes that "the intensive cultivation of *H. fusiforme* would remove nutrients more efficiently with the future elevation of CO<sub>2</sub> levels in seawater, which could be a possible solution to the problem of ongoing coastal eutrophication," suggesting that rising CO<sub>2</sub> levels may also assist in the amelioration of this environmental problem.

In light of these several observations, the ongoing rise in the air's CO<sub>2</sub> content should help marine macroalgae to become more productive with the passage of time.

### 7.1.3.4. Marine Microalgae

How do marine microalgae respond to increases in the air's CO<sub>2</sub> content? Based on the late twentieth century work of Riebesell *et al.* (1993), Hein and Sand-Jensen (1997), and Wolf-Gladrow *et al.*, (1999), it would appear that the productivity of earth's marine microalgae may be significantly enhanced by elevated concentrations of atmospheric CO<sub>2</sub>. More recent work by other researchers suggests the same.

In a study of the unicellular marine diatom *Skeletonema costatum*, which is widely distributed in coastal waters throughout the world and is a major component of most natural assemblages of marine phytoplankton, Chen and Gao (2004) grew cell cultures of the species in filtered nutrient-enriched seawater maintained at 20°C under a light/dark cycle of 12/12 hours at a light intensity of  $200 \mu\text{mol m}^{-2} \text{s}^{-1}$ , while continuously aerating the culture solutions with air of either 350 or 1,000 ppm CO<sub>2</sub> and measuring a number of physiological parameters related to the diatom's photosynthetic activity. They report that cell numbers of the alga "increased steadily throughout the light period and they were 1.6 and 2.1 times higher after the 12 h light period for the alga grown at 350 and 1000 ppm CO<sub>2</sub>, respectively." They also say that chlorophyll *a* concentrations "increased 4.4- and 5.4-fold during the middle 8 h of the light period for the alga grown at 350 and 1000 ppm CO<sub>2</sub>, respectively," and that "the contents of cellular chlorophyll *a* were higher for the alga grown at 1000 ppm CO<sub>2</sub> than that at 350 ppm CO<sub>2</sub>." In addition, they note that the initial slope of the light saturation curve of photosynthesis and the photochemical efficiency of photosystem II "increased with increasing CO<sub>2</sub>, indicating that the efficiency of light-harvesting and energy conversion in photosynthesis were increased." The end result of these several responses, in the words of Chen and Gao, was that "*S. costatum* benefited from CO<sub>2</sub> enrichment."

In another report of a study of marine microalgae that would appear to have enormous implications, Gordillo *et al.* (2003) begin by noting that "one of the main queries for depicting future scenarios of evolution of atmospheric composition and temperature is whether an atmospheric CO<sub>2</sub> increase stimulates primary production, especially in aquatic plants." Why do they say that? They say it because, as they put it, "aquatic primary producers account for about 50 percent of the total carbon fixation in the biosphere (Falkowski and Raven, 1997)."

Although the question addressed by Gordillo *et al.* sounds simple enough, its answer is not straightforward. In many phytoplankton, both freshwater and marine, photosynthesis appears to be saturated under current environmental conditions. Raven (1991), however, has suggested that those very same species, many of which employ carbon-concentrating mechanisms, could well decrease the amount of energy they expend in this latter activity in a CO<sub>2</sub>-enriched world, which metabolic readjustment

would leave a larger proportion of their captured energy available for fueling enhanced growth.

To explore this possibility, the four researchers studied various aspects of the growth response of the microalgal chlorophyte *Dunaliella viridis* (which possesses a carbon concentrating mechanism and has been used as a model species for the study of inorganic carbon uptake) to atmospheric CO<sub>2</sub> enrichment. Specifically, they batch-cultured the chlorophyte, which is one of the most ubiquitous eukaryotic organisms in hypersaline environments, in 250-ml Perspex cylinders under controlled laboratory conditions at high (5 mM) and low (0.5 mM) nitrate concentrations, while continuously aerating half of the cultures with ambient air of approximately 350 ppm CO<sub>2</sub> and the other half with air of approximately 10,000 ppm CO<sub>2</sub>. In doing so, they discovered that atmospheric CO<sub>2</sub> enrichment had little effect on dark respiration in both N treatments. Likewise, it had little effect on photosynthesis in the low-N treatment. In the high-N treatment, the extra CO<sub>2</sub> increased photosynthesis by 114 percent. In the case of biomass production, the results were even more extreme: in the low-N treatment elevated CO<sub>2</sub> had no effect at all, while in the high-N treatment it nearly tripled the cell density of the culture solution.

In discussing their findings, Gordillo *et al.* note that "it has long been debated whether phytoplankton species are growth-limited by current levels of CO<sub>2</sub> in aquatic systems, i.e. whether an increase in atmospheric CO<sub>2</sub> could stimulate growth (Riebesell *et al.*, 1993)." Their results clearly indicate that it can, as long as sufficient nitrogen is available. But that was not all that Gordillo *et al.* learned. In the high-N treatment, where elevated CO<sub>2</sub> greatly stimulated photosynthesis and biomass production, once the logarithmic growth phase had run its course and equilibrium growth was attained, approximately 70 percent of the carbon assimilated by the chlorophyte was released to the water, while in the low-CO<sub>2</sub> treatment only 35 percent was released.

With respect to this suite of observations, Gordillo *et al.* say "the release of organic carbon to the external medium has been proposed as a mechanism for maintaining the metabolic integrity of the cell (Ormerod, 1983)," and that "according to Wood and Van Valen (1990), organic carbon release would be a sink mechanism protecting the photosynthetic apparatus from an overload of products that cannot be invested in growth or stored." They additionally state that stores of photosynthetic products "are reduced to avoid overload and produce

a high demand for photosynthates.” Under these conditions, they conclude that “the process would then divert assimilated C to either the production of new biomass, or the release to the external medium once the culture conditions do not allow further exponential growth.”

A second consequence of enhanced organic carbon release in the face of atmospheric CO<sub>2</sub> enrichment and sufficient N availability is that the internal C:N balance of the phytoplankton is maintained within a rather tight range. This phenomenon has also been observed in the green seaweed *Ulva rigida* (Gordillo *et al.*, 2001) and the cyanobacterium *Spirulina platensis* (Gordillo *et al.*, 1999). Hence, what the study of Gordillo *et al.* implies about the response of *Dunaliella viridis* to atmospheric CO<sub>2</sub> enrichment may well be widely applicable to many, if not most, aquatic plants, not the least of which may be the zooxanthellae that by this means (enhanced organic carbon release) could provide their coral hosts with the source of extra energy they need to continue building their skeletons at a non-reduced rate in the face of the negative calcification pressure produced by the changes in seawater chemistry that have been predicted to result from the ongoing rise in the air’s CO<sub>2</sub> concentration.

In light of these several observations, there would appear to be ample reason to be optimistic about the response of earth’s marine macroalgae to the ongoing rise in the air’s CO<sub>2</sub> content.

## 7.2. Water Use Efficiency

Another major consequence of atmospheric CO<sub>2</sub> enrichment is that plants exposed to elevated levels of atmospheric CO<sub>2</sub> generally do not open their leaf stomatal pores—through which they take in carbon dioxide and give off water vapor—as wide as they do at lower CO<sub>2</sub> concentrations and tend to produce fewer of these pores per unit area of leaf surface. Both changes tend to reduce most plants’ rates of water loss by transpiration. The amount of carbon they gain per unit of water lost—or water-use efficiency—therefore typically rises, increasing their ability to withstand drought. In this section, we explore the phenomena of water use efficiency as it pertains to agricultural, grassland, and woody species.

Additional information on this topic, including reviews water use efficiency not discussed here, can be found at [http://www.co2science.org/subject/w/subject\\_w.php](http://www.co2science.org/subject/w/subject_w.php) under the heading Water Use Efficiency.

### 7.2.1. Agricultural Species

In the study of Serraj *et al.* (1999), soybeans grown at 700 ppm CO<sub>2</sub> displayed 10 to 25 percent reductions in total water loss while simultaneously exhibiting increases in dry weight of as much as 33 percent. Thus, elevated CO<sub>2</sub> significantly increased the water-use efficiencies of the studied plants. Likewise, Garcia *et al.* (1998) determined that spring wheat grown at 550 ppm CO<sub>2</sub> exhibited a water-use efficiency that was about one-third greater than that exhibited by plants grown at 370 ppm CO<sub>2</sub>. Similarly, Hakala *et al.* (1999) reported that twice-ambient CO<sub>2</sub> concentrations increased the water-use efficiency of spring wheat by 70 to 100 percent, depending on experimental air temperature. In addition, Hunsaker *et al.* (2000) reported CO<sub>2</sub>-induced increases in water-use efficiency for field-grown wheat that were 20 and 10 percent higher than those displayed by ambiently grown wheat subjected to high and low soil nitrogen regimes, respectively. Also, pea plants grown for two months in growth chambers receiving atmospheric CO<sub>2</sub> concentrations of 700 ppm displayed an average water-use efficiency that was 27 percent greater than that exhibited by ambiently grown control plants (Gavito *et al.*, 2000).

In some cases, the water-use efficiency increases caused by atmospheric CO<sub>2</sub> enrichment are spectacularly high. De Luis *et al.* (1999), for example, demonstrated that alfalfa plants subjected to atmospheric CO<sub>2</sub> concentrations of 700 ppm had water-use efficiencies that were 2.6 and 4.1 times greater than those displayed by control plants growing at 400 ppm CO<sub>2</sub> under water-stressed and well-watered conditions, respectively. Also, when grown at an atmospheric CO<sub>2</sub> concentration of 700 ppm, a 2.7-fold increase in water-use efficiency was reported by Malmstrom and Field (1997) for oats infected with the barley yellow dwarf virus.

In addition to enhancing the water-use efficiencies of agricultural C<sub>3</sub> crops, as reported in the preceding paragraphs, elevated CO<sub>2</sub> also enhances the water-use efficiencies of crops possessing alternate carbon fixation pathways. Maroco *et al.* (1999), for example, demonstrated that maize—a C<sub>4</sub> crop—grown for 30 days at an atmospheric CO<sub>2</sub> concentration of 1,100 ppm exhibited an intrinsic water-use efficiency that was 225 percent higher than that of plants grown at 350 ppm CO<sub>2</sub>. In addition, Conley *et al.* (2001) reported that a 200-ppm increase in the air's CO<sub>2</sub> content boosted the water-use efficiency of field-grown sorghum by 9 and 19

percent under well-watered and water-stressed conditions, respectively. Also, Zhu *et al.* (1999) reported that pineapple—a CAM plant—grown at 700 ppm CO<sub>2</sub> exhibited water-use efficiencies that were always significantly greater than those displayed by control plants grown at 350 ppm CO<sub>2</sub> over a range of growth temperatures.

It is clear from the studies above that as the CO<sub>2</sub> content of the air continues to rise, earth's agricultural species will respond favorably by exhibiting increases in water-use efficiency. It is likely that food and fiber production will increase on a worldwide basis, even in areas where productivity is severely restricted due to limited availability of soil moisture.

### 7.2.2. Grassland Species

In the study of Grunzweig and Korner (2001), model grasslands representative of the semi-arid Negev of Israel, which were grown for five months at atmospheric CO<sub>2</sub> concentrations of 440 and 600 ppm, exhibited cumulative water-use efficiencies that were 17 and 28 percent greater, respectively, than control communities grown at 280 ppm CO<sub>2</sub>. Similarly, Szente *et al.* (1998) reported a doubling of the atmospheric CO<sub>2</sub> concentration increased the water-use efficiency of two C<sub>3</sub> grasses and two broad-leaved species common to the loess grasslands of Budapest by 72 and 266 percent, respectively. In addition, Leymarie *et al.* (1999) calculated that twice-ambient CO<sub>2</sub> concentrations increased the water-use efficiency of the herbaceous weedy species *Arabidopsis thaliana* by 41 and 120 percent under well-watered and water-stressed conditions, respectively. Other CO<sub>2</sub>-induced increases in C<sub>3</sub> plant water-use efficiency have been documented by Clark *et al.* (1999) for several New Zealand pasture species and Roumet *et al.* (2000) for various Mediterranean herbs.

Elevated CO<sub>2</sub> also has been shown to substantially increase the water-use efficiency of C<sub>4</sub> grassland species. Adams *et al.* (2000), for example, reported that twice-ambient CO<sub>2</sub> concentrations enhanced the daily water-use efficiency of a C<sub>4</sub> tallgrass prairie in Kansas, USA, dominated by *Andropogon gerardii*. LeCain and Morgan (1998) also documented enhanced water-use efficiencies for six different C<sub>4</sub> grasses grown with twice-ambient CO<sub>2</sub> concentrations. Likewise, Seneweera *et al.*

(1998) reported that a 650-ppm increase in the air's CO<sub>2</sub> content dramatically increased the water-use efficiency of the perennial C<sub>4</sub> grass *Panicum coloratum*.

As the air's CO<sub>2</sub> content continues to rise, nearly all of earth's grassland species—including both C<sub>3</sub> and C<sub>4</sub> plants—will likely experience increases in water-use efficiency. Concomitantly, the productivity of the world's grasslands should increase, even if available moisture decreases in certain areas. Moreover, such CO<sub>2</sub>-induced increases in water-use efficiency will likely allow grassland species to expand their ranges into desert areas where they previously could not survive due to lack of sufficient moisture.

### 7.2.3. Woody Species

The effect of elevated atmospheric CO<sub>2</sub> concentrations on the water-use efficiencies of trees is clearly positive, having been documented in a number of different single-species studies of longleaf pine (Runion *et al.*, 1999), red oak (Anderson and Tomlinson, 1998), scrub oak (Lodge *et al.*, 2001), silver birch (Rey and Jarvis, 1998), beech (Bucher-Wallin *et al.*, 2000; Egli *et al.*, 1998), sweetgum (Gunderson *et al.*, 2002; Wullschlegel and Norby, 2001), and spruce (Roberntz and Stockfors, 1998). Likewise, in a multi-species study performed by Tjoelker *et al.* (1998), seedlings of quaking aspen, paper birch, tamarack, black spruce, and jack pine, which were grown at 580 ppm CO<sub>2</sub> for three months, displayed water-use efficiencies that were 40 to 80 percent larger than those exhibited by their respective controls grown at 370 ppm CO<sub>2</sub>.

Similar results are also obtained when trees are exposed to different environmental stresses. In a study conducted by Centritto *et al.* (1999), for example, cherry seedlings grown at twice-ambient levels of atmospheric CO<sub>2</sub> displayed water-use efficiencies that were 50 percent greater than their ambient controls, regardless of soil moisture status. And in the study of Wayne *et al.* (1998), yellow birch seedlings grown at 800 ppm CO<sub>2</sub> had water-use efficiencies that were 52 and 94 percent greater than their respective controls, while simultaneously subjected to uncharacteristically low and high air temperature regimes.

In some parts of the world, perennial woody species have been exposed to elevated atmospheric CO<sub>2</sub> concentrations for decades, due to their proximity to CO<sub>2</sub>-emitting springs and vents in the earth, allowing scientists to assess the long-term effects of this phenomenon. In Venezuela, for example, the water-use efficiency of a common tree exposed to a lifetime atmospheric CO<sub>2</sub> concentration of approximately 1,000 ppm rose 2-fold and 19-fold during the local wet and dry seasons, respectively (Fernandez *et al.*, 1998). Similarly, Bartak *et al.*

(1999) reported that 30-year-old *Arbutus unedo* trees growing in central Italy at a lifetime atmospheric CO<sub>2</sub> concentration around 465 ppm exhibited water-use efficiencies that were 100 percent greater than control trees growing at a lifetime CO<sub>2</sub> concentration of 355 ppm. In addition, two species of oaks in central Italy that had been growing for 15 to 25 years at an atmospheric CO<sub>2</sub> concentration ranging from 500 to 1,000 ppm displayed “such marked increases in water-use efficiency under elevated CO<sub>2</sub>,” in the words of the scientists who studied them, that this phenomenon “might be of great importance in Mediterranean environments in the perspective of global climate change” (Blaschke *et al.*, 2001; Tognetti *et al.*, 1998). Thus, the long-term effects of elevated CO<sub>2</sub> concentrations on water-use efficiency are likely to persist and increase with increasing atmospheric CO<sub>2</sub> concentrations.

In some cases, scientists have looked to the past and determined the positive impact the historic rise in the air’s CO<sub>2</sub> content has already had on plant water-use efficiency. Duquesnay *et al.* (1998), for example, used tree-ring data derived from beech trees to determine that over the past century the water-use efficiency of such trees in north-eastern France increased by approximately 33 percent. Similarly, Feng (1999) used tree-ring chronologies derived from a number of trees in western North America to calculate a 10 to 25 percent increase in tree water-use efficiency from 1750 to 1970, during which time the atmospheric CO<sub>2</sub> concentration rose by approximately 16 percent. In another study, Knapp *et al.* (2001) developed tree-ring chronologies from western juniper stands located in Oregon, USA, for the past century, determining that growth recovery from drought was much greater in the latter third of their chronologies (1964-1998) than it was in the first third (1896-1930). In this case, the authors suggested that the greater atmospheric CO<sub>2</sub> concentrations of the latter period allowed the trees to more quickly recover from water stress. Finally, Beerling *et al.* (1998) grew *Ginkgo* saplings at 350 and 650 ppm CO<sub>2</sub> for three years, finding that elevated atmospheric CO<sub>2</sub> concentrations reduced leaf stomatal densities to values comparable to those measured on fossilized *Ginkgo* leaves dating back to the Triassic and Jurassic periods, implying greater water-use efficiencies for those times too.

On another note, Prince *et al.* (1998) demonstrated that rain-use efficiency, which is similar to water-use efficiency, slowly increased in the African Sahel from 1982 to 1990, while Nicholson *et*

al. (1998) observed neither an increase nor a decrease in this parameter from 1980 to 1995 for the central and western Sahel.

In summary, it is clear that as the CO<sub>2</sub> content of the air continues to rise, nearly all of earth's trees will respond favorably by exhibiting increases in water-use efficiency. It is thus likely that as time progresses, earth's woody species will expand into areas where they previously could not exist due to limiting amounts of available moisture. Therefore, one can expect the earth to become a greener biospheric body with greater carbon sequestering capacity as the atmospheric CO<sub>2</sub> concentration continues to rise.

### 7.3. Amelioration of Environmental Stresses

Atmospheric CO<sub>2</sub> enrichment has been shown to help ameliorate the detrimental effects of several environmental stresses on plant growth and development, including disease, herbivory (predation by insects), shade (caused by increased cloudiness), ozone (a common air pollutant), low temperatures, nitrogen deficiency, UV-B radiation, and water stress. In this section we survey research on each of these types of stress.

Additional information on this topic, including reviews on stresses not discussed here, can be found at [http://www.co2science.org/subject/g/subject\\_g.php](http://www.co2science.org/subject/g/subject_g.php) under the heading Growth Response to CO<sub>2</sub> with Other Variables.

#### 7.3.1. Disease

According to the IPCC, CO<sub>2</sub>-induced global warming will increase the risk of plant disease outbreaks, resulting in negative consequences for food, fiber, and forestry across all world regions (IPCC, 2007-II). But it appears the IPCC has omitted the results of real-world observations that contradict this forecast.

Chakraborty and Datta (2003) note there are a number of CO<sub>2</sub>-induced changes in plant physiology, anatomy and morphology that have been implicated in increased plant resistance to disease and that “can potentially enhance host resistance at elevated CO<sub>2</sub>.” Among these phenomena they list “increased net photosynthesis allowing mobilization of resources into host resistance (Hibberd *et al.*, 1996a.); reduced stomatal density and conductance (Hibberd *et al.*, 1996b); greater accumulation of carbohydrates in leaves; more waxes, extra layers of epidermal cells and increased fibre content (Owensby, 1994); production of papillae and accumulation of silicon at penetration sites (Hibberd *et al.*, 1996a); greater number of mesophyll cells (Bowes, 1993); and increased biosynthesis of phenolics (Hartley *et al.*, 2000), among others.”

Malmstrom and Field (1997) grew individual oat plants for two months in pots placed within phytocells maintained at atmospheric CO<sub>2</sub> concentrations of 350 and 700 ppm, while they infected one-third of the plants with the barley yellow dwarf virus (BYDV), which plagues more than 150 plant species worldwide, including all major cereal crops. Over the course of their study, they found that elevated CO<sub>2</sub> stimulated rates of net photosynthesis in all plants, regardless of pathogen infection. However, the greatest percentage increase occurred in diseased individuals (48 percent vs. 34 percent). Moreover, atmospheric CO<sub>2</sub> enrichment decreased stomatal conductance by 50 percent in infected plants but by only 34 percent in healthy ones, which led to a CO<sub>2</sub>-induced doubling of the instantaneous water-use efficiency of the healthy plants, but an increase of fully 2.7-fold in the diseased plants. Last, after 60 days of growth under these conditions, they determined that the extra CO<sub>2</sub> increased total plant biomass by 36 percent in infected plants, but by only 12 percent in healthy plants. In addition, while elevated CO<sub>2</sub> had little effect on root growth in the healthy plants, it increased root biomass in the infected plants by up to 60 percent. Consequently, it can be appreciated that as the CO<sub>2</sub> content of the air continues to rise, its many positive effects will likely offset some, if not most, of the negative effects of the destructive BYDV. Quoting Malmstrom and Field with respect to two specific examples, they say in their concluding remarks that CO<sub>2</sub> enrichment “may reduce losses of infected plants to drought” and “may enable diseased plants to compete better with healthy neighbors.”

Tiedemann and Firsching (2000) grew spring wheat plants from germination to maturity in controlled-environment chambers maintained at ambient (377 ppm) and elevated (612 ppm) concentrations of atmospheric CO<sub>2</sub> and at ambient (20 ppb) and elevated (61 ppb) concentrations of ozone (and combinations thereof), the latter of which gases is typically toxic to most plants. In addition, half of the plants in each treatment were inoculated with a leaf rust-causing fungus. Under these conditions, the elevated CO<sub>2</sub> increased the photosynthetic rates of the diseased plants by 20 and 42 percent at the ambient and elevated ozone concentrations, respectively. It also enhanced the yield of the infected plants, increasing it by 57 percent, even in the presence of high ozone concentrations.

Jwa and Walling (2001) grew tomato plants hydroponically for eight weeks in controlled-environment chambers maintained at atmospheric CO<sub>2</sub> concentrations of 350 and 700 ppm. In addition, at week five of the study, half of all plants growing in each CO<sub>2</sub> concentration were infected with a fungal pathogen that attacks plant roots and induces a water stress that decreases growth and yield. At the end of the study, they found that the pathogenic infection had reduced total plant biomass by nearly 30 percent at both atmospheric CO<sub>2</sub> concentrations. However, the elevated CO<sub>2</sub> had increased the total biomass of the healthy and diseased plants by the same amount (+30 percent), with the result that the infected tomato plants grown at 700 ppm CO<sub>2</sub> had biomass values that were essentially identical to those of the healthy tomato plants grown at 350 ppm CO<sub>2</sub>. Thus, the extra CO<sub>2</sub> completely counterbalanced the negative effect of the pathogenic infection on overall plant productivity.

Chakraborty and Datta (2003) studied the aggressiveness of the fungal anthracnose pathogen *Colletotrichum gloeosporioides* by inoculating two isolates of the pathogen onto two cultivars of the tropical pasture legume *Stylosanthes scabra* (Fitzroy, which is susceptible to the fungal pathogen, and Seca, which is more resistant) over 25 sequential infection cycles in controlled-environment chambers filled with air of either 350 or 700 ppm CO<sub>2</sub>. By these means they determined that the aggressiveness of the pathogen was reduced at the twice-ambient level of atmospheric CO<sub>2</sub>, where aggressiveness is defined as “a property of the pathogen reflecting the relative amount of damage caused to the host without regard to resistance genes (Shaner *et al.*, 1992).” As they describe it, “at twice-ambient CO<sub>2</sub> the overall level of

aggressiveness of the two [pathogen] isolates was significantly reduced on both cultivars.”

Simultaneously, however, pathogen fecundity was found to increase at twice-ambient CO<sub>2</sub>. Of this finding, Chakraborty and Datta report that their results “concur with the handful of studies that have demonstrated increased pathogen fecundity at elevated CO<sub>2</sub> (Hibberd *et al.*, 1996a; Kironomos *et al.*, 1997; Chakraborty *et al.*, 2000).” How this happened in the situation they investigated, according to Chakraborty and Datta, is that the overall increase in fecundity at high CO<sub>2</sub> “is a reflection of the altered canopy environment,” wherein “the 30% larger *S. scabra* plants at high CO<sub>2</sub> (Chakraborty *et al.*, 2000) makes the canopy microclimate more conducive to anthracnose development.”

In view of these opposing changes in pathogen behavior at elevated levels of atmospheric CO<sub>2</sub>, it is difficult to know the outcome of atmospheric CO<sub>2</sub> enrichment for this specific pathogen-host relationship. More research, especially under realistic field conditions, will be needed to clarify the situation; and, of course, different results are likely to be observed for different pathogen-host associations. What is more, results could also differ under different climatic conditions. Nevertheless, the large number of ways in which elevated CO<sub>2</sub> has been demonstrated to increase plant resistance to pathogen attack gives us reason to believe that plants will gain the advantage as the air's CO<sub>2</sub> content continues to climb in the years ahead.

Another study that fuels this optimism was conducted by Parsons *et al.* (2003), who grew two-year-old saplings of paper birch and three-year-old saplings of sugar maple in well-watered and fertilized pots from early May until late August in glasshouse rooms maintained at either 400 or 700 ppm CO<sub>2</sub>. In these circumstances, the whole-plant biomass of paper birch was increased by 55 percent in the CO<sub>2</sub>-enriched portions of the glasshouse, while that of sugar maple was increased by 30 percent. Also, concentrations of condensed tannins were increased by 27 percent in the paper birch (but not the sugar maple) saplings grown in the CO<sub>2</sub>-enriched air; in light of this finding, Parsons *et al.* conclude that “the higher condensed tannin concentrations that were present in the birch fine roots may offer these tissues greater protection against soil-borne pathogens and herbivores.”

Within this context, it is interesting to note that Parsons *et al.* report that CO<sub>2</sub>-induced increases in fine root concentrations of total phenolics and

condensed tannins have also been observed in warm temperate conifers by King *et al.* (1997), Entry *et al.* (1998), Gebauer *et al.* (1998), and Runion *et al.* (1999), as well as in cotton by Booker (2000).

In another intriguing study, Gamper *et al.* (2004) begin by noting that arbuscular mycorrhizal fungi (AMF) are expected to modulate plant responses to elevated CO<sub>2</sub> by “increasing resistance/tolerance of plants against an array of environmental stressors (Smith and Read, 1997).” In investigating this subject in a set of experiments conducted over a seven-year period of free-air CO<sub>2</sub>-enrichment on two of the world’s most extensively grown cool-season forage crops (*Lolium perenne* and *Trifolium repens*) at the Swiss free-air CO<sub>2</sub> enrichment (FACE) facility near Zurich, they determined that “at elevated CO<sub>2</sub> and under [two] N treatments, AMF root colonization of both host plant species was increased,” and that “colonization levels of all three measured intraradical AMF structures (hyphae, arbuscules and vesicles) tended to be higher.” Hence, they concluded that these CO<sub>2</sub>-induced benefits may lead to “increased protection against pathogens and/or herbivores.”

Pangga *et al.* (2004) grew well-watered and fertilized seedlings of a cultivar (Fitzroy) of the pencilflower (*Stylosanthes scabra*)—an important legume crop that is susceptible to anthracnose disease caused by *Colletotrichum gloeosporioides* (Penz.) Penz. & Sacc.—within a controlled-environment facility maintained at atmospheric CO<sub>2</sub> concentrations of either 350 or 700 ppm, where they inoculated six-, nine- and 12-week-old plants with conidia of *C. gloeosporioides*. Then, 10 days after inoculation, they counted the anthracnose lesions on the plants and classified them as either resistant or susceptible.

Adherence to this protocol revealed, in their words, that “the mean number of susceptible, resistant, and total lesions per leaf averaged over the three plant ages was significantly ( $P < 0.05$ ) greater at 350 ppm than at 700 ppm CO<sub>2</sub>, reflecting the development of a level of resistance in susceptible cv. Fitzroy at high CO<sub>2</sub>.” In fact, with respect to the plants inoculated at 12 weeks of age, they say that those grown “at 350 ppm had 60 and 75% more susceptible and resistant lesions per leaf, respectively, than those [grown] at 700 ppm CO<sub>2</sub>.”

In terms of infection efficiency (IE), the Australian scientists say their work “clearly shows that at 350 ppm overall susceptibility of the canopy increases with increasing age because more young leaves are produced on secondary and tertiary branches of the more advanced plants.” However,

they report that “at 700 ppm CO<sub>2</sub>, IE did not increase with increasing plant age despite the presence of many more young leaves in the enlarged canopy,” which finding, in their words, “points to reduced pathogen efficiency or an induced partial resistance to anthracnose in Fitzroy at 700 ppm CO<sub>2</sub>.” Consequently, as the air’s CO<sub>2</sub> content continues to rise, it would appear that the Fitzroy cultivar of the pasture legume *Stylosanthes scabra* will acquire a greater intrinsic resistance to the devastating anthracnose disease.

McElrone *et al.* (2005) “assessed how elevated CO<sub>2</sub> affects a foliar fungal pathogen, *Phyllosticta minima*, of *Acer rubrum* [red maple] growing in the understory at the Duke Forest free-air CO<sub>2</sub> enrichment experiment in Durham, North Carolina, USA ... in the 6th, 7th, and 8th years of the CO<sub>2</sub> exposure.” Surveys conducted in those years, in their words, “revealed that elevated CO<sub>2</sub> [to 200 ppm above ambient] significantly reduced disease incidence, with 22%, 27% and 8% fewer saplings and 14%, 4%, and 5% fewer leaves infected per plant in the three consecutive years, respectively.” In addition, they report that the elevated CO<sub>2</sub> “also significantly reduced disease severity in infected plants in all years (e.g. mean lesion area reduced 35%, 50%, and 10% in 2002, 2003, and 2004, respectively).”

What underlying mechanism or mechanisms produced these beneficent consequences? Thinking it could have been a direct deleterious effect of elevated CO<sub>2</sub> on the fungal pathogen, McElrone *et al.* performed some side experiments in controlled-environment chambers. However, they found that the elevated CO<sub>2</sub> benefited the fungal pathogen as well as the red maple saplings, observing that “exponential growth rates of *P. minima* were 17% greater under elevated CO<sub>2</sub>.” And they obtained similar results when they repeated the *in vitro* growth analysis two additional times in different growth chambers.

Taking another tack when “scanning electron micrographs verified that conidia germ tubes of *P. minima* infect *A. rubrum* leaves by entering through the stomata,” the researchers turned their attention to the pathogen’s mode of entry into the saplings’ foliage. In this investigation they found that both stomatal size and density were unaffected by atmospheric CO<sub>2</sub> enrichment, but that “stomatal conductance was reduced by 21-36% under elevated CO<sub>2</sub>, providing smaller openings for infecting germ tubes.” In addition, they concluded that reduced disease severity under elevated CO<sub>2</sub> was also likely due to altered leaf chemistry, as elevated CO<sub>2</sub>

increased total leaf phenolic concentrations by 15 percent and tannin concentrations by 14 percent.

Because the phenomena they found to be important in reducing the amount and severity of fungal pathogen infection (leaf spot disease) of red maple have been demonstrated to be operative in most other plants as well, McElrone *et al.* say these CO<sub>2</sub>-enhanced leaf defensive mechanisms “may be prevalent in many plant pathosystems where the pathogen targets the stomata.” Indeed, they state that their results “provide concrete evidence for a potentially generalizable mechanism to predict disease outcomes in other pathosystems under future climatic conditions.”

Matros *et al.* (2006) grew tobacco plants (*Nicotiana tabacum* L.) in 16-cm-diameter pots filled with quartz sand in controlled-climate chambers maintained at either 350 or 1,000 ppm CO<sub>2</sub> for a period of eight weeks, where they were irrigated daily with a complete nutrient solution containing either 5 or 8 mM NH<sub>4</sub>NO<sub>3</sub>. In addition, some of the plants in each treatment were mechanically infected with the *potato virus Y* (PVY) when they were six weeks old. Then, at the end of the study, the plants were harvested and a number of their chemical constituents identified and quantified.

This work revealed, in the researchers words, that “plants grown at elevated CO<sub>2</sub> and 5 mM NH<sub>4</sub>NO<sub>3</sub> showed a marked and significant decrease in content of nicotine in leaves as well as in roots,” while at 8 mM NH<sub>4</sub>NO<sub>3</sub> the same was found to be true of upper leaves but not of lower leaves and roots. With respect to the PVY part of the study, they further report that the “plants grown at high CO<sub>2</sub> showed a markedly decreased spread of virus.” Both of these findings would likely be considered beneficial by most people, as *potato virus Y* is an economically important virus that infects many crops and ornamental plants throughout the world, while nicotine is nearly universally acknowledged to have significant negative impacts on human health (Topliss *et al.*, 2002).

Braga *et al.* (2006) conducted three independent experiments where they grew well-watered soybean (*Glycine max* (L.) Merr) plants of two cultivars (IAC-14, susceptible to stem canker disease, and IAC-18, resistant to stem canker disease) from seed through the cotyledon stage in five-liter pots placed within open-top chambers maintained at atmospheric CO<sub>2</sub> concentrations of either 360 or 720 ppm in a glasshouse, while they measured various plant properties and processes, concentrating on the production of *glyceollins* (the major *phytoalexins*, or

anti-microbial compounds, produced in soybeans) in response to the application of β-glucan elicitor (derived from mycelial walls of *Phytophthora sojae*) to carefully created and replicated wounds in the surfaces of several soybean cotyledons. In doing so, they found that the IAC-14 cultivar did *not* exhibit a CO<sub>2</sub>-induced change in glyceollin production in response to elicitation—as Braga *et al.* had hypothesized would be the case, since this cultivar is susceptible to stem canker disease—but they found that the IAC-18 cultivar (which has the potential to resist the disease to varying degrees) experienced a 100 percent CO<sub>2</sub>-induced increase in the amount of glyceollins produced after elicitation, a response the researchers described as *remarkable*. As for its significance, Braga *et al.* say the CO<sub>2</sub>-induced response they observed “may increase the potential of the soybean defense since infection at early stages of plant development, followed by a long incubation period before symptoms appear, is characteristic of the stem canker disease cycle caused by Dpm [*Diaporthe phaseolorum* (Cooke & Ellis) Sacc. f. sp. *meridionalis* Morgan-Jones].” They say the response they observed “indicates that raised CO<sub>2</sub> levels forecasted for next decades may have a real impact on the defensive chemistry of the cultivars.”

Last, in a study conducted within the BioCON (Biodiversity, Carbon dioxide, and Nitrogen effects on ecosystem functioning) FACE facility located at the Cedar Creek Natural History Area in east-central Minnesota, USA, Strengbom and Reich (2006) evaluated the effects of an approximate 190-ppm increase in the air’s daytime CO<sub>2</sub> concentration on leaf photosynthetic rates of stiff goldenrod (*Solidago rigida*) growing in monoculture for two full seasons, together with its concomitant effects on the incidence and severity of leaf spot disease. Although they found that elevated CO<sub>2</sub> had no significant effect on plant photosynthetic rate in their study, they report that “both disease incidence and severity were lower on plants grown under elevated CO<sub>2</sub>.” More specifically, they found that “disease incidence was on average *more than twice as high* [our italics] under ambient as under elevated CO<sub>2</sub>,” and that “disease severity (proportion of leaf area with lesions) was on average 67% lower under elevated CO<sub>2</sub> compared to ambient conditions.”

In discussing their results, Strengbom and Reich say the “indirect effects from elevated CO<sub>2</sub>, i.e., lower disease incidence, had a stronger effect on realized photosynthetic rate than the direct effect of higher CO<sub>2</sub>,” which as noted above was negligible in their

study. They conclude “it may be necessary to consider potential changes in susceptibility to foliar diseases to correctly estimate the effects on plant photosynthetic rates of elevated CO<sub>2</sub>.” In addition, they note that the plants grown in CO<sub>2</sub>-enriched air had lower leaf nitrogen concentrations than the plants grown in ambient air, as is often observed in studies of this type; and they say that their results “are, thus, also in accordance with other studies that have found reduced pathogen performance following reduced nitrogen concentration in plants grown under elevated CO<sub>2</sub> (Thompson and Drake, 1994).” What is more, they conclude that their results are “also in accordance with studies that have found increased [disease] susceptibility following increased nitrogen concentration of host plants (Huber and Watson, 1974; Nordin *et al.*, 1998; Strengbom *et al.*, 2002).” It is possible, therefore, that the ongoing rise in the air’s CO<sub>2</sub> content may help many plants of the future reduce the deleterious impacts of various pathogenic fungal diseases that currently beset them, thereby enabling them to increase their productivities above and beyond what is typically provided by the more direct growth stimulation resulting from the aerial fertilization effect of elevated atmospheric CO<sub>2</sub> concentrations.

In summation, the bulk of the available data shows atmospheric CO<sub>2</sub> enrichment asserts its greatest positive influence on infected as opposed to healthy plants. Moreover, it would appear that elevated CO<sub>2</sub> has the ability to significantly ameliorate the deleterious effects of various stresses imposed upon plants by numerous pathogenic invaders. Consequently, as the atmosphere’s CO<sub>2</sub> concentration continues its upward climb, earth’s vegetation should be increasingly better equipped to successfully deal with pathogenic organisms and the damage they have traditionally done to mankind’s crops, as well as to the plants that sustain the rest of the planet’s animal life.

### 7.3.2. Herbivory

Insect pests have greatly vexed earth's plants in the past and will likely continue to do so in the future. It is possible, however, that the ongoing rise in the atmosphere's CO<sub>2</sub> content may affect this phenomenon, for better or for worse. In this section we review the results of several studies that have addressed this subject as it applies to herbaceous and woody plants.

Additional information on this topic, including reviews on herbivory not discussed here, can be found at [http://www.co2science.org/subject/h/subject\\_h.php](http://www.co2science.org/subject/h/subject_h.php) under the heading Herbivory.

#### 7.3.2.1. Herbaceous Plants

Kerslake *et al.* (1998) grew five-year-old heather (*Calluna vulgaris*) plants collected from a Scottish moor in open-top chambers maintained at atmospheric CO<sub>2</sub> concentrations of 350 and 600 ppm. At two different times during the study, larvae of the

destructive winter moth *Operophtera brumata*—whose outbreaks periodically cause extensive damage to heather moorland—were allowed to feed upon current-year shoots. Feeding upon the high-CO<sub>2</sub>-grown foliage did not affect larval growth rates, development, or final pupal weights; neither was moth survivorship significantly altered. The authors concluded that their study “provides no evidence that increasing atmospheric CO<sub>2</sub> concentrations will affect the potential for outbreak of *Operophtera brumata* on this host.” What it did show, however, was a significant CO<sub>2</sub>-induced increase in heather water use efficiency.

Newman *et al.* (1999) inoculated tall fescue (*Festuca arundinacea*) plants growing in open-top chambers maintained at atmospheric CO<sub>2</sub> concentrations of 350 and 700 ppm with bird cherry-oat aphids (*Rhopalosiphum padi*). After nine weeks, the plants growing in the CO<sub>2</sub>-enriched air had experienced a 37 percent increase in productivity and were covered with many fewer aphids than the plants growing in ambient air.

Goverde *et al.* (1999) collected four genotypes of *Lotus corniculatus* near Paris and grew them in controlled environment chambers kept at atmospheric CO<sub>2</sub> concentrations of 350 and 700 ppm. Larvae of the Common Blue Butterfly (*Polyommatus icarus*) that were allowed to feed upon the foliage produced in the CO<sub>2</sub>-enriched air ate more, grew larger, and experienced shorter development times than larvae feeding on the foliage produced in the ambient-air treatment, suggesting that this butterfly species will likely become more robust and plentiful as the air's CO<sub>2</sub> content continues to rise.

Brooks and Whittaker (1999) removed grassland monoliths containing eggs of the xylem-feeding spittlebug *Neophilaenus lineatus* from the UK's Great Dun Fell in Cumbria and placed them in glasshouses maintained at atmospheric CO<sub>2</sub> concentrations of 350 and 600 ppm for two years. Survival of the spittlebug's nymphal states was reduced by 24 percent in both of the generations produced in their experiment, suggesting that this particular insect will likely cause less tissue damage to the plants of this species-poor grassland in a CO<sub>2</sub>-enriched world of the future.

Joutei *et al.* (2000) grew bean (*Phaseolus vulgaris*) plants in controlled environments kept at atmospheric CO<sub>2</sub> concentrations of 350 and 700 ppm, to which they introduced the destructive agricultural mite *Tetranychus urticae*, observing that female mites produced 34 percent and 49 percent less offspring in

the CO<sub>2</sub>-enriched chambers in their first and second generations, respectively. This CO<sub>2</sub>-induced reduction in the reproductive success of this invasive insect, which negatively affects more than 150 crop species worldwide, bodes well for mankind's ability to grow the food we will need to feed our growing numbers in the years ahead.

Peters *et al.* (2000) fed foliage derived from FACE plots of calcareous grasslands of Switzerland (maintained at 350 and 650 ppm CO<sub>2</sub>) to terrestrial slugs, finding they exhibited no preference with respect to the CO<sub>2</sub> treatment from which the foliage was derived. Also, in a study that targeted no specific insect pest, Castells *et al.* (2002) found that a doubling of the air's CO<sub>2</sub> content enhanced the total phenolic concentrations of two Mediterranean perennial grasses (*Dactylis glomerata* and *Bromus erectus*) by 15 percent and 87 percent, respectively, which compounds tend to enhance plant defensive and resistance mechanisms to attacks by both herbivores and pathogens.

Coviella and Trumbel (2000) determined that toxins produced by *Bacillus thuringiensis* (Bt), which are applied to crop plants by spraying as a means of combating various crop pests, were “more efficacious” in cotton grown in an elevated CO<sub>2</sub> environment than in ambient air, which is a big plus for modern agriculture. In addition, Coviella *et al.* (2000) determined that “elevated CO<sub>2</sub> appears to eliminate differences between transgenic [Bt-containing] and nontransgenic plants for some key insect developmental/fitness variables including length of the larval stage and pupal weight.”

In summary, the majority of evidence that has been accumulated to date suggests that rising atmospheric CO<sub>2</sub> concentrations may reduce the frequency and severity of pest outbreaks that are detrimental to agriculture, while not seriously impacting herbivorous organisms found in natural ecosystems that are normally viewed in a more favorable light.

### 7.3.2.2. Woody Plants

#### 7.3.2.2.1. Maple

Working with *Acer rubrum* saplings beginning their fourth year of growth in open-top chambers maintained at four different atmospheric CO<sub>2</sub>/temperature conditions—(1) ambient temperature, ambient CO<sub>2</sub>, (2) ambient temperature, elevated CO<sub>2</sub> (ambient + 300 ppm), (3) elevated temperature (ambient + 3.5°C), ambient CO<sub>2</sub>, and (4) elevated temperature, elevated CO<sub>2</sub>—Williams *et al.* (2003) bagged first instar gypsy moth larvae on various branches of the trees and observed their behavior. The data they obtained demonstrated, in

their words, “that larvae feeding on CO<sub>2</sub>-enriched foliage ate a comparably poorer food source than those feeding on ambient CO<sub>2</sub>-grown plants, irrespective of temperature,” and that there was a minor reduction in leaf water content due to CO<sub>2</sub> enrichment. Nevertheless, they found the “CO<sub>2</sub>-induced reductions in foliage quality (e.g. nitrogen and water) were unrelated [our italics] to insect mortality, development rate and pupal weight,” and that these and any other phytochemical changes that may have occurred “resulted in no negative effects on gypsy moth performance.” They also found that “irrespective of CO<sub>2</sub> concentration, on average, male larvae pupated 7.5 days earlier and female larvae 8 days earlier at elevated temperature,” and noting that anything that prolongs the various development stages of insects potentially exposes them to greater predation and parasitism risk, they concluded that the observed temperature-induced hastening of the insects’ development would likely expose them to *less* predation and parasitism risk.

One year later, Hamilton *et al.* (2004) began the report of their study of this important subject by noting that many single-species investigations have suggested that increases in atmospheric CO<sub>2</sub> will increase herbivory (Bezemer and Jones, 1998; Cannon, 1998; Coviella and Trumble, 1999; Hunter, 2001; Lincoln *et al.*, 1993; Whittaker, 1999). However, because there are so many feedbacks and complex interactions among the numerous components of real-world ecosystems, they warned that one ought not put too much faith in these predictions until relevant real-world ecosystem-level experiments have been completed.

In one such study they conducted at the Duke Forest FACE facility near Chapel Hill, North Carolina, USA, Hamilton *et al.* “measured the amount of leaf tissue damaged by insects and other herbivorous arthropods during two growing seasons in a deciduous forest understory continuously exposed to ambient (360 ppm) and elevated (560 ppm) CO<sub>2</sub> conditions.” This forest is dominated by loblolly pine trees that account for fully 92 percent of the ecosystem’s total woody biomass. In addition, it contains 48 species of other woody plants (trees, shrubs, and vines) that have naturally established themselves in the forest’s understory. In their study of this ecosystem, Hamilton *et al.* quantified the loss of foliage due to herbivory that was experienced by three deciduous tree species, one of which was *Acer rubrum*.

As Hamilton *et al.* describe it, “we found that elevated CO<sub>2</sub> led to a trend toward *reduced herbivory* [our italics] in [the] deciduous understory in a situation that included the full complement of naturally occurring plant and insect species.” In 1999, for example, they determined that “elevated CO<sub>2</sub> reduced overall herbivory by more than 40 percent,” while in 2000 they say they observed “the same pattern and magnitude of reduction.”

With respect to changes in foliage properties that might have been expected to lead to increases in herbivory, Hamilton *et al.* report they “found no evidence for significant changes in leaf nitrogen, C/N ratio, sugar, starch or total leaf phenolics in either year of [the] study,” noting that these findings agree with those of “another study performed at the Duke Forest FACE site that also found no effect of elevated CO<sub>2</sub> on the chemical composition of leaves of understory trees (Finzi and Schlesinger, 2002).”

Hamilton *et al.* thus concluded their landmark paper by emphasizing that “despite the large number of studies that predict increased herbivory, particularly from leaf chewers, under elevated CO<sub>2</sub>, our study found a trend toward reduced herbivory two years in a row.” In addition, they note that their real-world results “agree with the only other large-scale field experiment that quantified herbivory for a community exposed to elevated CO<sub>2</sub> (Stiling *et al.*, 2003).”

Consequently, and in spite of the predictions of increased destruction of natural ecosystems by insects and other herbivorous arthropods in a CO<sub>2</sub>-enriched world of the future, just the opposite would appear to be the more likely outcome; i.e., greater plant productivity plus less foliage consumption by herbivores, “whether expressed on an absolute or a percent basis,” as Hamilton *et al.* found to be the case in their study.

In another study conducted at the same site, Knepp *et al.* (2005) quantified leaf damage by chewing insects on saplings of seven species (including *Acer rubrum*) in 2001, 2002, and 2003, while five additional species (including *Acer barbatum*) were included in 2001 and 2003. This work revealed, in their words, that “across the seven species that were measured in each of the three years, elevated CO<sub>2</sub> caused a reduction in the percentage of leaf area removed by chewing insects,” which was such that “the percentage of leaf tissue damaged by insect herbivores was 3.8 percent per leaf under ambient CO<sub>2</sub> and 3.3 percent per leaf under elevated CO<sub>2</sub>.” Greatest effects were observed in 2001, when

they report that “across 12 species the average damage per leaf under ambient CO<sub>2</sub> was 3.1 percent compared with 1.7 percent for plants under elevated CO<sub>2</sub>,” which was “indicative of a 46 percent decrease in the total area and total mass of leaf tissue damaged by chewing insects in the elevated CO<sub>2</sub> plots.”

What was responsible for these welcome results? Knepp *et al.* say that “given the consistent reduction in herbivory under high CO<sub>2</sub> across species in 2001, it appears that some universal feature of chemistry or structure that affected leaf suitability was altered by the treatment.” Another possibility they discuss is that “forest herbivory may decrease under elevated CO<sub>2</sub> because of a decline in the abundance of chewing insects,” citing the observations of Stiling *et al.* (2002) to this effect and noting that “slower rates of development under elevated CO<sub>2</sub> prolongs the time that insect herbivores are susceptible to natural enemies, which may be abundant in open-top chambers and FACE experiments but absent from greenhouse experiments.” In addition, they suggest that “decreased foliar quality and increased per capita consumption under elevated CO<sub>2</sub> may increase exposure to toxins and insect mortality,” also noting that “CO<sub>2</sub>-induced changes in host plant quality directly decrease insect fecundity,” citing the work of Coviella and Trumble (1999) and Awmack and Leather (2002).

So what’s the bottom line with respect to the outlook for earth’s forests, and especially its maple trees, in a high-CO<sub>2</sub> world of the future? In their concluding paragraph, Knepp *et al.* say that “By contrast to the view that herbivore damage will increase under elevated CO<sub>2</sub> as a result of compensatory feeding on lower quality foliage, our results and those of Stiling *et al.* (2002) and Hamilton *et al.* (2004) in open experimental systems suggest that damage to trees may decrease.”

But what if herbivore-induced damage in fact increases in a future CO<sub>2</sub>-enriched world? The likely answer is provided by the work of Kruger *et al.* (1998), who grew well-watered and fertilized one-year-old *Acer saccharum* saplings in glasshouses maintained at atmospheric CO<sub>2</sub> concentrations of either 356 or 645 ppm for 70 days to determine the effects of elevated CO<sub>2</sub> on photosynthesis and growth. In addition, on the 49th day of differential CO<sub>2</sub> exposure, 50 percent of the saplings’ leaf area was removed from half of the trees in order to study the impact of simulated herbivory. This protocol revealed that the 70-day CO<sub>2</sub> enrichment treatment increased the total dry weight of the non-defoliated seedlings by

about 10 percent. When the trees were stressed by simulated herbivory, however, the CO<sub>2</sub>-enriched maples produced 28 percent more dry weight over the final phase of the study than the maples in the ambient-air treatment did. This result thus led Kruger *et al.* to conclude that in a high-CO<sub>2</sub> world of the future “sugar maple might be more capable of tolerating severe defoliation events which in the past have been implicated in widespread maple declines.”

It appears that earth’s maple trees—and probably many, if not most, other trees—will fare much better in the future with respect to the periodic assaults of leaf-damaging herbivores, as the air’s CO<sub>2</sub> content continues its upward climb.

### 7.3.2.2.2. Oak

Dury *et al.* (1998) grew four-year-old *Quercus robur* seedlings in pots in greenhouses maintained at ambient and twice-ambient atmospheric CO<sub>2</sub> concentrations in combination with ambient and elevated (ambient plus 3°C) air temperatures for approximately one year to study the interactive effects of elevated CO<sub>2</sub> and temperature on leaf nutritional quality. In doing so, they found that the elevated air temperature treatment significantly reduced leaf palatability, and that leaf toughness increased as a consequence of temperature-induced increases in condensed tannin concentrations. In addition, the higher temperatures significantly reduced leaf nitrogen content, while elevated CO<sub>2</sub> caused a temporary increase in leaf phenolic concentrations and a decrease in leaf nitrogen content.

In one of the first attempts to move outside the laboratory/greenhouse and study the effects of atmospheric CO<sub>2</sub> enrichment on trophic food webs in a natural ecosystem, Stiling *et al.* (1999) enclosed portions of a native scrub-oak community in Florida (USA) within 3.6-m-diameter open-top chambers and fumigated them with air having CO<sub>2</sub> concentrations of either 350 or 700 ppm for approximately one year, in order to see if elevated CO<sub>2</sub> would impact leaf miner

densities, feeding rates, and mortality in this nutrient-poor ecosystem.

Adherence to this protocol led to the finding that total leaf miner densities were 38 percent less on the foliage of trees growing in CO<sub>2</sub>-enriched air than on the foliage of trees growing in ambient air. In addition, atmospheric CO<sub>2</sub> enrichment consistently reduced the absolute numbers of the study's six leaf miner species. At the same time, however, the elevated CO<sub>2</sub> treatment increased the leaf area consumed by the less abundant herbivore miners by approximately 40 percent relative to the areas mined by the more abundant herbivores present on the foliage exposed to ambient air; but in spite of this increase in feeding, the leaf miners in the CO<sub>2</sub>-enriched chambers experienced significantly greater mortality than those in the ambient-air chambers. Although CO<sub>2</sub>-induced reductions in leaf nitrogen content played a role in this phenomenon, the greatest factor contributing to increased herbivore mortality was a four-fold increase in parasitization by various wasps, which could more readily detect the more-exposed leaf miners on the CO<sub>2</sub>-enriched foliage.

If extended to agricultural ecosystems, these findings suggest that crops may experience less damage from such herbivores in a high-CO<sub>2</sub> world of the future, thus increasing potential harvest and economic gains. In addition, with reduced numbers of leaf miners in CO<sub>2</sub>-enriched air, farmers could reduce their dependency upon chemical pesticides to control them.

In another study conducted on five scrub-oak forest species at the same experimental facility, Stiling *et al.* (2003) investigated the effects of an approximate doubling of the air's CO<sub>2</sub> concentration on a number of characteristics of several insect herbivores. As before, they found that the "relative levels of damage by the two most common herbivore guilds, leaf-mining moths and leaf-chewers (primarily larval lepidopterans and grasshoppers), were significantly lower in elevated CO<sub>2</sub> than in ambient CO<sub>2</sub>, for all five plant species," and they found that "the response to elevated CO<sub>2</sub> was the same across all plant species." In addition, they report that "more host-plant induced mortality was found for all miners on all plants in elevated CO<sub>2</sub> than in ambient CO<sub>2</sub>." These effects were so powerful that in addition to the relative densities of insect herbivores being reduced in the CO<sub>2</sub>-enriched chambers, and "even though there were more leaves of most plant species in the elevated CO<sub>2</sub> chambers," the total densities of leaf miners in the high-CO<sub>2</sub> chambers were also lower for

all plant species. Consequently, it would appear that in a high-CO<sub>2</sub> world of the future, many of earth's plants may be able to better withstand the onslaughts of various insect pests that have plagued them in the past. Another intriguing implication of this finding, as Stiling *et al.* note, is that "reductions in herbivore loads in elevated CO<sub>2</sub> could boost plant growth beyond what might be expected based on pure plant responses to elevated CO<sub>2</sub>."

Continuing to investigate the same ecosystem, which is dominated by two species of scrub oak (*Quercus geminata* and *Q. myrtifolia*) that account for more than 90 percent of the ecosystem's biomass, and focusing on the abundance of a guild of lepidopteran leafminers that attack the leaves of *Q. myrtifolia*, as well as various leaf chewers that also like to munch on this species, Rossi *et al.* (2004) followed 100 marked leaves in each of 16 open-top chambers (half exposed to ambient air and half exposed to air containing an extra 350 ppm of CO<sub>2</sub>) for a total of nine months, after which, in their words, "differences in mean percent of leaves with leafminers and chewed leaves on trees from ambient and elevated chambers were assessed using paired *t*-tests."

In reporting their findings the researchers wrote that "both the abundance of the guild of leafmining lepidopterans and damage caused by leaf chewing insects attacking myrtle oak were depressed in elevated CO<sub>2</sub>." Specifically, they found that leafminer abundance was 44 percent lower ( $P = 0.096$ ) in the CO<sub>2</sub>-enriched chambers compared to the ambient-air chambers, and that the abundance of leaves suffering chewing damage was 37 percent lower ( $P = 0.072$ ) in the CO<sub>2</sub>-enriched air. The implications of these findings are obvious: Myrtle oak trees growing in their natural habitat will likely suffer less damage from both leaf miners and leaf chewers as the air's CO<sub>2</sub> concentration continues to rise in the years and decades ahead.

Still concentrating on the same ecosystem, where atmospheric enrichment with an extra 350 ppm of CO<sub>2</sub> was begun in May 1996, Hall *et al.* (2005b) studied the four species that dominate the community and are present in every experimental chamber: the three oaks (*Quercus myrtifolia*, *Q. chapmanii* and *Q. geminata*) plus the nitrogen-fixing legume *Galactia elliotii*. At three-month intervals from May 2001 to May 2003, undamaged leaves were removed from each of these species in all chambers and analyzed for various chemical constituents, while 200 randomly selected leaves of each species in each chamber were

scored for the presence of six types of herbivore damage.

Throughout the study there were no significant differences between the CO<sub>2</sub>-enriched and ambient-treatment leaves of any single species in terms of either condensed tannins, hydrolyzable tannins, total phenolics, or lignin. However, in all four species together there were always greater concentrations of all four leaf constituents in the CO<sub>2</sub>-enriched leaves, with across-species mean increases of 6.8 percent for condensed tannins, 6.1 percent for hydrolyzable tannins, 5.1 percent for total phenolics, and 4.3 percent for lignin. In addition, there were large and often significant CO<sub>2</sub>-induced decreases in all leaf damage categories among all species: chewing (-48 percent,  $P < 0.001$ ), mines (-37 percent,  $P = 0.001$ ), eye spot gall (-45 percent,  $P < 0.001$ ), leaf tier (-52 percent,  $P = 0.012$ ), leaf mite (-23 percent,  $P = 0.477$ ), and leaf gall (-16 percent,  $P = 0.480$ ). Hall *et al.* thus concluded that the changes they observed in leaf chemical constituents and herbivore damage “suggest that damage to plants may decline as atmospheric CO<sub>2</sub> levels continue to rise.”

In one additional study to come out of the Florida scrub-oak ecosystem, Hall *et al.* (2005a) studied the effects of an extra 350 ppm of CO<sub>2</sub> on litter quality, herbivore activity and their interactions. Over the three years of this experiment (2000, 2001, 2002), they determined that “changes in litter chemistry from year to year were far larger than effects of CO<sub>2</sub> or insect damage, suggesting that these may have only minor effects on litter decomposition.” The one exception to this finding, in their words, was that “condensed tannin concentrations increased under elevated CO<sub>2</sub> regardless of species, herbivore damage, or growing season,” rising by 11 percent in 2000, 18 percent in 2001, and 41 percent in 2002 as a result of atmospheric CO<sub>2</sub> enrichment, as best we can determine from their bar graphs. Also, the five researchers report that “lepidopteran larvae can exhibit slower growth rates when feeding on elevated CO<sub>2</sub> plants (Fajer *et al.*, 1991) and become more susceptible to pathogens, parasitoids, and predators (Lindroth, 1996; Stiling *et al.*, 1999),” noting further that at their field site, “which hosts the longest continuous study of the effects of elevated CO<sub>2</sub> on insects, herbivore populations decline[d] markedly under elevated CO<sub>2</sub> (Stiling *et al.*, 1999, 2002, 2003; Hall *et al.*, 2005b).”

In conclusion, from the evidence accumulated to date with respect to herbivory in oak trees, it would appear that ever less damage will be done to such

trees by various insect pests as the air's CO<sub>2</sub> concentration continues to climb ever higher.

## 7.3.2.2.3. Other

Stiling *et al.* (1999) enclosed portions of a Florida scrub-oak community in open-top chambers and maintained them at atmospheric CO<sub>2</sub> concentrations of 350 and 700 ppm for approximately one year, while they studied the effects of this treatment on destructive leaf miners. Among their many findings, the researchers noted that the individual areas consumed by leaf miners munching on leaves in the CO<sub>2</sub>-enriched chambers were larger than those created by leaf miners dining on leaves in the ambient-air chambers. As a result, there was a *four-fold increase* in parasitization by various wasps that could more readily detect the more-exposed leaf miners on the CO<sub>2</sub>-enriched foliage. Consequently, leaf miners in the elevated CO<sub>2</sub> chambers suffered significantly greater mortality than those in the control chambers.

In a subsequent and much expanded study of the same ecosystem, Stiling *et al.* (2002) investigated several characteristics of a number of insect herbivores found on the five species of plants that accounted for more than 98 percent of the total plant biomass within the chambers. As they describe their results, the “relative levels of damage by the two most common herbivore guilds, leaf-mining moths and leaf-chewers (primarily larval lepidopterans and grasshoppers), were significantly lower in elevated CO<sub>2</sub> than in ambient CO<sub>2</sub>, for all five plant species.”

In another study that did not involve herbivores, Gleadow *et al.* (1998) grew eucalyptus seedlings in glasshouses maintained at 400 and 800 ppm CO<sub>2</sub> for a period of six months, observing biomass increases of 98 percent and 134 percent in high and low nitrogen treatments, respectively. They also studied a sugar-based compound called *prunasin*, which produces cyanide in response to tissue damage caused by foraging herbivores. Although elevated CO<sub>2</sub> caused no significant change in leaf prunasin content, it was determined that the proportion of nitrogen allocated to prunasin increased by approximately 20 percent in the CO<sub>2</sub>-enriched saplings, suggestive of a *potential* for increased prunasin production had the saplings been under attack by herbivores.

Lovelock *et al.* (1999) grew seedlings of the tropical tree *Copaifera aromatica* for 50 days in pots placed within open-top chambers maintained at atmospheric CO<sub>2</sub> concentrations of 390 and 860 ppm. At the 14-day point of the experiment, half of the seedlings in each treatment had about 40 percent of their total leaf area removed. In this case, none of the

defoliated trees of either CO<sub>2</sub> treatment fully recovered from this manipulation, but at the end of the experiment, the total plant biomass of the defoliated trees in the CO<sub>2</sub>-enriched treatment was 15 percent greater than that of the defoliated trees in the ambient-CO<sub>2</sub> treatment, again attesting to the benefits of atmospheric CO<sub>2</sub> enrichment in helping trees to deal with herbivory.

Docherty *et al.* (1997) grew beech and sycamore saplings in glasshouses maintained at atmospheric CO<sub>2</sub> concentrations of 350 and 600 ppm, while groups of three sap-feeding aphid species and two sap-feeding leafhopper species were allowed to feed on them. Overall, elevated CO<sub>2</sub> had few significant effects on the performance of the insects, although there was a non-significant tendency for elevated CO<sub>2</sub> to reduce the individual weights and population sizes of the aphids.

Finally, Hattenschwiler and Schafellner (1999) grew seven-year-old spruce (*Picea abies*) trees at atmospheric CO<sub>2</sub> concentrations of 280, 420, and 560 ppm and various nitrogen deposition treatments for three years, allowing nun moth larvae to feed on current-year needles for a period of 12 days. Larvae placed upon the CO<sub>2</sub>-enriched foliage consumed less needle biomass than larvae placed upon the ambiently grown foliage, regardless of nitrogen treatment. This effect was so pronounced that the larvae feeding on needles produced by the CO<sub>2</sub>-enriched trees attained an average final biomass that was only two-thirds of that attained by the larvae that fed on needles produced at 280 ppm CO<sub>2</sub>. Since the nun moth is a deadly defoliator that resides in most parts of Europe and East Asia between 40° and 60°N latitude and is commonly regarded as the coniferous counterpart of its close relative the gypsy moth, which feeds primarily on deciduous trees, the results of this study suggest that the ongoing rise in the air's CO<sub>2</sub> content will likely lead to significant reductions in damage to spruce and other coniferous trees by this voracious insect pest in the years and decades ahead.

In light of these several observations, the balance of evidence seems to suggest that earth's woody plants will be better able to deal with the challenges provided by herbivorous insects as the air's CO<sub>2</sub> content continues to rise.

### 7.3.3. Insects

As the atmosphere's CO<sub>2</sub> concentration climbs ever higher, it is important to determine how this phenomenon will affect the delicate balance that exists between earth's plants and the insects that feed on them. In this section we thus review what has been learned about this subject with respect to aphids, moths, and other insects.

Additional information on this topic, including reviews on insects not discussed here, can be found at [http://www.co2science.org/subject/i/subject\\_i.php](http://www.co2science.org/subject/i/subject_i.php) under the heading Insects.

#### 7.3.3.1. Aphids

Docherty *et al.* (1997) grew beech and sycamore saplings in glasshouses maintained at atmospheric CO<sub>2</sub> concentrations of 350 and 600 ppm, while groups of three sap-feeding aphid species were

allowed to feed on the saplings. Overall, the elevated CO<sub>2</sub> had few significant effects on aphid feeding and performance. There was, however, a non-significant tendency for elevated CO<sub>2</sub> to reduce the individual weights and population sizes of the aphids, suggesting that future increases in the air's CO<sub>2</sub> content *might* reduce aphid feeding pressures on beech and sycamore saplings, and possibly other plants as well.

Whittaker (1999) reviewed the scientific literature dealing with population responses of herbivorous insects to atmospheric CO<sub>2</sub> enrichment, concentrating on papers resulting from relatively long-term studies. Based on all pertinent research reports available at that time, the only herbivorous insects that exhibited population increases in response to elevated CO<sub>2</sub> exposure were those classified as phloem feeders, specifically, aphids. Although this finding appeared to favor aphids over plants, additional studies would complicate the issue and swing the pendulum back the other way.

Newman *et al.* (1999) grew tall fescue plants for two weeks in open-top chambers maintained at atmospheric CO<sub>2</sub> concentrations of 350 and 700 ppm before inoculating them with aphids (*Rhopalosiphum padi*). After nine additional weeks of differential CO<sub>2</sub> exposure, the plants were harvested and their associated aphids counted. Although elevated CO<sub>2</sub> increased plant dry matter production by 37 percent, the plants grown in air of elevated CO<sub>2</sub> concentration contained fewer aphids than the plants grown in ambient air.

Percy *et al.* (2002) grew the most widely distributed tree species in all of North America—trembling aspen—in twelve 30-m-diameter FACE rings in air maintained at (1) ambient CO<sub>2</sub> and O<sub>3</sub> concentrations, (2) ambient O<sub>3</sub> and elevated CO<sub>2</sub> (560 ppm during daylight hours), (3) ambient CO<sub>2</sub> and elevated O<sub>3</sub> (46.4-55.5 ppb during daylight hours), and (4) elevated CO<sub>2</sub> and O<sub>3</sub> over each growing season from 1998 through 2001. Throughout their experiment they assessed a number of the young trees' growth characteristics, as well as the responses of the sap-feeding aphid *Chaitophorus stevensis*, which they say "infests aspen throughout its range." This experiment revealed that, by itself, elevated CO<sub>2</sub> did not affect aphid abundance, but it increased the densities of natural enemies of the aphids, which over the long term would tend to reduce aphid numbers. Also, by itself, elevated O<sub>3</sub> did not affect aphid abundance, but it had a strong negative effect on natural enemies of aphids, which over the long term would tend to increase aphid numbers. When both

trace gases were applied together, elevated CO<sub>2</sub> *completely counteracted* the reduction in the abundance of natural enemies of aphids caused by elevated O<sub>3</sub>. Hence, elevated CO<sub>2</sub> tended to reduce the negative impact of aphids on trembling aspen in this comprehensive study.

At about the same time, Holopainen (2002) reviewed the scientific literature dealing with the joint effects of elevated concentrations of atmospheric O<sub>3</sub> and CO<sub>2</sub> on aphid-plant interactions. After compiling the results of 26 pertinent studies, it was found that atmospheric CO<sub>2</sub> enrichment increased aphid performance in six studies, decreased it in six studies, and had no significant impact on it in the remaining 14 studies. Similar results were found for aphid-plant interactions in the presence of elevated O<sub>3</sub> concentrations.

Newman (2003) reviewed what was known and not known about aphid responses to concurrent increases in atmospheric CO<sub>2</sub> and air temperature, while also investigating the subject via the aphid population model of Newman *et al.* (2003). This literature review and model analysis led him to conclude that when the air's CO<sub>2</sub> concentration and temperature are both elevated, "aphid population dynamics will be more similar to current ambient conditions than expected from the results of experiments studying either factor alone." We can draw only the general conclusion, according to Newman, that "insect responses to CO<sub>2</sub> are *unlikely* to all be in the same direction." Nevertheless, he says that "the lack of a simple common phenomenon does not deny that there is some overriding generality in the responses by the system." It's just that we did not at that time know what that overriding generality was, which is why experimental work on the subject has continued apace.

Concentrating on thermal effects alone, Ma *et al.* (2004) conducted detailed experiments on the effects of high temperature, period of exposure, and developmental stage on the survival of the aphid *Metopolophium dirhodum*, which they say "is the most abundant of the three cereal aphid species in Germany and central European countries." This protocol revealed, in their words, that "temperatures over 29°C for 8 hours significantly reduced survival, which decreased generally as the temperature increased." They also determined that "exposing aphids to 32.5°C for 4 hours or longer significantly reduced survival," and that "mature aphids had a lower tolerance of high temperatures than nymphs." In light of what they observed, therefore, as well as

what a number of other scientists had observed, Ma *et al.* concluded that "global warming may play a role in the long-term changes in the population abundance of *M. dirhodum*." Specifically, they say that "an increase in TX [daily average temperature] of 1°C and MaxT [maximum daily temperature] of 1.3°C during the main period of the aphid population increase would result in a 33 percent reduction in peak population size," while "an increase in TX of 2°C and MaxT of 2.6°C would result in an early population collapse (74 percent reduction of population size)." It would appear that a little global warming could greatly decrease aphid infestations of cereal crops grown throughout Germany and Central Europe.

Returning to the subject of joint CO<sub>2</sub> and O<sub>3</sub> effects on aphids, Awmack *et al.* (2004) conducted a two-year study at the Aspen FACE site near Rhinelander, Wisconsin, USA, of the individual and combined effects of elevated CO<sub>2</sub> (+200 ppm) and O<sub>3</sub> (1.5 x ambient) on the performance of *Cepigillettea betulaefoliae* aphids feeding on paper birch trees in what they call "the first investigation of the long-term effects of elevated CO<sub>2</sub> and O<sub>3</sub> atmospheres on natural insect herbivore populations." At the individual scale, they report that "elevated CO<sub>2</sub> and O<sub>3</sub> did not significantly affect [aphid] growth rates, potential fecundity (embryo number) or offspring quality." At the population scale, on the other hand, they found that "elevated O<sub>3</sub> had a strong positive effect," but that "elevated CO<sub>2</sub> did not significantly affect aphid populations."

In comparing their results with those of prior related studies, the three scientists report that "the responses of other aphid species to elevated CO<sub>2</sub> or O<sub>3</sub> are also complex." In particular, they note that "tree-feeding aphids show few significant responses to elevated CO<sub>2</sub> (Docherty *et al.*, 1997), while crop-feeding species may respond positively (Awmack *et al.*, 1997; Bezemer *et al.*, 1998; Hughes and Bazzaz, 2001; Zhang *et al.*, 2001; Stacey and Fellowes, 2002), negatively (Newman *et al.*, 1999), or not at all (Hughes and Bazzaz, 2001), and the same species may show different responses on different host plant species (Awmack *et al.*, 1997; Bezemer *et al.*, 1999)." In summarizing their observations, they stated that "aphid individual performance did not predict population responses to CO<sub>2</sub> and O<sub>3</sub>," and they concluded that "elevated CO<sub>2</sub> and O<sub>3</sub> atmospheres are unlikely to affect *C. betulaefoliae* populations in the presence of natural enemy communities."

In a study of a different aphid (*Chaitophorus stevensis*) conducted at the same FACE site, Mondor

*et al.* (2004) focused on the subject of pheromones, which they say “are utilized by insects for several purposes, including alarm signaling,” and which in the case of phloem-feeding aphids induces high-density groups of them on exposed leaves of trembling aspen trees to disperse and move to areas of lower predation risk. In this experiment the four treatments were: control (367 ppm CO<sub>2</sub>, 38 ppb O<sub>3</sub>), elevated CO<sub>2</sub> (537 ppm), elevated O<sub>3</sub> (51 ppb), and elevated CO<sub>2</sub> and O<sub>3</sub> (537 ppm CO<sub>2</sub>, 51 ppb O<sub>3</sub>). Within each treatment, several aspen leaves containing a single aphid colony of 25 ± 2 individuals were treated in one of two different ways: (1) an aphid was prodded lightly on the thorax so as to *not* produce a visible pheromone droplet, or (2) an aphid was prodded more heavily on the thorax and induced to emit a visible pheromone droplet, after which, in the words of the scientists, “aphids exhibiting any dispersal reactions in response to pheromone emission as well as those exhibiting the most extreme dispersal response, walking down the petiole and off the leaf, were recorded over 5 min.”

Mondor *et al.*'s observations were striking. They found that the aphids they studied “have diminished escape responses in enriched carbon dioxide environments, while those in enriched ozone have augmented escape responses, to alarm pheromone.” In fact, they report that “0 percent of adults dispersed from the leaf under elevated CO<sub>2</sub>, while 100 percent dispersed under elevated O<sub>3</sub>,” indicating that the effects of elevated CO<sub>2</sub> and elevated O<sub>3</sub> on aphid response to pheromone alarm signaling are diametrically opposed to each other, with elevated O<sub>3</sub> (which is detrimental to vegetation) helping aphids to escape predation and therefore live to do further harm to the leaves they infest, but with elevated CO<sub>2</sub> (which is beneficial to vegetation) making it more difficult for aphids to escape predation and thereby providing yet an additional benefit to plant foliage. Within this context, therefore, ozone may be seen to be doubly bad for plants, while carbon dioxide may be seen to be doubly good. In addition, Mondor *et al.* state that this phenomenon may be of broader scope than what is revealed by their specific study, noting that other reports suggest that “parasitoids and predators are more abundant and/or efficacious under elevated CO<sub>2</sub> levels (Stiling *et al.*, 1999; Percy *et al.*, 2002), but are negatively affected by elevated O<sub>3</sub> (Gate *et al.*, 1995; Percy *et al.*, 2002).”

In another intriguing study, Chen *et al.* (2004) grew spring wheat from seed to maturity in high-fertility well-watered pots out-of-doors in open-top

chambers (OTCs) maintained at atmospheric CO<sub>2</sub> concentrations of 370, 550, and 750 ppm. Approximately two months after seeding, 20 apterous adult aphids (*Sitobion avenae*) from an adjacent field were placed upon the wheat plants of each of 25 pots in each OTC, while 15 pots were left as controls; and at subsequent 5-day intervals, both apterous and alate aphids were counted. Then, about one month later, 10 alate morph fourth instar nymphs were introduced onto the plants of each of nine control pots; for the next two weeks the number of offspring laid on those plants were recorded and removed daily to measure reproductive activity. At the end of the study, the wheat plants were harvested and their various growth responses determined.

Adherence to these protocols revealed that the introduced aphid populations increased after infestation, peaked during the grain-filling stage, and declined a bit as the wheat matured. On the final day of measurement, aphids in the 550-ppm CO<sub>2</sub> treatment were 32 percent more numerous than those in ambient air, while aphids in the 750-ppm treatment were 50 percent more numerous. Alate aphids also produced more offspring on host plants grown in elevated CO<sub>2</sub>: 13 percent more in the 550-ppm treatment and 19 percent more in the 750-ppm treatment. As for the wheat plants, Chen *et al.* report that “elevated CO<sub>2</sub> generally enhanced plant height, aboveground biomass, ear length, and number of and dry weight of grains per ear, consistent with most other studies.” With respect to above-ground biomass, for example, the 550-ppm treatment displayed an increase of 36 percent, while the 750-ppm treatment displayed an increase of 50 percent, in the case of both aphid-infested and non-infested plants.

In commenting on their findings, Chen *et al.* report that “aphid infestation caused negative effects on all the plant traits measured ... but the negative effects were smaller than the positive effects of elevated CO<sub>2</sub> on the plant traits.” Hence, they concluded that “the increased productivity occurring in plants exposed to higher levels of CO<sub>2</sub> more than compensate for the increased capacity of the aphids to cause damage.” In this experiment, therefore, we have a situation where both the plant and the insect that feeds on it were simultaneously benefited by the applied increases in atmospheric CO<sub>2</sub> concentration.

Last, in a study that investigated a number of plant-aphid-predator relationships, Chen *et al.* (2005) grew transgenic cotton plants for 30 days in well watered and fertilized sand/vermiculite mixtures in pots set in controlled-environment chambers

maintained at atmospheric CO<sub>2</sub> concentrations of 370, 700, and 1050 ppm. A subset of aphid-infected plants was additionally supplied with predatory ladybugs, while three generations of cotton aphids (*Aphis gossypii*) were subsequently allowed to feed on some of the plants. Based on measurements made throughout this complex set of operations, Chen *et al.* found that (1) “plant height, biomass, leaf area, and carbon:nitrogen ratios were significantly higher in plants exposed to elevated CO<sub>2</sub> levels,” (2) “more dry matter and fat content and less soluble protein were found in *A. gossypii* in elevated CO<sub>2</sub>,” (3) “cotton aphid fecundity significantly increased ... through successive generations reared on plants grown under elevated CO<sub>2</sub>,” (4) “significantly higher mean relative growth rates were observed in lady beetle larvae under elevated CO<sub>2</sub>,” and (5) “the larval and pupal durations of the lady beetle were significantly shorter and [their] consumption rates increased when fed *A. gossypii* from elevated CO<sub>2</sub> treatments.” In commenting on the significance of their findings, Chen *et al.* say their study “provides the first empirical evidence that changes in prey quality mediated by elevated CO<sub>2</sub> can alter the prey preference of their natural enemies,” and in this particular case, they found that this phenomenon could “enhance the biological control of aphids by lady beetle.”

In considering the totality of these many experimental findings, it would appear that the ongoing rise in the air’s CO<sub>2</sub> content will likely not have a major impact, one way or the other, on aphid-plant interactions, although the scales do appear to be slightly tipped in favor of plants over aphids. Yet a third possibility is that both plants and aphids will be benefited by atmospheric CO<sub>2</sub> enrichment, but with plants benefiting more.

Additional information on this topic, including reviews of newer publications as they become available, can be found at <http://www.co2science.org/subject/i/insectsapahids.php>.

### 7.3.3.2. Butterflies

How will earth's butterflies respond to atmospheric CO<sub>2</sub> enrichment and global warming? We here explore what has been learned about the question over the past few years, beginning with a review of studies that focus on carbon dioxide and concluding with studies that focus on temperature.

In a study of *Lotus corniculatus* (a cyanogenic plant that produces foliar cyanoglycosides to deter against herbivory by insects) and the Common Blue Butterfly (*Polyommatus icarus*, which regularly feeds upon *L. corniculatus* because it possesses an enzyme that detoxifies cyanide-containing defensive compounds), Goverde *et al.* (1999) collected four genotypes of *L. corniculatus* differing in their concentrations of cyanoglycosides and tannins (another group of defensive compounds) near Paris, France. They then grew them in controlled-environment chambers maintained at atmospheric CO<sub>2</sub> concentrations of 350 and 700 ppm, after which they determined the effects of the doubled CO<sub>2</sub> concentration on leaf quality and allowed the larvae of the Common Blue Butterfly to feed upon the plants' leaves. This work revealed that elevated CO<sub>2</sub> significantly increased leaf tannin and starch contents in a genotypically dependent and -independent

manner, respectively, while decreasing leaf cyanoglycoside contents independent of genotype. These CO<sub>2</sub>-induced changes in leaf chemistry increased leaf palatability, as indicated by greater dry weight consumption of CO<sub>2</sub>-enriched leaves by butterfly larvae. In addition, the increased consumption of CO<sub>2</sub>-enriched leaves led to greater larval biomass and shorter larval development times, positively influencing the larvae of the Common Blue Butterfly. Hence, it is not surprising that larval mortality was lower when feeding upon CO<sub>2</sub>-enriched as opposed to ambiently grown leaves.

Goverde *et al.* (2004) grew *L. corniculatus* plants once again, this time from seed in tubes recessed into the ground under natural conditions in a nutrient-poor calcareous grassland, where an extra 232 ppm of CO<sub>2</sub> was supplied to them via a Screen-Aided CO<sub>2</sub> Control (SACC) system (Leadley *et al.*, 1997, 1999), and where insect larvae were allowed to feed on the plants (half of which received extra phosphorus fertilizer) for the final month of the experiment. The atmospheric CO<sub>2</sub> enrichment employed in this experiment increased the total dry weight of plants growing on the unfertilized soil by 21.5 percent and that of plants growing on the phosphorus-enriched soil by 36.3 percent. However, the elevated CO<sub>2</sub> treatment had no effect on pupal and adult insect mass, although Goverde *et al.* report there were "genotype-specific responses in the development time of *P. icarus* to elevated CO<sub>2</sub> conditions," with larvae originating from different mothers developing better under either elevated CO<sub>2</sub> or ambient CO<sub>2</sub>, while for still others the air's CO<sub>2</sub> concentration had no effect on development.

In another study by some of the same researchers, Goverde *et al.* (2002) raised larvae of the satyrid butterfly (*Coenonympha pamphilus*) in semi-natural undisturbed calcareous grassland plots exposed to atmospheric CO<sub>2</sub> concentrations of 370 and 600 ppm for five growing seasons. In doing so, they found that the elevated CO<sub>2</sub> concentration increased foliar concentrations of total nonstructural carbohydrates and condensed tannins in the grassland plants; but in what is often considered a negative impact, they found that it also decreased foliar nitrogen concentrations. Nevertheless, this phenomenon had no discernible effect on butterfly growth and performance. Larval development time, for example, was not affected by elevated CO<sub>2</sub>, nor was adult dry mass. In fact, the elevated CO<sub>2</sub> increased lipid concentrations in adult male butterflies by nearly 14 percent, while it marginally increased the number of

eggs in female butterflies. The former of these responses is especially important, because lipids are used as energy resources in these and other butterflies, while increased egg numbers in females also suggests an increase in fitness.

Turning to the study of temperature effects on butterflies, Parmesan *et al.* (1999) analyzed distributional changes over the past century of non-migratory species whose northern boundaries were in northern Europe (52 species) and whose southern boundaries were in southern Europe or northern Africa (40 species). This work revealed that the northern boundaries of the first group shifted northward for 65 percent of them, remained stable for 34 percent, and shifted southward for 2 percent, while the southern boundaries of the second group shifted northward for 22 percent of them, remained stable for 72 percent, and shifted southward for 5 percent, such that “nearly all northward shifts involved extensions at the northern boundary with the southern boundary remaining stable.”

This behavior is precisely what we would expect to see if the butterflies were responding to shifts in the ranges of the plants upon which they depend for their sustenance, because increases in atmospheric CO<sub>2</sub> concentration tend to ameliorate the effects of heat stress in plants and induce an upward shift in the temperature at which they function optimally. These phenomena tend to cancel the impetus for poleward migration at the warm edge of a plant’s territorial range, yet they continue to provide the opportunity for poleward expansion at the cold edge of its range. Hence, it is possible that the observed changes in butterfly ranges over the past century of concomitant warming and rising atmospheric CO<sub>2</sub> concentration are related to matching changes in the ranges of the plants upon which they feed. Or, this similarity could be due to some more complex phenomenon, possibly even some direct physiological effect of temperature and atmospheric CO<sub>2</sub> concentration on the butterflies themselves.

In any event, and in the face of the 0.8°C of global warming that occurred in Europe over the twentieth century, the consequences for European butterflies were primarily beneficial because, as Parmesan *et al.* describe the situation, “most species effectively expanded the size of their range when shifting northwards,” since “nearly all northward shifts involved extensions at the northern boundary with the southern boundary remaining stable.”

Across the Atlantic in America, Fleishman *et al.* (2001) used comprehensive data on butterfly

distributions from six mountain ranges in the U.S. Great Basin to study how butterfly assemblages of that region may respond to IPCC-projected climate change. Whereas prior, more-simplistic analyses have routinely predicted the extirpation of great percentages of the butterfly species in this region in response to model-predicted increases in air temperature, Fleishman *et al.*’s study revealed that “few if any species of montane butterflies are likely to be extirpated from the entire Great Basin (i.e., lost from the region as a whole).”

In further discussing their results, the three researchers note that “during the Middle Holocene, approximately 8000-5000 years ago, temperatures in the Great Basin were several degrees warmer than today.” Thus, they go on say that “we might expect that most of the montane species—including butterflies—that currently inhabit the Great Basin would be able to tolerate the magnitude of climatic warming forecast over the next several centuries.” Consequently, it would appear that even if the global warming projections of the IPCC were true, the predictions of butterfly extinctions associated with those projections are almost certainly false.

Returning to the British Isles, Thomas *et al.* (2001) documented an unusually rapid expansion of the ranges of two butterfly species (the silver-spotted skipper butterfly and the brown argus butterfly) along with two cricket species (the long-winged cone-head and Roesel’s bush cricket). They write that the warming-induced “increased habitat breadth and dispersal tendencies have resulted in about 3- to 15-fold increases in expansion rates.”

In commenting on these findings, Pimm (2001) truly states the obvious when he says the geographical ranges of these insects are “expanding faster than expected,” and that the synergies involved in the many intricacies of the range expansion processes are also “unexpected.”

Crozier (2004) writes that “*Atalopedes campestris*, the sagem skipper butterfly, expanded its range from northern California into western Oregon in 1967, and into southwestern Washington in 1990,” where she reports that temperatures rose by 2-4°C over the prior half-century. Thus intrigued, and in an attempt to assess the importance of this regional warming for the persistence of *A. campestris* in the recently colonized areas, Crozier “compared population dynamics at two locations (the butterfly’s current range edge and just inside the range) that differ by 2-3°C.” Then, to determine the role of over-

winter larval survivorship, she “transplanted larvae over winter to both sites.”

This work revealed, in her words, that “combined results from population and larval transplant analyses indicate that winter temperatures directly affect the persistence of *A. campestris* at its northern range edge, and that winter warming was a prerequisite for this butterfly’s range expansion.” Noting that “populations are more likely to go extinct in colder climates,” Crozier says “the good news about rapid climate change [of the warming type] is that new areas may be available for the introduction of endangered species.” Her work also demonstrates that the species she studied has responded to regional warming by extending its northern range boundary and thereby expanding its range.

Two years later, Davies *et al.* (2006) introduced their study of the silver-spotted skipper butterfly (*Hesperia comma* L.) by noting that during the twentieth century it “became increasingly rare in Britain [as] a result of the widespread reduction of sparse, short-turfed calcareous grassland containing the species’ sole larval host plant, sheep’s fescue grass [*Festuca ovina* L.]” As a result, they describe the “refuge” colonies of 1982 as but a “remnant” of what once had been. The four researchers analyzed population density data together with estimates of the percentage bare ground and the percentage of sheep’s fescue available to the butterflies, based on surveys conducted in Surrey in the chalk hills of the North Downs, south of London, in 1982 (Thomas *et al.*, 1986), 1991 (Thomas and Jones, 1993), 2000 (Thomas *et al.*, 2001; Davies *et al.*, 2005), and 2001 (R.J. Wilson, unpublished data). In addition, they assessed egg-laying rates in different microhabitats, as well as the effects of ambient and oviposition site temperatures on egg laying, and the effects of sward composition on egg location. This work revealed, in their words, that “in 1982, 45 habitat patches were occupied by *H. comma* [but] in the subsequent 18-year period, the species expanded and, by 2000, a further 29 patches were colonized within the habitat network.” In addition, they found that “the mean egg-laying rate of *H. comma* females increased with rising ambient temperatures,” and that “a wider range of conditions have become available for egg-laying.”

In discussing their findings, Davies *et al.* state that “climate warming has been an important driving force in the recovery of *H. comma* in Britain [as] the rise in ambient temperature experienced by the butterfly will have aided the metapopulation re-expansion in a number of ways.” First, they suggest

that “greater temperatures should increase the potential fecundity of *H. comma* females,” and that “if this results in larger populations, for which there is some evidence (e.g. 32 of the 45 habitat patches occupied in the Surrey network experienced site-level increases in population density between 1982 and 2000), they will be less prone to extinction,” with “larger numbers of dispersing migrant individuals being available to colonize unoccupied habitat patches and establish new populations.” Second, they state that “the wider range of thermal and physical microhabitats used for egg-laying increased the potential resource density within each grassland habitat fragment,” and that “this may increase local population sizes.” Third, they argue that “colonization rates are likely to be greater as a result of the broadening of the species realized niche, [because] as a larger proportion of the calcareous grassland within the species’ distribution becomes thermally suitable, the relative size and connectivity of habitat patches within the landscape increases.” Fourth, they note that “higher temperatures may directly increase flight (dispersal) capacity, and the greater fecundity of immigrants may improve the likelihood of successful population establishment.” Consequently, Davies *et al.* conclude that “the warmer summers predicted as a consequence of climate warming are likely to be beneficial to *H. comma* within Britain,” and they suggest that “warmer winter temperatures could also allow survival in a wider range of microhabitats.”

In a concurrent study, Menendez *et al.* (2006) provided what they call “the first assessment, at a geographical scale, of how species richness has changed in response to climate change,” concentrating on British butterflies. This they did by testing “whether average species richness of resident British butterfly species has increased in recent decades, whether these changes are as great as would be expected given the amount of warming that has taken place, and whether the composition of butterfly communities is changing towards a dominance by generalist species.” By these means they determined that “average species richness of the British butterfly fauna at 20 x 20 km grid resolution has increased since 1970-82, during a period when climate warming would lead us to expect increases.” They also found, as expected, that “southerly habitat generalists increased more than specialists,” which require a specific type of habitat that is sometimes difficult for them to find, especially in the modern world where habitat destruction is commonplace. In addition, they were able to determine that observed species richness

increases lagged behind those expected on the basis of climate change.

These results “confirm,” according to the nine UK researchers, “that the average species richness of British butterflies has increased since 1970-82.” However, some of the range shifts responsible for the increase in species richness take more time to occur than those of other species; they say their results imply “it may be decades or centuries before the species richness and composition of biological communities adjusts to the current climate.”

Also working in Britain, Hughes *et al.* (2007) examined evolutionary changes in adult flight morphology in six populations of the speckled wood butterfly—*Pararge aegeria* L. (Satyrinae)—along a transect from its distribution core to its warming-induced northward expanding range margin. The results of this exercise were then compared with the output of an individual-based spatially explicit model that was developed “to investigate impacts of habitat availability on the evolution of dispersal in expanding populations.” This work indicated that the empirical data the researchers gathered “were in agreement with model output,” and that they “showed increased dispersal ability with increasing distance from the distribution core,” which included favorable changes in thorax shape, abdomen mass, and wing aspect ratio for both males and females, as well as thorax mass and wing loading for females. In addition, they say that “increased dispersal ability was evident in populations from areas colonized >30 years previously.”

In discussing their findings, Hughes *et al.* suggest that “evolutionary increases in dispersal ability in expanding populations may help species track future climate changes and counteract impacts of habitat fragmentation by promoting colonization.” However, they report that in the specific situation they investigated, “at the highest levels of habitat loss, increased dispersal was less evident during expansion and reduced dispersal was observed at equilibrium, indicating that for many species, continued habitat fragmentation is likely to outweigh any benefits from dispersal.” Put another way, it would appear that global warming is proving not to be an insurmountable problem for the speckled wood butterfly, which is evolving physical characteristics that allow it to better keep up with the poleward migration of its current environmental niche, but that the direct destructive assaults of humanity upon its natural habitat could still end up driving it to extinction.

Analyzing data pertaining to the general abundance of Lepidoptera in Britain over the period 1864-1952, based on information assembled by Beirne (1955) via his examination of “several thousand papers in entomological journals describing annual abundances of moths and butterflies,” were Dennis and Sparks (2007), who report that “abundances of British Lepidoptera were significantly positively correlated with Central England temperatures in the current year for each month from May to September and November,” and that “increased overall abundance in Lepidoptera coincided significantly with increased numbers of migrants,” which latter data were derived from the work of Williams (1965). In addition, they report that Pollard (1988) subsequently found much the same thing for 31 butterfly species over the period 1976-1986, and that Roy *et al.* (2001) extended the latter investigation to 1997, finding “strong associations between weather and population fluctuations and trends in 28 of 31 species which confirmed Pollard’s (1988) findings,” all of which observations indicate that the warming-driven increase in Lepidopteran species and numbers in Britain has been an ongoing phenomenon ever since the end of the Little Ice Age.

Returning to North America for one final study, White and Kerr (2006), as they describe it, “report butterfly species’ range shifts across Canada between 1900 and 1990 and develop spatially explicit tests of the degree to which observed shifts result from climate or human population density,” the latter of which factors they describe as “a reasonable proxy for land use change,” within which broad category they include such things as “habitat loss, pesticide use, and habitat fragmentation,” all of which anthropogenic-driven factors have been tied to declines of various butterfly species. In addition, they say that to their knowledge, “this is the broadest scale, longest term dataset yet assembled to quantify global change impacts on patterns of species richness.”

This exercise led White and Kerr to discover that butterfly species richness “generally increased over the study period, a result of range expansion among the study species,” and they further found that this increase “from the early to late part of the twentieth century was positively correlated with temperature change,” which had to have been the *cause* of the change, for they also found that species richness was “negatively correlated with human population density change.”

Contrary to the doom-and-gloom prognostications of some experts, the supposedly unprecedented global

warming of the twentieth century has been beneficial for the butterfly species that inhabit Canada, Britain, and the United States, as their ranges have expanded and greater numbers of species are now being encountered in each country.

Additional information on this topic, including reviews of newer publications as they become available, can be found at <http://www.co2science.org/subject/i/summaries/butterflies.php>.

7.3.3.3. *Moths*

Kerslake *et al.* (1998) collected five-year-old heather plants from a Scottish moor and grew them in open-top chambers maintained at atmospheric CO<sub>2</sub> concentrations of 350 and 600 ppm for 20 months, with and without soil nitrogen fertilization. At two different times during the study, larvae of *Operophtera brumata*, a voracious winter moth whose outbreaks have caused extensive damage to heather moorland in recent years, were allowed to feed upon current-year shoots for up to one month. The results obtained from this experiment revealed that the survivorship of larvae placed on CO<sub>2</sub>-enriched foliage was not significantly different from that of larvae placed on foliage produced in ambient air, regardless of nitrogen treatment. In addition, feeding upon CO<sub>2</sub>-enriched foliage did not affect larval growth rate, development, or final pupal weight. Consequently, Kerslake *et al.* concluded that their study “provides no evidence that increasing atmospheric CO<sub>2</sub> concentrations will affect the potential for outbreak of *Operophtera brumata* on this host.”

Hattenschwiler and Schafellner (1999) grew seven-year-old spruce trees at atmospheric CO<sub>2</sub> concentrations of 280, 420, and 560 ppm in various nitrogen deposition treatments for three years, after which they performed needle quality assessments and allowed nun moth (*Lymantria monacha*) larvae to feed upon current-year needles for 12 days. This moth is an especially voracious defoliator that resides in most parts of Europe and East Asia between 40 and 60° N latitude, and it is commonly regarded as the “coniferous counterpart” of its close relative the gypsy moth, which feeds primarily upon deciduous trees.

The two scientists determined from their observations that elevated CO<sub>2</sub> significantly enhanced needle starch, tannin, and phenolic concentrations, while significantly decreasing needle water and nitrogen contents. Thus, atmospheric CO<sub>2</sub> enrichment reduced overall needle quality from the perspective of this foliage-consuming moth, as nitrogen content is the primary factor associated with leaf quality. Increasing nitrogen deposition, on the other hand, tended to enhance needle quality, for it lowered starch, tannin, and phenolic concentrations while boosting needle nitrogen content. Nevertheless, the positive influence of nitrogen deposition on needle quality was not large enough to completely offset the quality reduction caused by elevated CO<sub>2</sub>.

In light of these observations, it was no surprise that larvae placed on CO<sub>2</sub>-enriched foliage consumed less needle biomass than larvae placed on low-CO<sub>2</sub>-grown foliage, regardless of nitrogen treatment, and that the larvae feeding on CO<sub>2</sub>-enriched foliage exhibited reduced relative growth rates and attained an average biomass that was only two-thirds of that attained by larvae consuming foliage produced at 280 ppm CO<sub>2</sub>. As a result, Hattenschwiler and Schafellner concluded that “altered needle quality in response to elevated CO<sub>2</sub> will impair the growth and development of *Lymantria monacha* larvae,” which should lead to reductions in the degree of spruce tree destruction caused by this voracious defoliator.

Stiling *et al.* (2002) studied the effects of an approximate doubling of the air’s CO<sub>2</sub> concentration on a number of characteristics of several insect herbivores feeding on plants native to a scrub-oak forest ecosystem at the Kennedy Space Center, Florida, USA, in eight ambient and eight CO<sub>2</sub>-enriched open-top chambers. They say that the “relative levels of damage by the two most common herbivore guilds, leaf-mining moths and leaf-chewers (primarily larval lepidopterans and grasshoppers), were significantly lower in elevated CO<sub>2</sub> than in ambient CO<sub>2</sub>,” and that “the response to elevated CO<sub>2</sub> was the same across all plant species.”

In a follow-up study to that of Stiling *et al.*, which was conducted at the same facilities, Rossi *et al.* (2004), focused on the abundance of a guild of lepidopteran leafminers that attack the leaves of myrtle oak, as well as various leaf chewers that also like to munch on this species. Specifically, they periodically examined 100 marked leaves in each of the 16 open-top chambers for a total of nine months, after which, in their words, “differences in mean percent of leaves with leafminers and chewed leaves on trees from ambient and elevated chambers were assessed using paired *t*-tests.” This protocol revealed, in their words, that “both the abundance of the guild of leafmining lepidopterans and damage caused by leaf chewing insects attacking myrtle oak were depressed in elevated CO<sub>2</sub>.” Leafminer abundance was 44 percent lower ( $P = 0.096$ ) in the CO<sub>2</sub>-enriched chambers compared to the ambient-air chambers, while the abundance of leaves suffering chewing damage was 37 percent lower ( $P = 0.072$ ) in the CO<sub>2</sub>-enriched air.

Working with red maple saplings, Williams *et al.* (2003) bagged first instar gypsy moth larvae on branches of trees that were entering their fourth year of growth within open-top chambers maintained at

four sets of CO<sub>2</sub>/temperature conditions: (1) ambient temperature, ambient CO<sub>2</sub>, (2) ambient temperature, elevated CO<sub>2</sub> (ambient + 300 ppm), (3) elevated temperature (ambient + 3.5°C), ambient CO<sub>2</sub>, and (4) elevated temperature, elevated CO<sub>2</sub>. For these conditions they measured several parameters that were required to test their hypothesis that a CO<sub>2</sub>-enriched atmosphere would lead to reductions in foliar nitrogen concentrations and increases in defensive phenolics that would in turn lead to increases in insect mortality. The results they obtained indicated, in their words, “that larvae feeding on CO<sub>2</sub>-enriched foliage ate a comparably poorer food source than those feeding on ambient CO<sub>2</sub>-grown plants, irrespective of temperature.” Nevertheless, they determined that “CO<sub>2</sub>-induced reductions in foliage quality were unrelated to insect mortality, development rate and pupal weight.” As a result, they were forced to conclude that “phytochemical changes resulted in no negative effects on gypsy moth performance,” but neither did they help them.

Noting that increases in the atmosphere’s CO<sub>2</sub> concentration typically lead to greater decreases in the concentrations of nitrogen in the foliage of C<sub>3</sub> as opposed to C<sub>4</sub> grasses, Barbehenn *et al.* (2004) say “it has been predicted that insect herbivores will increase their feeding damage on C<sub>3</sub> plants to a greater extent than on C<sub>4</sub> plants (Lincoln *et al.*, 1984, 1986; Lambers, 1993). To test this hypothesis, they grew *Lolium multiflorum* (Italian ryegrass, a common C<sub>3</sub> pasture grass) and *Bouteloua curtipendula* (sideoats gramma, a native C<sub>4</sub> rangeland grass) in chambers maintained at either the ambient atmospheric CO<sub>2</sub> concentration of 370 ppm or the doubled CO<sub>2</sub> concentration of 740 ppm for two months, after which newly molted sixth-instar larvae of *Pseudaletia unipuncta* (a grass-specialist noctuid) and *Spodoptera frugiperda* (a generalist noctuid) were allowed to feed upon the two grasses.

As expected, Barbehenn *et al.* found that foliage protein concentration decreased by 20 percent in the C<sub>3</sub> grass, but by only 1 percent in the C<sub>4</sub> grass, when they were grown in CO<sub>2</sub>-enriched air; and they say that “to the extent that protein is the most limiting of the macronutrients examined, these changes represent a decline in the nutritional quality of the C<sub>3</sub> grass.” However, and “contrary to our expectations,” in the words of Barbehenn *et al.*, “neither caterpillar species significantly increased its consumption rate to compensate for the lower concentration of protein in [the] C<sub>3</sub> grass,” and they note that “this result does not

support the hypothesis that C<sub>3</sub> plants will be subject to greater rates of herbivory relative to C<sub>4</sub> plants in future [high-CO<sub>2</sub>] atmospheric conditions (Lincoln *et al.*, 1984).” In addition, and “despite significant changes in the nutritional quality of *L. multiflorum* under elevated CO<sub>2</sub>,” they note that “no effect on the relative growth rate of either caterpillar species on either grass species resulted,” and that there were “no significant differences in insect performance between CO<sub>2</sub> levels.” By way of explanation of these results, they suggest that “post-ingestive mechanisms could provide a sufficient means of compensation for the lower nutritional quality of C<sub>3</sub> plants grown under elevated CO<sub>2</sub>.”

In light of these observations, Barbehenn *et al.* suggest “there will not be a single pattern that characterizes all grass feeders” with respect to their feeding preferences and developmental responses in a world where certain C<sub>3</sub> plants may experience foliar protein concentrations that are lower than those they exhibit today, nor will the various changes that may occur necessarily be detrimental to herbivore development or to the health and vigor of their host plants. Nevertheless, subsequent studies continue to suggest that various moth species will likely be negatively affected by the ongoing rise in the air’s CO<sub>2</sub> content.

A case in point is the study of Chen *et al.* (2005), who grew well watered and fertilized cotton plants of two varieties (one expressing *Bacillus thuringiensis* toxin genes and one a non-transgenic cultivar from the same recurrent parent) in pots placed within open-top chambers maintained at either 376 or 754 ppm CO<sub>2</sub> in Sanhe County, Hebei Province, China, from planting in mid-May to harvest in October, while immature bolls were periodically collected and analyzed for various chemical characteristics and others were stored under refrigerated conditions for later feeding to larvae of the cotton bollworm. By these means they found that the elevated CO<sub>2</sub> treatment increased immature boll concentrations of condensed tannins by approximately 22 percent and 26 percent in transgenic and non-transgenic cotton, respectively, and that it slightly decreased the body biomass of the cotton bollworm and reduced moth fecundity. The Bt treatment was even more effective in this regard; and in the combined Bt-high-CO<sub>2</sub> treatment, the negative cotton bollworm responses were expressed most strongly of all.

Bidart-Bouzat *et al.* (2005) grew three genotypes of mouse-ear cress (*Arabidopsis thaliana*) from seed in pots within controlled-environment chambers

maintained at either ambient CO<sub>2</sub> (360 ppm) or elevated CO<sub>2</sub> (720 ppm). On each of half of the plants (the herbivory treatment) in each of these CO<sub>2</sub> treatments, they placed two second-instar larvae of the diamondback moth (*Plutella xylostella*) at bolting time and removed them at pupation, which resulted in an average of 20 percent of each plant's total leaf area in the herbivory treatment being removed. Then, each pupa was placed in a gelatin capsule until adult emergence and ultimate death, after which insect gender was determined and the pupa's weight recorded. At the end of this herbivory trial, the leaves of the control and larvae-infested plants were analyzed for concentrations of individual glucosinolates—a group of plant-derived chemicals that can act as herbivore deterrents (Maruicio and Rausher, 1997)—while total glucosinolate production was determined by summation of the individual glucosinolate assays. Last, influences of elevated CO<sub>2</sub> on moth performance and its association with plant defense-related traits were evaluated.

Overall, it was determined by these means that herbivory by larvae of the diamondback moth did not induce any increase in the production of glucosinolates in the mouse-ear cress in the ambient CO<sub>2</sub> treatment. However, the three scientists report that “herbivory-induced increases in glucosinolate contents, ranging from 28% to 62% above basal levels, were found under elevated CO<sub>2</sub> in two out of the three genotypes studied.” In addition, they determined that “elevated CO<sub>2</sub> decreased the overall performance of diamondback moths.” And because “induced defenses can increase plant fitness by reducing subsequent herbivore attacks (Agrawal, 1999; Kessler and Baldwin, 2004),” according to Bidart-Bouzat *et al.*, they suggest that “the pronounced increase in glucosinolate levels under CO<sub>2</sub> enrichment may pose a threat not only for insect generalists that are likely to be more influenced by rapid changes in the concentration of these chemicals, but also for other insect specialists more susceptible than diamondback moths to high glucosinolate levels (Stowe, 1998; Kliebenstein *et al.*, 2002).”

In a study of a major crop species, Wu *et al.* (2006) grew spring wheat (*Triticum aestivum* L.) from seed to maturity in pots placed within open-top chambers maintained at either 370 or 750 ppm CO<sub>2</sub> in Sanhe County, Hebei Province, China, after which they reared three generations of cotton bollworms (*Helicoverpa armigera* Hubner) on the milky grains of the wheat, while monitoring a number of different bollworm developmental characteristics. In doing so,

as they describe it, “significantly lower pupal weights were observed in the first, second and third generations,” and “the fecundity of *H. armigera* decreased by 10% in the first generation, 13% in the second generation and 21% in the third generation,” resulting in a “potential population decrease in cotton bollworm by 9% in the second generation and 24% in the third generation.” In addition, they say that “population consumption was significantly reduced by 14% in the second generation and 24% in the third generation,” and that the efficiency of conversion of ingested food was reduced “by 18% in the first generation, 23% in the second generation and 30% in the third generation.” As a result, they concluded that the “net damage of cotton bollworm on wheat will be less under elevated atmospheric CO<sub>2</sub>,” while noting that “at the same time, gross wheat production is expected to increase by 63% under elevated CO<sub>2</sub>.”

In another report of their work, Wu *et al.* (2007) write that “significant decreases in the protein, total amino acid, water and nitrogen content by 15.8%, 17.7%, 9.1% and 20.6% and increases in free fatty acid by 16.1% were observed in cotton bolls grown under elevated CO<sub>2</sub>.” And when fed with these cotton bolls, they say that the larval survival rate of *H. armigera* “decreased by 7.35% in the first generation, 9.52% in the second generation and 11.48% in the third generation under elevated CO<sub>2</sub> compared with ambient CO<sub>2</sub>.” In addition, they observed that “the fecundity of *H. armigera* decreased by 7.74% in the first generation, 14.23% in the second generation and 16.85% in the third generation,” while noting that “fecundity capacity is likely to be reduced even further in the next generation.”

The synergistic effects of these several phenomena, in the words of Wu *et al.*, “resulted in a potential population decrease in cotton bollworm by 18.1% in the second generation and 52.2% in the third generation under elevated CO<sub>2</sub>,” with the result that “the potential population consumption of cotton bollworm decreased by 18.0% in the second generation and 55.6% in the third generation ... under elevated CO<sub>2</sub> compared with ambient CO<sub>2</sub>.” And in light of these several findings, they concluded that “the potential population dynamics and potential population consumption of cotton bollworm will alleviate the harm to [cotton] plants in the future rising-CO<sub>2</sub> atmosphere.”

In a different type of study, Esper *et al.* (2007) reconstructed an annually resolved history of population cycles of a foliage-feeding Lepidopteran commonly known as the larch budmoth (*Zeiraphera*

*diniana* Gn.)—or LBM for short—within the European Alps in the southern part of Switzerland. As is typical of many such insect pests, they note that “during peak activity, populations may reach very high densities over large areas,” resulting in “episodes of massive defoliation and/or tree mortality” that could be of great ecological and economic significance.

The first thing the team of Swiss and US researchers thus did in this regard was develop a history of LBM outbreaks over the 1,173-year period AD 832-2004, which they describe as “the longest continuous time period over which any population cycle has ever been documented.”

They accomplished this feat using radiodensitometric techniques to characterize the tree-ring density profiles of 180 larch (*Larix deciduas* Mill.) samples, where “LBM outbreaks were identified based upon characteristic maximum latewood density (MXD) patterns in wood samples, and verified using more traditional techniques of comparison with tree-ring chronologies from non-host species,” i.e., fir and spruce. Then, they developed a matching temperature history for the same area, which was accomplished by combining “a tree-ring width-based reconstruction from AD 951 to 2002 integrating 1527 pine and larch samples (Buntgen *et al.*, 2005) and a MXD-based reconstruction from AD 755 to 2004 based upon the same 180 larch samples used in the current study for LBM signal detection (Buntgen *et al.*, 2006).”

Over almost the entire period studied, from its start in AD 832 to 1981, there were a total of 123 LBM outbreaks with a mean reoccurrence time of 9.3 years. In addition, the researchers say “there was never a gap that lasted longer than two decades.” From 1981 to the end of their study in 2004, however, there were *no* LBM outbreaks; since there had never before (within their record) been such a long outbreak hiatus, they concluded that “the absence of mass outbreaks since the 1980s is truly exceptional.”

To what do Esper *et al.* attribute this unprecedented recent development? Noting that “conditions during the late twentieth century represent the warmest period of the past millennium”—as per their temperature reconstruction for the region of the Swiss Alps within which they worked—they point to “the role of extraordinary climatic conditions as the cause of outbreak failure,” and they discuss what they refer to as the “probable hypothesis” of Baltensweiler (1993), who described a

scenario by which local warmth may lead to reduced LBM populations.

Such may well be the case, but we hasten to add that atmospheric CO<sub>2</sub> concentrations since 1980 have also been unprecedented over the 1,173-year period of Esper *et al.*'s study. Hence, the suppression of LBM outbreaks over the past quarter-century may have been the result of some *synergistic* consequence of the two factors (temperature and CO<sub>2</sub>) acting in unison, while a third possibility may involve only the increase in the air's CO<sub>2</sub> content.

Esper *et al.* say their findings highlight the “vulnerability of an otherwise stable ecological system in a warming environment,” in what would appear to be an attempt to attach an undesirable connotation to the observed outcome. This wording seems strange indeed, for it is clear that the “recent disruption of a major disturbance regime,” as Esper *et al.* refer to the suppression of LBM outbreaks elsewhere in their paper, would be considered by most people to be a positive outcome, and something to actually be welcomed.

Working with *Antheraea polyphemus*—a leaf-chewing generalist lepidopteran herbivore that represents the most abundant feeding guild in the hardwood trees that grow beneath the canopy of the unmanaged loblolly pine plantation that hosts the Forest Atmosphere Carbon Transfer and Storage (FACTS-1) research site in the Piedmont region of North Carolina, USA, where the leaf-chewer can consume 2-15 percent of the forest's net primary production in any given year—Knepp *et al.* (2007) focused their attention on two species of oak tree—*Quercus alba* L. (white oak) and *Quercus velutina* Lam. (black oak)—examining host plant preference and larval performance of *A. polyphemus* when fed foliage of the two tree species that had been grown in either ambient or CO<sub>2</sub>-enriched air (to 200 ppm above ambient) in this long-running FACE experiment. In doing so, they determined that “growth under elevated CO<sub>2</sub> reduced the food quality of oak leaves for caterpillars,” while “consuming leaves of either oak species grown under elevated CO<sub>2</sub> slowed the rate of development of *A. polyphemus* larvae.” In addition, they found that feeding on foliage of *Q. velutina* that had been grown under elevated CO<sub>2</sub> led to reduced consumption by the larvae and greater mortality. As a result, they concluded that “reduced consumption, slower growth rates, and increased mortality of insect larvae may explain [the] lower total leaf damage observed previously in plots of this forest exposed to elevated CO<sub>2</sub>,” as documented by Hamilton *et al.*

(2004) and Knepp *et al.* (2005), which finding bodes well indeed for the growth and vitality of such forests in the years and decades ahead, as the air's CO<sub>2</sub> content continues to rise.

Kampichler *et al.* (2008) also worked with oak trees. Noting, however, that “systems studied so far have not included mature trees,” they attempted to remedy this situation by determining “the abundance of dominant leaf-galls (spangle-galls induced by the cynipid wasps *Neuroterus quercusbaccarum* and *N. numismalis*) and leaf-mines (caused by the larvae of the moth *Tischeria ekebladella*) on freely colonized large oaks in a mixed forest in Switzerland, which received CO<sub>2</sub> enrichment [540 ppm vs. 375 ppm during daylight hours] from 2001 to 2004” via “the Swiss Canopy Crane (SCC) and a new CO<sub>2</sub> enrichment technique (web-FACE)” in a forest that they say “is 80-120 years old with a canopy height of 32-38 m, consisting of seven deciduous and four coniferous species.” This work allowed the German, Mexican, and Swiss researchers to discover that although elevated CO<sub>2</sub> reduced various leaf parameters (water content, proteins, non-structural carbohydrates, tannins, etc.) at the SCC site, “on the long term, their load with cynipid spangle-galls and leaf-mines of *T. ekebladella* was not distinguishable from that in oaks exposed to ambient CO<sub>2</sub> after 4 years of treatment.” Kampichler *et al.* concluded that in the situation they investigated, “CO<sub>2</sub> enrichment had no lasting effect in all three [animal] taxa, despite the substantial and consistent change in leaf chemistry of oak due to growth in elevated CO<sub>2</sub>.”

In conclusion, therefore, and considering the results of all of the studies reviewed in this section, it would appear that the ongoing rise in the air's CO<sub>2</sub> content will *not* result in greater damage to earth's vegetation by the larvae of the many moths that inhabit the planet, and could reduce the damage they cause.

### 7.3.3.4. Other Insects

Docherty *et al.* (1997), in addition to studying aphids, studied two sap-feeding leafhopper species that were allowed to feed on saplings of beech and sycamore that were grown in glasshouses maintained at atmospheric CO<sub>2</sub> concentrations of 350 and 600 ppm. As far as they could determine, there were no significant effects of the extra CO<sub>2</sub> on either the feeding or performance characteristics of either leafhopper species.

In a literature review of more than 30 studies published two years later, Whittaker (1999) found that chewing insects (leaf chewers and leaf miners) showed either no change or reductions in abundance in response to atmospheric CO<sub>2</sub> enrichment, noting, however, that population reductions in this feeding guild were often accompanied by increased herbivory in response to CO<sub>2</sub>-induced reductions in leaf nitrogen content.

In an experiment conducted on a natural ecosystem in Wisconsin, USA—comprised predominantly of trembling aspen (*Populus tremuloides* Michx.)—Percy *et al.* (2002) studied the effects of increases in CO<sub>2</sub> alone (to 560 ppm during daylight hours), O<sub>3</sub> alone (to 46.4-55.5 ppb during daylight hours), and CO<sub>2</sub> and O<sub>3</sub> together on the forest tent caterpillar (*Malacosoma disstria*), a common leaf-chewing lepidopteran found in North American hardwood forests. By itself, elevated CO<sub>2</sub> reduced caterpillar performance by reducing female pupal mass; while elevated O<sub>3</sub> alone improved caterpillar performance by increasing female pupal mass. When both gases were applied together, however, the elevated CO<sub>2</sub> completely counteracted the enhancement of female pupal mass caused by elevated O<sub>3</sub>. Hence, either alone or in combination with undesirable increases in the air's O<sub>3</sub> concentration, elevated CO<sub>2</sub> tended to reduce the performance of the forest tent caterpillar. This finding is particularly satisfying because, in the words of Percy *et al.*, “historically, the forest tent caterpillar has defoliated more deciduous forest than any other insect in North America,” and because “outbreaks can reduce timber yield up to 90% in one year, and

increase tree vulnerability to disease and environmental stress.”

In a study of yet another type of insect herbivore, Brooks and Whittaker (1999) removed grassland monoliths from the Great Dun Fell of Cumbria, UK—which contained eggs of a destructive xylem-feeding spittlebug (*Neophilaenus lineatus*)—and grew them in glasshouses maintained for two years at atmospheric CO<sub>2</sub> concentrations of 350 and 600 ppm. During the course of their experiment, two generations of the xylem-feeding insect were produced; in each case, elevated CO<sub>2</sub> reduced the survival of nymphal stages by an average of 24 percent. Brooks and Whittaker suggest that this reduction in survival rate may have been caused by CO<sub>2</sub>-induced reductions in stomatal conductance and transpirational water loss, which may have reduced xylem nutrient-water availability. Whatever the mechanism, the results of this study bode well for the future survival of these species-poor grasslands as the air’s CO<sub>2</sub> content continues to rise.

In summing up the implications of the various phenomena described in this section, it would appear that both CO<sub>2</sub>-induced and warming-induced changes in the physical characteristics and behavioral patterns of a diverse assemblage of insect types portend good things for the biosphere in the years and decades to come.

### 7.3.4. Shade

Is the growth-enhancing effect of atmospheric CO<sub>2</sub> enrichment reduced when light intensities are less than optimal? The question may be important if a warmer world is also a cloudier world, as some climate models predict.

In a review of the scientific literature designed to answer this question, Kerstiens (1998) analyzed the results of 15 previously published studies of trees having differing degrees of shade tolerance, finding that elevated CO<sub>2</sub> caused greater relative biomass increases in shade-tolerant species than in shade-intolerant or sun-loving species. In more than half of the studies analyzed, shade-tolerant species experienced CO<sub>2</sub>-induced relative growth increases that were two to three times greater than those of less shade-tolerant species.

In an extended follow-up review analyzing 74 observations from 24 studies, Kerstiens (2001) reported that twice-ambient CO<sub>2</sub> concentrations increased the relative growth response of shade-tolerant and shade-intolerant woody species by an average of 51 and 18 percent, respectively. Similar results were reported by Poorter and Perez-Soba (2001), who performed a detailed meta-analysis of research results pertaining to this topic, and more recently by Kubiske *et al.* (2002), who measured photosynthetic acclimation in aspen and sugar maple trees. On the other hand, a 200-ppm increase in the air’s CO<sub>2</sub> concentration was found to enhance the photosynthetic rates of sunlit and shaded leaves of sweetgum trees by 92 and 54 percent, respectively, at one time of year, and by 166 and 68 percent at another time (Herrick and Thomas, 1999). Likewise,

Naumburg and Ellsworth (2000) reported that a 200-ppm increase in the air's CO<sub>2</sub> content boosted steady-state photosynthetic rates in leaves of four hardwood understory species by an average of 60 and 40 percent under high and low light intensities, respectively. Even though these photosynthetic responses were significantly less in shaded leaves, they were still substantial, with mean increases ranging from 40 to 68 percent for a 60 percent increase in atmospheric CO<sub>2</sub> concentration.

Under extremely low light intensities, the benefits arising from atmospheric CO<sub>2</sub> enrichment may be small, but oftentimes they are very important in terms of plant carbon budgeting. In the study of Hattenschwiler (2001), for example, seedlings of five temperate forest species subjected to an additional 200-ppm CO<sub>2</sub> under light intensities that were only 3.4 and 1.3 percent of full sunlight exhibited CO<sub>2</sub>-induced biomass increases that ranged from 17 to 74 percent. Similarly, in the study of Naumburg *et al.* (2001), a 200-ppm increase in the air's CO<sub>2</sub> content enhanced photosynthetic carbon uptake in three of four hardwood understory species by more than two-fold in three of the four species under light irradiances that were as low as 3 percent of full sunlight.

In a final study, in which potato plantlets inoculated with an arbuscular mycorrhizal fungus were grown at various light intensities and *super* CO<sub>2</sub> enrichment of approximately 10,000 ppm, Louche-Tessandier *et al.* (1999) found that the unusually high CO<sub>2</sub> concentration produced an unusually high degree of root colonization by the beneficial mycorrhizal fungus, which typically helps supply water and nutrients to plants. And it did so irrespective of the degree of light intensity to which the potato plantlets were exposed.

So, whether light intensity is high or low, or leaves are shaded or sunlit, when the CO<sub>2</sub> content of the air is increased, so too are the various biological processes that lead to plant robustness. Less than optimal light intensities do not negate the beneficial effects of atmospheric CO<sub>2</sub> enrichment.

Additional information on this topic, including reviews of newer publications as they become available, can be found at <http://www.co2science.org/subject/g/lightinteraction.php>.

### 7.3.5. Ozone

Plants grown in CO<sub>2</sub>-enriched air nearly always exhibit increased photosynthetic rates and biomass production relative to plants grown at the current ambient CO<sub>2</sub> concentration. By contrast, plants exposed to elevated ozone concentrations typically display reductions in photosynthesis and growth in comparison with plants grown at the current ambient ozone concentration.

In discussing the problem of elevated tropospheric ozone (O<sub>3</sub>) concentrations, Liu *et al.*

(2004) wrote that “ozone is considered to be one of the air pollutants most detrimental to plant growth and development in both urban and rural environments (Lefohn, 1992; Skarby *et al.*, 1998; Matyssek and Innes, 1999),” because it “reduces the growth and yield of numerous agronomic crops as well as fruit and forest trees (Retzlaff *et al.*, 1997; Fumagalli *et al.*, 2001; Matyssek and Sandermann, 2003).” In addition, they say that ozone concentrations are “currently two to three times higher than in the early 1900s (Galloway, 1998; Fowler *et al.*, 1999),” and that they likely “will remain high in the future (Elvingson, 2001).”

It is important to determine how major plants respond to concomitant increases in the abundances of these two trace gases of the atmosphere, as their concentrations will likely continue to increase for many years to come. We begin with a review of the literature with respect to various agriculture species, followed by a discussion on trees.

Additional information on this topic, including reviews on the interaction of CO<sub>2</sub> and O<sub>3</sub> not discussed here, can be found at [http://www.co2science.org/subject/o/subject\\_o.php](http://www.co2science.org/subject/o/subject_o.php) under the heading Ozone.

### 7.3.5.1. Agricultural Species

Several studies have used soybean as a model plant to study the effects of elevated CO<sub>2</sub> and ozone on photosynthesis and growth. Reid *et al.* (1998), for example, grew soybeans for an entire season at different combinations of atmospheric CO<sub>2</sub> and ozone, reporting that elevated CO<sub>2</sub> enhanced rates of photosynthesis in the presence or absence of ozone and that it typically ameliorated the negative effects of elevated ozone on carbon assimilation. At the cellular level, Heagle *et al.* (1998a) reported that at twice the current ambient ozone concentration, soybeans simultaneously exposed to twice the current ambient atmospheric CO<sub>2</sub> concentration exhibited less foliar injury while maintaining significantly greater leaf chlorophyll contents than control plants exposed to elevated ozone and ambient CO<sub>2</sub> concentrations. By harvest time, the plants grown in the elevated ozone/elevated CO<sub>2</sub> treatment combination had produced 53 percent more total biomass than their counterparts did at elevated ozone and ambient CO<sub>2</sub> concentrations (Miller *et al.*, 1998). Finally, in analyzing seed yield, it was determined that atmospheric CO<sub>2</sub> enrichment enhanced this parameter by 20 percent at ambient ozone, while it increased it by 74 percent at twice the ambient ozone

concentration (Heagle *et al.*, 1998b). Thus, elevated CO<sub>2</sub> completely ameliorated the negative effects of elevated ozone concentration on photosynthetic rate and yield production in soybean.

The ameliorating responses of elevated CO<sub>2</sub> to ozone pollution also have been reported for various cultivars of spring and winter wheat. In the study of Tiedemann and Firsching (2000), for example, atmospheric CO<sub>2</sub> enrichment not only overcame the detrimental effects of elevated ozone on photosynthesis and growth, it overcame the deleterious consequences resulting from inoculation with a biotic pathogen as well. Although infected plants displayed less absolute yield than non-infected plants at elevated ozone concentrations, atmospheric CO<sub>2</sub> enrichment caused the greatest relative yield increase in infected plants (57 percent vs. 38 percent).

McKee *et al.* (2000) reported that O<sub>3</sub>-induced reductions in leaf rubisco contents in spring wheat were reversed when plants were simultaneously exposed to twice-ambient concentrations of atmospheric CO<sub>2</sub>. In the study of Vilhena-Cardoso and Barnes (2001), elevated ozone concentrations reduced photosynthetic rates in spring wheat grown at three different soil nitrogen levels. However, when concomitantly exposed to twice-ambient atmospheric CO<sub>2</sub> concentrations, elevated ozone had no effect on rates of photosynthesis, regardless of soil nitrogen. Going a step further, Pleijel *et al.* (2000) observed that ozone-induced reductions in spring wheat yield were partially offset by concomitant exposure to elevated CO<sub>2</sub> concentrations. Similar results have been reported in spring wheat by Hudak *et al.* (1999) and in winter wheat by Heagle *et al.* (2000).

Cotton plants grown at elevated ozone concentrations exhibited 25 and 48 percent reductions in leaf mass per unit area and foliar starch concentration, respectively, relative to control plants grown in ambient air. When simultaneously exposed to twice-ambient CO<sub>2</sub> concentrations, however, the reductions in these parameters were only 5 and 7 percent, respectively (Booker, 2000). With respect to potato, Wolf and van Oijen (2002) used a validated potato model to predict increases in European tuber production ranging from 1,000 to 3,000 kg of dry matter per hectare in spite of concomitant increases in ozone concentrations and air temperatures.

It is clear from these studies that elevated CO<sub>2</sub> reduces, and nearly always completely overrides, the negative effects of ozone pollution on plant photosynthesis, growth, and yield. When explaining the mechanisms behind such responses, most authors

suggest that atmospheric CO<sub>2</sub> enrichment tends to reduce stomatal conductance, which causes less indiscriminate uptake of ozone into internal plant air spaces and reduces subsequent conveyance to tissues where damage often results to photosynthetic pigments and proteins, reducing plant growth and biomass production.

### 7.3.5.2. Woody Species

#### 7.3.5.2.1. Aspen

Karnosky *et al.* (1999) grew O<sub>3</sub>-sensitive and O<sub>3</sub>-tolerant aspen clones in 30-m diameter plots at the Aspen FACE site near Rhinelander, Wisconsin, USA, which were maintained at atmospheric CO<sub>2</sub> concentrations of 360 and 560 ppm with and without exposure to elevated O<sub>3</sub> (1.5 times ambient ozone concentration). After one year of growth at ambient CO<sub>2</sub>, elevated O<sub>3</sub> had caused visible injury to leaves of both types of aspen, with the average percent damage in O<sub>3</sub>-sensitive clones being more than three times as great as that observed in O<sub>3</sub>-tolerant clones (55 percent vs. 17 percent, respectively). In combination with elevated CO<sub>2</sub>, however, O<sub>3</sub>-induced damage to leaves of these same clones was only 38 percent and 3 percent, respectively. Thus, elevated CO<sub>2</sub> ameliorated much of the foliar damage induced by high O<sub>3</sub> concentrations.

King *et al.* (2001) studied the same plants for a period of two years, concentrating on below-ground growth, where elevated O<sub>3</sub> alone had no effect on fine-root biomass. When the two aspen clones were simultaneously exposed to elevated CO<sub>2</sub> and O<sub>3</sub>, however, there was an approximate 66 percent increase in the fine-root biomass of both of them.

Also in the same experiment, Noormets *et al.* (2001) studied the interactive effects of O<sub>3</sub> and CO<sub>2</sub> on photosynthesis, finding that elevated CO<sub>2</sub> increased rates of photosynthesis in both clones at all leaf positions. Maximum rates of photosynthesis were increased in the O<sub>3</sub>-tolerant clone by averages of 33 and 49 percent due to elevated CO<sub>2</sub> alone and in

combination with elevated O<sub>3</sub>, respectively, while in the O<sub>3</sub>-sensitive clone they were increased by 38 percent in both situations. Hence, CO<sub>2</sub>-induced increases in maximal rates of net photosynthesis were typically maintained, and sometimes increased, during simultaneous exposure to elevated O<sub>3</sub>.

Yet again in the same experiment, Oksanen *et al.* (2001) reported that after three years of treatment, ozone exposure caused significant structural injuries to thylakoid membranes and the stromal compartment within chloroplasts, but that these injuries were largely ameliorated by atmospheric CO<sub>2</sub> enrichment. Likewise, leaf thickness, mesophyll tissue thickness, the amount of chloroplasts per unit cell area, and the amount of starch in leaf chloroplasts were all decreased in the high ozone treatment, but simultaneous exposure of the ozone-stressed trees to elevated CO<sub>2</sub> more than compensated for the ozone-induced reductions.

After four years of growing five aspen clones with varying degrees of tolerance to ozone under the same experimental conditions, McDonald *et al.* (2002) developed what they termed a “competitive stress index,” based on the heights of the four nearest neighbors of each tree, to study the influence of competition on the CO<sub>2</sub> growth response of the various clones as modified by ozone. In general, elevated O<sub>3</sub> reduced aspen growth independent of competitive status, while the authors noted an “apparent convergence of competitive performance responses in +CO<sub>2</sub> +O<sub>3</sub> conditions,” which they say suggests that “stand diversity may be maintained at a higher level” in such circumstances.

Percy *et al.* (2002) utilized the same experimental setting to assess a number of the trees’ growth characteristics, as well as the responses of one plant pathogen and two insects with different feeding strategies that typically attack the trees. Of the plant pathogen studied, they say that “the poplar leaf rust, *Melampsora medusae*, is common on aspen and belongs to the most widely occurring group of foliage diseases.” As for the two insects, they report that “the forest tent caterpillar, *Malacosoma disstria*, is a common leaf-chewing lepidopteran in North American hardwood forests” and that “the sap-feeding aphid, *Chaitophorus stevensis*, infests aspen throughout its range.” Hence, the rust and the two insect pests the scientists studied are widespread and have significant deleterious impacts on trembling aspen and other tree species. As but one example of this fact, the authors note that, “historically, the forest tent caterpillar has defoliated more deciduous forest

than any other insect in North America” and that “outbreaks can reduce timber yield up to 90% in one year, and increase tree vulnerability to disease and environmental stress.”

Percy *et al.* found that by itself, elevated O<sub>3</sub> decreased tree height and trunk diameter, increased rust occurrence by nearly fourfold, improved tent caterpillar performance by increasing female pupal mass by 31 percent, and had a strong negative effect on the natural enemies of aphids. The addition of the extra CO<sub>2</sub>, however, completely ameliorated the negative effects of elevated O<sub>3</sub> on tree height and trunk diameter, reduced the O<sub>3</sub>-induced enhancement of rust development from nearly fourfold to just over twofold, completely ameliorated the enhancement of female tent caterpillar pupal mass caused by elevated O<sub>3</sub>, and completely ameliorated the reduction in the abundance of natural enemies of aphids caused by elevated O<sub>3</sub>.

In a final study from the Aspen FACE site, Holton *et al.* (2003) raised parasitized and non-parasitized forest tent caterpillars on two quaking aspen genotypes (O<sub>3</sub>-sensitive and O<sub>3</sub>-tolerant) alone and in combination for one full growing season; they, too, found that elevated O<sub>3</sub> improved tent caterpillar performance under ambient CO<sub>2</sub> conditions, but not in CO<sub>2</sub>-enriched air.

In summary, it is clear that elevated ozone concentrations have a number of significant negative impacts on the well-being of North America’s most widely distributed tree species, while elevated carbon dioxide concentrations have a number of significant positive impacts. In addition, elevated CO<sub>2</sub> often completely eliminates the negative impacts of elevated O<sub>3</sub>. If the tropospheric O<sub>3</sub> concentration continues to rise as expected (Percy *et al.* note that “damaging O<sub>3</sub> concentrations currently occur over 29% of the world’s temperate and subpolar forests but are predicted to affect fully 60% by 2100”), we might hope the air’s CO<sub>2</sub> content continues to rise as well.

### 7.3.5.2.2. Beech

Liu *et al.* (2005) grew three- and four-year-old seedlings of European beech (*Fagus sylvatica* L.) for five months in well watered and fertilized soil in containers located within walk-in phytotrons maintained at either ambient or ambient + 300 ppm CO<sub>2</sub> (each subdivided into ambient and double-ambient O<sub>3</sub> concentration treatments, with maximum ozone levels restricted to <150 ppb), in both monoculture and in competition with Norway spruce, after which they examined the effects of each treatment on leaf non-structural carbohydrate levels (soluble sugars and starch). They found that the effects of elevated O<sub>3</sub> alone on non-structural carbohydrate levels were small when the beech

seedlings were grown in monoculture. When they were grown in mixed culture, however, the elevated O<sub>3</sub> slightly enhanced leaf sugar levels, but reduced starch levels by 50 percent.

With respect to elevated CO<sub>2</sub> alone, for the beech seedlings grown in both monoculture and mixed culture, levels of sugar and starch were significantly enhanced. Hence, when elevated O<sub>3</sub> and CO<sub>2</sub> significantly affected non-structural carbohydrate levels, elevated CO<sub>2</sub> tended to enhance them, whereas elevated O<sub>3</sub> tended to reduce them. In addition, the combined effects of elevated CO<sub>2</sub> and O<sub>3</sub> acting together were such as to produce a significant increase in leaf non-structural carbohydrates in both mixed and monoculture conditions. As a result, the researchers concluded that “since the responses to the combined exposure were more similar to elevated pCO<sub>2</sub> than to elevated pO<sub>3</sub>, apparently elevated pCO<sub>2</sub> overruled the effects of elevated pO<sub>3</sub> on non-structural carbohydrates.”

In a slightly longer study, Grams *et al.* (1999) grew European beech seedlings in glasshouses maintained at average atmospheric CO<sub>2</sub> concentrations of either 367 or 667 ppm for a period of one year. Then, throughout the following year, in addition to being exposed to the same set of CO<sub>2</sub> concentrations the seedlings were exposed to either ambient or twice-ambient levels of O<sub>3</sub>. This protocol revealed that elevated O<sub>3</sub> significantly reduced photosynthesis in beech seedlings grown at ambient CO<sub>2</sub> concentrations by a factor of approximately three. By contrast, in the CO<sub>2</sub>-enriched air the seedlings did not exhibit any photosynthetic reduction due to the doubled O<sub>3</sub> concentrations. In fact, the photosynthetic rates of the CO<sub>2</sub>-enriched seedlings actually rose by 8 percent when simultaneously fumigated with elevated O<sub>3</sub>, leading the researchers to conclude that “long-term acclimation to elevated CO<sub>2</sub> supply does counteract the O<sub>3</sub>-induced decline of photosynthetic light and dark reactions.”

In a still longer study, Liu *et al.* (2004) grew three- and four-year-old beech seedlings for two growing seasons under the same experimental conditions as Liu *et al.* (2005) after the seedlings had been pre-acclimated for one year to either the ambient or elevated CO<sub>2</sub> treatment. At the end of the study, the plants were harvested and fresh weights and dry biomass values were determined for leaves, shoot axes, coarse roots, and fine roots, as were carbohydrate (starch and soluble sugar) contents and concentrations for the same plant parts. This work falsified the hypothesis that “prolonged exposure to

elevated CO<sub>2</sub> does not compensate for the adverse ozone effects on European beech,” as it revealed that all “adverse effects of ozone on carbohydrate concentrations and contents were counteracted when trees were grown in elevated CO<sub>2</sub>.”

### 7.3.5.2.3. Birch

At the FACE facility near Rhinelander, Wisconsin, USA, King *et al.* (2001) grew a mix of paper birch and quaking aspen trees in 30-m diameter plots that were maintained at atmospheric CO<sub>2</sub> concentrations of 360 and 560 ppm with and without exposure to elevated O<sub>3</sub> (1.5 times the ambient O<sub>3</sub> concentration) for a period of two years. In their study of the below-ground environment of the trees, they found that the extra O<sub>3</sub> had no effect on the growth of fine roots over that time period, but that elevated O<sub>3</sub> and CO<sub>2</sub> together increased the fine-root biomass of the mixed stand by 83 percent.

One year later at the same FACE facility, Oksanen *et al.* (2001) observed O<sub>3</sub>-induced injuries in the thylakoid membranes of the chloroplasts of the birch trees' leaves; the injuries were partially ameliorated in the elevated CO<sub>2</sub> treatment. And in a study conducted two years later, Oksanen *et al.*

(2003) say they “were able to visualize and locate ozone-induced H<sub>2</sub>O<sub>2</sub> accumulation within leaf mesophyll cells, and relate oxidative stress with structural injuries.” However, they report that “H<sub>2</sub>O<sub>2</sub> accumulation was found only in ozone-exposed leaves and not in the presence of elevated CO<sub>2</sub>,” adding that “CO<sub>2</sub> enrichment appears to alleviate chloroplastic oxidative stress.”

Across the Atlantic in Finland, Kull *et al.* (2003) constructed open-top chambers around two clones (V5952 and K1659) of silver birch saplings that were rooted in the ground and had been growing there for the past seven years. These chambers were fumigated with air containing 360 and 720 ppm CO<sub>2</sub> in combination with 30 and 50 ppb O<sub>3</sub> for two growing seasons, after which it was noted that the extra O<sub>3</sub> had significantly decreased branching in the trees’ crowns. This malady, however, was almost completely ameliorated by a doubling of the air’s CO<sub>2</sub> concentration. In addition, after one more year of study, Eichelmann *et al.* (2004) reported that, by itself, the increase in the air’s CO<sub>2</sub> content increased the average net photosynthetic rates of both clones by approximately 16 percent, while the increased O<sub>3</sub> by itself caused a 10 percent decline in the average photosynthetic rate of clone V5952, but not of clone K1659. When both trace gases were simultaneously increased, however, the photosynthetic rate of clone V5952 once again experienced a 16 percent increase in net photosynthesis, as if the extra O<sub>3</sub> had had no effect when applied in the presence of the extra CO<sub>2</sub>.

After working with the same trees for one additional year, Riikonen *et al.* (2004) harvested them and reported finding that “the negative effects of elevated O<sub>3</sub> were found mainly in ambient CO<sub>2</sub>, not in elevated CO<sub>2</sub>.” In fact, whereas doubling the air’s O<sub>3</sub> concentration decreased total biomass production by 13 percent across both clones, simultaneously doubling the air’s CO<sub>2</sub> concentration increased total biomass production by 30 percent, thereby more than compensating for the deleterious consequences of doubling the atmospheric ozone concentration.

In commenting on this ameliorating effect of elevated CO<sub>2</sub>, the team of Finnish scientists said it “may be associated with either increased detoxification capacity as a consequence of higher carbohydrate concentrations in leaves grown in elevated CO<sub>2</sub>, or decreased stomatal conductance and thus decreasing O<sub>3</sub> uptake in elevated CO<sub>2</sub> conditions (e.g., Rao *et al.*, 1995).” They also noted that “the ameliorating effect of elevated CO<sub>2</sub> is in accordance with the results of single-season open-top chamber

and growth chamber studies on small saplings of various deciduous tree species (Mortensen 1995; Dickson *et al.*, 1998; Loats and Rebbeck, 1999) and long-term open-field and OTC studies with aspen and yellow-poplar (Percy *et al.*, 2002; Rebbeck and Scherzer, 2002).”

In another paper to come out of the Finnish silver birch study, Peltonen *et al.* (2005) evaluated the impacts of doubled atmospheric CO<sub>2</sub> and O<sub>3</sub> concentrations on the accumulation of 27 phenolic compounds in the leaves of the trees, finding that elevated CO<sub>2</sub> increased the concentration of phenolic acids (+25 percent), myricetin glycosides (+18 percent), catechin derivatives (+13 percent), and soluble condensed tannins (+19 percent). Elevated O<sub>3</sub>, on the other hand, increased the concentration of one glucoside by 22 percent, chlorogenic acid by 19 percent, and flavone aglycons by 4 percent. However, Peltonen *et al.* say this latter O<sub>3</sub>-induced production of antioxidant phenolic compounds “did not seem to protect the birch leaves from detrimental O<sub>3</sub> effects on leaf weight and area, but may have even exacerbated them.” Last, in the combined elevated CO<sub>2</sub> and O<sub>3</sub> treatment, they found that “elevated CO<sub>2</sub> did seem to protect the leaves from elevated O<sub>3</sub> because all the O<sub>3</sub>-derived effects on the leaf phenolics and traits were prevented by elevated CO<sub>2</sub>.”

Meanwhile, back at the FACE facility near Rhinelander, Wisconsin, USA, Agrell *et al.* (2005) examined the effects of ambient and elevated concentrations of atmospheric CO<sub>2</sub> and O<sub>3</sub> on the foliar chemistry of birch and aspen trees, plus the consequences of these effects for host plant preferences of forest tent caterpillar larvae. In doing so, they found that “the only chemical component showing a somewhat consistent co-variation with larval preferences was condensed tannins,” and they discovered that “the tree becoming relatively less preferred as a result of CO<sub>2</sub> or O<sub>3</sub> treatment was in general also the one for which average levels of condensed tannins were most positively (or least negatively) affected by that treatment.” The mean condensed tannin concentration of birch leaves was 18 percent higher in the elevated CO<sub>2</sub> and O<sub>3</sub> treatment. Consequently, as atmospheric concentrations of CO<sub>2</sub> and O<sub>3</sub> continue to rise, the increases in condensed tannin concentrations likely to occur in the foliage of birch trees should lead to their leaves becoming less preferred for consumption by the forest tent caterpillar.

Concurrent with the work of Agrell *et al.*, King *et al.* (2005) evaluated the effect of CO<sub>2</sub> enrichment

alone, O<sub>3</sub> enrichment alone, and the net effect of both CO<sub>2</sub> and O<sub>3</sub> enrichment together on the growth of the Rhinelander birch trees, finding that relative to the ambient-air control treatment, elevated CO<sub>2</sub> increased total biomass by 45 percent in the aspen-birch community, while elevated O<sub>3</sub> caused a 13 percent reduction in total biomass relative to the control. Of most interest, the combination of elevated CO<sub>2</sub> and O<sub>3</sub> resulted in a total biomass increase of 8.4 percent relative to the control aspen-birch community. King *et al.* thus concluded that “exposure to even moderate levels of O<sub>3</sub> significantly reduces the capacity of net primary productivity to respond to elevated CO<sub>2</sub> in some forests.” Consequently, they suggested it makes sense to move forward with technologies that reduce anthropogenic precursors to photochemical O<sub>3</sub> formation, because the implementation of such a policy would decrease an important constraint on the degree to which forest ecosystems can positively respond to the ongoing rise in the air’s CO<sub>2</sub> concentration.

Another paper to come out of the Finnish silver birch study was that of Kostianen *et al.* (2006), who studied the effects of elevated CO<sub>2</sub> and O<sub>3</sub> on various wood properties. Their work revealed that the elevated CO<sub>2</sub> treatment had no effect on wood structure, but that it increased annual ring width by 21 percent, woody biomass by 23 percent, and trunk starch concentration by 7 percent. Elevated O<sub>3</sub>, on the other hand, decreased stem vessel percentage in one of the clones by 10 percent; it had no effect on vessel percentage in the presence of elevated CO<sub>2</sub>.

In discussing their results, Kostianen *et al.* note that “in the xylem of angiosperms, water movement occurs principally in vessels (Kozłowski and Pallardy, 1997),” and that “the observed decrease in vessel percentage by elevated O<sub>3</sub> may affect water transport,” lowering it. However, as they continue, “elevated CO<sub>2</sub> ameliorated the O<sub>3</sub>-induced decrease in vessel percentage.” In addition, they note that “the concentration of nonstructural carbohydrates (starch and soluble sugars) in tree tissues is considered a measure of carbon shortage or surplus for growth (Korner, 2003).” They conclude that “starch accumulation observed under elevated CO<sub>2</sub> in this study indicates a surplus of carbohydrates produced by enhanced photosynthesis of the same trees (Riikonen *et al.*, 2004).” In addition, they report that “during winter, starch reserves in the stem are gradually transformed to soluble carbohydrates involved in freezing tolerance (Bertrand *et al.*, 1999; Piispanen and Saranpaa, 2001), so the increase in

starch concentration may improve acclimation in winter.”

Rounding out the suite of Rhinelander FACE studies of paper birch is the report of Darbah *et al.* (2007), who found that the total number of trees that flowered increased by 139 percent under elevated CO<sub>2</sub> but only 40 percent under elevated O<sub>3</sub>. Likewise, with respect to the quantity of flowers produced, they found that elevated CO<sub>2</sub> led to a 262 percent increase, while elevated O<sub>3</sub> led to only a 75 percent increase. They also determined that elevated CO<sub>2</sub> had significant positive effects on birch catkin size, weight, and germination success rate, with elevated CO<sub>2</sub> increasing the germination rate of birch by 110 percent, decreasing seedling mortality by 73 percent, increasing seed weight by 17 percent, and increasing new seedling root length by 59 percent. They found just the *opposite* was true of elevated O<sub>3</sub>, as it decreased the germination rate of birch by 62 percent, decreased seed weight by 25 percent, and increased new seedling root length by only 15 percent.

In discussing their findings, Darbah *et al.* additionally report that “the seeds produced under elevated O<sub>3</sub> had much less stored carbohydrate, lipids, and proteins for the newly developing seedlings to depend on and, hence, the slow growth rate.” As a result, they conclude that “seedling recruitment will be enhanced under elevated CO<sub>2</sub> but reduced under elevated O<sub>3</sub>.”

In summary, from their crowns to their roots, birch trees are generally negatively affected by rising ozone concentrations. When the air’s CO<sub>2</sub> content is also rising, however, these negative consequences may often be totally eliminated and replaced by positive responses.

#### 7.3.5.2.4. Yellow-Poplar

Scherzel *et al.* (1998) grew yellow-poplar seedlings in open-top chambers for four years at three different combinations of atmospheric O<sub>3</sub> and CO<sub>2</sub>—(1) ambient O<sub>3</sub> and ambient CO<sub>2</sub>, (2) doubled O<sub>3</sub> and ambient CO<sub>2</sub>, and (3) doubled O<sub>3</sub> and doubled CO<sub>2</sub>—to study the interactive effects of these gases on leaf-litter decomposition. This experiment revealed that the decomposition rates of yellow-poplar leaves were similar for all three treatments for nearly five months, after which time litter produced in the elevated O<sub>3</sub> and elevated CO<sub>2</sub> air decomposed at a significantly slower rate, such that even after two years of decomposition, litter from the elevated O<sub>3</sub> and elevated CO<sub>2</sub> treatment still contained about 12 percent more biomass than litter produced in the other two treatments. This reduced rate of decomposition under elevated O<sub>3</sub> and CO<sub>2</sub> conditions will likely result in greater carbon

sequestration in soils supporting yellow-poplar trees over the next century or more.

Loats and Rebbeck (1999) grew yellow-poplar seedlings for ten weeks in pots they placed within growth chambers filled with ambient air, air with twice the ambient CO<sub>2</sub> concentration, air with twice the ambient O<sub>3</sub> concentration, and air with twice the ambient CO<sub>2</sub> and O<sub>3</sub> concentrations to determine the effects of elevated CO<sub>2</sub> and O<sub>3</sub> on photosynthesis and growth in this deciduous tree species. In doing so, they found that doubling the air's CO<sub>2</sub> concentration increased the rate of net photosynthesis by 55 percent in ambient O<sub>3</sub> air, and that at twice the ambient level of O<sub>3</sub> it stimulated net photosynthesis by an average of 50 percent. Similarly, the doubled CO<sub>2</sub> concentration significantly increased total biomass by 29 percent, while the doubled O<sub>3</sub> concentration had little impact on growth.

Last, Rebbeck *et al.* (2004) grew yellow poplar seedlings for five years within open-top chambers in a field plantation at Delaware, Ohio, USA, exposing them continuously from mid-May through mid-October of each year to either (1) charcoal-filtered air to remove ambient O<sub>3</sub>, (2) ambient O<sub>3</sub>, (3) 1.5 times ambient O<sub>3</sub>, and (4) 1.5 times ambient O<sub>3</sub> plus 350 ppm CO<sub>2</sub> above ambient CO<sub>2</sub>, while they periodically measured a number of plant parameters and processes. Throughout the study, the trees were never fertilized, and they received no supplemental water beyond some given in the first season.

Averaged over the experiment's five growing seasons, the midseason net photosynthetic rate of upper canopy foliage at saturating light intensities declined by 10 percent when the trees were grown in ambient O<sub>3</sub>-air and by 14 percent when they were grown in elevated O<sub>3</sub>-air, when compared to the trees that were grown in the charcoal-filtered air, while seasonal net photosynthesis of foliage grown in the combination of elevated O<sub>3</sub> and elevated CO<sub>2</sub> was 57-80 percent higher than it was in the trees exposed to elevated O<sub>3</sub> alone. There was also no evidence of any photosynthetic down regulation in the trees exposed to the elevated O<sub>3</sub> and CO<sub>2</sub> air, with some of the highest rates being observed during the final growing season. Consequently, Rebbeck *et al.* concluded that "elevated CO<sub>2</sub> may ameliorate the negative effects of increased tropospheric O<sub>3</sub> on yellow-poplar." In fact, their results suggest that a nominally doubled atmospheric CO<sub>2</sub> concentration more than compensates for the deleterious effects of a 50 percent increase in ambient O<sub>3</sub> levels.

As the air's CO<sub>2</sub> content continues to rise, earth's yellow-poplar trees will likely display substantial increases in photosynthetic rate and biomass production, even under conditions of elevated O<sub>3</sub> concentrations; and the soils in which the trees grow should sequester ever greater quantities of carbon.

Additional information on this topic, including reviews of newer publications as they become available, can be found at <http://www.co2science.org/subject/o/ozoneyellowpoplar.php>.

### 7.3.6. Low Temperatures

Only a handful of studies have attempted to determine what relationship, if any, exists between atmospheric CO<sub>2</sub> enrichment and the ability of plants to withstand the rigors of low temperatures.

Loik *et al.* (2000) grew three *Yucca* species (*brevifolia*, *schidigera*, and *whipplei*) in pots placed within glasshouses maintained at atmospheric CO<sub>2</sub> concentrations of 360 and 700 ppm and day/night air temperatures of 40/24°C for seven months, after which some of the plants were subjected to a two-week day/night air temperature treatment of 20/5°C. In addition, leaves from each *Yucca* species were removed and placed in a freezer that was cooled at a rate of 3°C per hour until a minimum temperature of -15°C was reached. These manipulations indicated that elevated CO<sub>2</sub> lowered the air temperature at which 50 percent low-temperature-induced cell mortality occurred by 1.6, 1.4 and 0.8°C in *brevifolia*, *schidigera* and *whipplei*, respectively. On the basis of the result obtained for *Y. brevifolia*, Dole *et al.* (2003) estimated that "the increase in freezing tolerance

caused by doubled CO<sub>2</sub> would increase the potential habitat of this species by 14%.”

By contrast, Obrist *et al.* (2001) observed the opposite response. In an open-top chamber study of a temperate grass ecosystem growing on a nutrient-poor calcareous soil in northwest Switzerland, portions of which had been exposed to atmospheric CO<sub>2</sub> concentrations of 360 and 600 ppm for a period of six years, they determined that the average temperature at which 50 percent low-temperature-induced leaf mortality occurred in five prominent species actually *rose* by an average of 0.7°C in response to the extra 240 ppm of CO<sub>2</sub> employed in their experiment.

Most relevant investigations, however, have produced evidence of positive CO<sub>2</sub> effects on plant low temperature tolerance. Sigurdsson (2001), for example, grew black cottonwood seedlings near Gunnarsholt, Iceland within closed-top chambers maintained at ambient and twice-ambient atmospheric CO<sub>2</sub> concentrations for a period of three years, finding that elevated CO<sub>2</sub> tended to hasten the end of the growing season. This effect was interpreted as enabling the seedlings to better avoid the severe cold-induced dieback of newly produced tissues that often occurs with the approach of winter in this region. Likewise, Wayne *et al.* (1998) found that yellow birch seedlings grown at an atmospheric CO<sub>2</sub> concentration of 800 ppm exhibited greater dormant bud survivorship at low air temperatures than did seedlings grown at 400 ppm CO<sub>2</sub>.

Schwanz and Polle (2001) investigated the effects of elevated CO<sub>2</sub> on chilling stress in micropropagated hybrid poplar clones that were subsequently potted and transferred to growth chambers maintained at either ambient (360 ppm) or elevated (700 ppm) CO<sub>2</sub> for a period of three months. They determined that “photosynthesis was less diminished and electrolyte leakage was lower in stressed leaves from poplar trees grown under elevated CO<sub>2</sub> as compared with those from ambient CO<sub>2</sub>.” Although severe chilling did cause pigment and protein degradation in all stressed leaves, the damage was expressed to a lower extent in leaves from the elevated CO<sub>2</sub> treatment. This CO<sub>2</sub>-induced chilling protection was determined to be accompanied by a rapid induction of superoxide dismutase activity, as well as by slightly higher stabilities of other antioxidative enzymes.

Another means by which chilling-induced injury may be reduced in CO<sub>2</sub>-enriched air is suggested by the study of Sgherri *et al.* (1998), who reported that raising the air’s CO<sub>2</sub> concentration from 340 to 600 ppm increased lipid concentrations in alfalfa

thylakoid membranes while simultaneously inducing a higher degree of unsaturation in the most prominent of those lipids. Under well-watered conditions, for example, the 76 percent increase in atmospheric CO<sub>2</sub> enhanced overall thylakoid lipid concentration by about 25 percent, while it increased the degree of unsaturation of the two main lipids by approximately 17 percent and 24 percent. Under conditions of water stress, these responses were found to be even greater, as thylakoid lipid concentration rose by approximately 92 percent, while the degree of unsaturation of the two main lipids rose by about 22 percent and 53 percent.

Several studies conducted over the past decade explain what these observations have to do with a plant’s susceptibility to chilling injury. Working with wild-type *Arabidopsis thaliana* and two mutants deficient in thylakoid lipid unsaturation, Hugly and Somerville (1992) found that “chloroplast membrane lipid polyunsaturation contributes to the low-temperature fitness of the organism,” and that it “is required for some aspect of chloroplast biogenesis.” When lipid polyunsaturation was low, they observed “dramatic reductions in chloroplast size, membrane content, and organization in developing leaves.” There was a positive correlation “between the severity of chlorosis in the two mutants at low temperatures and the degree of reduction in polyunsaturated chloroplast lipid composition.”

Working with tobacco, Kodama *et al.* (1994) demonstrated that the low-temperature-induced suppression of leaf growth and concomitant induction of chlorosis observed in wild-type plants was much less evident in transgenic plants containing a gene that allowed for greater expression of unsaturation in the fatty acids of leaf lipids. This observation and others led them to conclude that substantially unsaturated fatty acids “are undoubtedly an important factor contributing to cold tolerance.”

In a closely related study, Moon *et al.* (1995) found that heightened unsaturation of the membrane lipids of chloroplasts stabilized the photosynthetic machinery of transgenic tobacco plants against low-temperature photoinhibition “by accelerating the recovery of the photosystem II protein complex.” Likewise, Kodama *et al.* (1995), also working with transgenic tobacco plants, showed that increased fatty acid desaturation is one of the prerequisites for normal leaf development at low, nonfreezing temperatures; and Ishizaki-Nishizawa *et al.* (1996) demonstrated that transgenic tobacco plants with a reduced level of saturated fatty acids in most

membrane lipids “exhibited a significant increase in chilling resistance.”

Many economically important crops, such as rice, maize and soybeans, are classified as chilling-sensitive and experience injury or death at temperatures between 0 and 15°C (Lyons, 1973). If atmospheric CO<sub>2</sub> enrichment enhances their production and degree-of-unsaturation of thylakoid lipids, as it does in alfalfa, a continuation of the ongoing rise in the air’s CO<sub>2</sub> content could increase the abilities of these important agricultural species to withstand periodic exposure to debilitating low temperatures. This phenomenon could provide the extra boost in food production that will be needed to sustain an increasing population in the years and decades ahead.

Earth’s natural ecosystems would also benefit from a CO<sub>2</sub>-induced increase in thylakoid lipids containing more-highly unsaturated fatty acids. Many plants of tropical origin, for example, suffer cold damage when temperatures fall below 20°C (Graham and Patterson, 1982). With improved lipid characteristics provided by the ongoing rise in the air’s CO<sub>2</sub> content, such plants would be able to expand their ranges both poleward and upward in a higher-CO<sub>2</sub> world.

More research remains to be done before we can accurately assess the extent of these potential biological benefits. In particular, we must conduct more studies of the effects of atmospheric CO<sub>2</sub> enrichment on the properties of thylakoid lipids in a greater variety of plants. In the same experiments, we must assess the efficacy of these lipid property changes in enhancing plant tolerance of low temperatures. Such studies should rank high on the to-do list of relevant funding agencies.

### 7.3.7. Nitrogen Deficiency

Numerous studies have investigated the effects of different soil nitrogen (N) concentrations on plant responses to increases in the air's CO<sub>2</sub> content, as it has been claimed that a deficiency of soil nitrogen lessens the relative growth stimulation in plants that is typically provided by elevated concentrations of atmospheric CO<sub>2</sub>. In this section, we evaluate the credibility of that claim for various crops, fungi, grasses and trees.

The results of these experiments indicate that some plants sometimes will not respond at all to atmospheric CO<sub>2</sub> enrichment at low levels of soil N, while some will. Some plants respond equally well to increases in the air's CO<sub>2</sub> content when growing in soils exhibiting a whole range of N concentrations. Most common, however, is the observation that plants respond ever better to rising atmospheric CO<sub>2</sub> concentrations as soil N concentrations rise. Interestingly, the current state of earth's atmosphere and land surface is one of jointly increasing CO<sub>2</sub> and N concentrations. Hence, the outlook is good for continually increasing terrestrial vegetative productivity in the years and decades ahead, as these trends continue.

Additional information on this topic, including reviews on nitrogen not discussed here, can be found at [http://www.co2science.org/subject/g/subject\\_g.php](http://www.co2science.org/subject/g/subject_g.php) under the heading Growth Response to CO<sub>2</sub> With Other Variables: Nutrients: Nitrogen, as well as at [http://www.co2science.org/subject/n/subject\\_n.php](http://www.co2science.org/subject/n/subject_n.php) under the headings Nitrogen, Nitrogen Fixation and Nitrogen Use Efficiency.

#### 7.3.7.1. Crops

##### 7.3.7.1.1. Rice

Does a deficiency of soil nitrogen lessen the relative growth and yield stimulation of rice that is typically provided by elevated levels of atmospheric CO<sub>2</sub>? In exploring this question, Weerakoon *et al.* (1999) grew seedlings of two rice cultivars for 28 days in glasshouses maintained at atmospheric CO<sub>2</sub>

concentrations of 373, 545, 723 and 895 ppm under conditions of low, medium and high soil nitrogen content. After four weeks of treatment, photosynthesis was found to significantly increase with increasing nitrogen availability and atmospheric CO<sub>2</sub> concentration. Averaged across all nitrogen regimes, plants grown at 895 ppm CO<sub>2</sub> exhibited photosynthetic rates that were 50 percent greater than those observed in plants grown at ambient CO<sub>2</sub>. Total plant dry weight also increased with increasing atmospheric CO<sub>2</sub>. In addition, the percentage growth enhancement resulting from CO<sub>2</sub> enrichment increased with increasing soil nitrogen; from 21 percent at the lowest soil nitrogen concentration to 60 percent at the highest concentration.

Using a different CO<sub>2</sub> enrichment technique, Weerakoon *et al.* (2000) grew rice in open-top chambers maintained at atmospheric CO<sub>2</sub> concentrations of approximately 350 and 650 ppm during a wet and dry growing season and under a range of soil nitrogen contents. Early in both growing seasons, plants exposed to elevated atmospheric CO<sub>2</sub> concentrations intercepted significantly more sunlight than plants fumigated with ambient air, due to CO<sub>2</sub>-induced increases in leaf area index. This phenomenon occurred regardless of soil nitrogen content, but disappeared shortly after canopy closure in all treatments. Later, mature canopies achieved similar leaf area indexes at identical levels of soil nitrogen supply; but mean season-long radiation use efficiency, which is the amount of biomass produced per unit of solar radiation intercepted, was 35 percent greater in CO<sub>2</sub>-enriched vs. ambiently grown plants and tended to increase with increasing soil nitrogen content.

Utilizing a third approach to enriching the air about a crop with elevated levels of atmospheric CO<sub>2</sub>, Kim *et al.* (2003) grew rice crops from the seedling stage to maturity at atmospheric CO<sub>2</sub> concentrations of ambient and ambient plus 200 ppm using FACE technology and three levels of applied nitrogen—low (LN, 4 g N m<sup>-2</sup>), medium (MN, 8 and 9 g N m<sup>-2</sup>) and high (HN, 15 g N m<sup>-2</sup>)—for three cropping seasons (1998-2000). They report that “the yield response to elevated CO<sub>2</sub> in crops supplied with MN (+14.6%) or HN (+15.2%) was about twice that of crops supplied with LN (+7.4%),” confirming the importance of nitrogen availability to the response of rice to atmospheric CO<sub>2</sub> enrichment previously determined by Kim *et al.* (2001) and Kobaysahi *et al.* (2001).

In light of these observations, it would appear that the maximum benefits of elevated levels of

atmospheric CO<sub>2</sub> for the growth and grain production of rice cannot be realized in soils that are highly deficient in nitrogen. Increasing nitrogen concentrations above what is considered adequate may not result in proportional gains in CO<sub>2</sub>-induced growth and yield enhancement.

### 7.3.7.1.2. Wheat

Smart *et al.* (1998) grew wheat from seed for 23 days in controlled environment chambers maintained at atmospheric CO<sub>2</sub> concentrations of 360 and 1000 ppm and two concentrations of soil nitrate, finding that the extra CO<sub>2</sub> increased average plant biomass by approximately 15 percent, irrespective of soil nitrogen content. In a more realistic FACE experiment, however, Brooks *et al.* (2000) grew spring wheat for two seasons at atmospheric CO<sub>2</sub> concentrations of 370 and 570 ppm at both high and low levels of nitrogen fertility; and they obtained *twice* the yield

enhancement (16 percent vs. 8 percent) in the high nitrogen treatment.

In an experiment with one additional variable, Vilhena-Cardoso and Barnes (2001) grew spring wheat for two months in environmental chambers fumigated with air containing atmospheric CO<sub>2</sub> concentrations of either 350 or 700 ppm at ambient and elevated (75 ppb) ozone concentrations, while the plants were simultaneously subjected to either low, medium or high levels of soil nitrogen. With respect to biomass production, the elevated CO<sub>2</sub> treatment increased total plant dry weight by 44, 29 and 12 percent at the high, medium and low soil nitrogen levels, respectively. In addition, although elevated ozone alone reduced plant biomass, the simultaneous application of elevated CO<sub>2</sub> completely ameliorated its detrimental effects on biomass production, irrespective of soil nitrogen supply.

Why do the plants of some studies experience a major reduction in the relative growth stimulation provided by atmospheric CO<sub>2</sub> enrichment under low soil nitrogen conditions, while other studies find the aerial fertilization effect of elevated CO<sub>2</sub> to be independent of root-zone nitrogen concentration? Based on studies of both potted and hydroponically grown plants, Farage *et al.* (1998) determined that low root-zone nitrogen concentrations need not lead to photosynthetic acclimation (less than maximum potential rates of photosynthesis) in elevated CO<sub>2</sub>, as long as root-zone nitrogen *supply* is adequate to meet plant nitrogen *needs* to maintain the enhanced relative growth rate that is made possible by atmospheric CO<sub>2</sub> enrichment. When supply cannot meet this need, as is often the case in soils with limited nitrogen reserves, the aerial fertilization effect of atmospheric CO<sub>2</sub> enrichment begins to be reduced and less-than-potential CO<sub>2</sub>-induced growth stimulation is observed. Nevertheless, the acclimation process is the plant's "first line of defense" to keep its productivity from falling even further than it otherwise would, as it typically mobilizes nitrogen from "excess" rubisco and sends it to more needy plant sink tissues to allow for their continued growth and development (Theobald *et al.*, 1998).

In conclusion, although atmospheric CO<sub>2</sub> enrichment tends to increase the growth and yield of wheat under a wide range of soil nitrogen concentrations, including some that are very low, considerably greater CO<sub>2</sub>-induced enhancements are possible when more soil nitrogen is available, although the response can saturate at high soil

nitrogen levels, with excess nitrogen providing little to no extra yield.

#### 7.3.7.1.3. Other

Zerihun *et al.* (2000) grew sunflowers for one month in pots of three different soil nitrogen concentrations that were placed within open-top chambers maintained at atmospheric CO<sub>2</sub> concentrations of 360 and 700 ppm. The extra CO<sub>2</sub> of the CO<sub>2</sub>-enriched chambers reduced average rates of root nitrogen uptake by about 25 percent, which reduction, by itself, would normally tend to reduce tissue nitrogen contents and the relative growth rates of the seedlings. However, the elevated CO<sub>2</sub> also increased photosynthetic nitrogen-use efficiency by an average of 50 percent, which increase normally tends to increase the relative growth rates of seedlings. Of

these two competing effects, the latter was the more powerful, leading to an increase in whole plant biomass. After the one month of the study, for example, the CO<sub>2</sub>-enriched plants exhibited whole plant biomass values that were 44, 13 and 115 percent greater than those of the plants growing in ambient air at low, medium and high levels of soil nitrogen, respectively, thus demonstrating that low tissue nitrogen contents do not necessarily preclude a growth response to atmospheric CO<sub>2</sub> enrichment, particularly if photosynthetic nitrogen-use efficiency is enhanced, which is typically the case, as it was in this study. Nevertheless, the greatest CO<sub>2</sub>-induced growth increase of Zerihun *et al.*'s study was exhibited by the plants growing in the high soil nitrogen treatment.

Deng and Woodward (1998) grew strawberries in environment-controlled glasshouses maintained at atmospheric CO<sub>2</sub> concentrations of 390 and 560 ppm for nearly three months. In addition, the strawberries were supplied with fertilizers containing three levels of nitrogen. The extra CO<sub>2</sub> increased rates of net photosynthesis and total plant dry weight at all three nitrogen levels, but the increases were not significant. Nevertheless, they provided the CO<sub>2</sub>-enriched plants with enough additional sugar and physical mass to support significantly greater numbers of flowers and fruits than the plants grown at 390 ppm CO<sub>2</sub>. This effect consequently led to total fresh fruit weights that were 42 and 17 percent greater in the CO<sub>2</sub>-enriched plants that received the highest and lowest levels of nitrogen fertilization, respectively, once again indicating a greater growth response at higher nitrogen levels.

Newman *et al.* (2003) investigated the effects of two levels of nitrogen fertilization and an approximate doubling of the air's CO<sub>2</sub> concentration on the growth of tall fescue, which is an important forage crop. The plants with which they worked were initially grown from seed in greenhouse flats, but after sixteen weeks they were transplanted into 19-liter pots filled with potting media that received periodic applications of a slow-release fertilizer. Then, over the next two years of outdoor growth, they were periodically clipped, divided and repotted to ensure they did not become root-bound; and at the end of that time, they were placed within twenty 1.3-m-diameter open-top chambers, half of which were maintained at the ambient atmospheric CO<sub>2</sub> concentration and half of which were maintained at an approximately doubled CO<sub>2</sub> concentration of 700 ppm. In addition, half of the pots in each CO<sub>2</sub>

treatment received 0.0673 kg N m<sup>-2</sup> applied over a period of three consecutive days, while half of them received only one-tenth that amount, with the entire procedure being repeated three times during the course of the 12-week experiment. Newman *et al.* report that the plants grown in the high-CO<sub>2</sub> air photosynthesized 15 percent more and produced 53 percent more dry matter (DM) under low N conditions and 61 percent more DM under high N conditions. In addition, they report that the percent organic matter (OM) was little changed, except under elevated CO<sub>2</sub> and high N, when %OM (as %DM) increased by 3 percent. In this study too, therefore, the greatest relative increase in productivity occurred under high, as opposed to low, soil N availability.

Demmers-Derks *et al.* (1998) grew sugar beets as an annual crop in controlled-environment chambers at atmospheric CO<sub>2</sub> concentrations of 360 and 700 ppm and air temperatures of ambient and ambient plus 3°C for three consecutive years. In addition to being exposed to these CO<sub>2</sub> and temperature combinations, the sugar beets were supplied with solutions of low and high nitrogen content. Averaged across all three years and both temperature regimes, the extra CO<sub>2</sub> of this study enhanced total plant biomass by 13 and 25 percent in the low and high nitrogen treatments, respectively. In addition, it increased root biomass by 12 and 26 percent for the same situations. As was the case with sunflowers, strawberries and tall fescue, elevated CO<sub>2</sub> elicited the largest growth responses in the sugar beets that received a high, as opposed to a low, supply of nitrogen.

Also working with sugar beets were Romanova *et al.* (2002), who grew them from seed for one month in controlled environment chambers maintained at atmospheric CO<sub>2</sub> concentrations of 350 and 700 ppm, while fertilizing them with three different levels of nitrate-nitrogen. In this study, the plants grown in CO<sub>2</sub>-enriched air exhibited rates of net photosynthesis that were approximately 50 percent greater than those displayed by the plants grown in ambient air, regardless of soil nitrate availability. These CO<sub>2</sub>-induced increases in photosynthetic carbon uptake contributed to 60, 40 and 30 percent above-ground organ dry weight increases in plants receiving one-half, standard, and three-fold levels of soil nitrate, respectively. Root weights, however, were less responsive to atmospheric CO<sub>2</sub> enrichment, displaying 10 and 30 percent increases in dry weight at one-half and standard nitrate levels, but no increase at the high soil nitrate concentration. In this study, therefore, the role of soil nitrogen fertility was clearly

opposite to that observed in the four prior studies in the case of above-ground biomass production, but was mixed in the case of belowground biomass production.

Switching to barley, Fangmeier *et al.* (2000) grew plants in containers placed within open-top chambers maintained at atmospheric CO<sub>2</sub> concentrations of either 360 or 650 ppm and either a high or low nitrogen fertilization regime. As in the case of the above-ground biomass response of the sugar beets of Romanova *et al.*, the elevated CO<sub>2</sub> had the greatest relative impact on yield when the plants were grown under the *less-than-optimum low-nitrogen* regime, i.e., a 48 percent increase vs. 31 percent under high-nitrogen conditions.

Last, we report the pertinent results of the review and analysis of Kimball *et al.* (2002), who summarized the findings of most FACE studies conducted on agricultural crops since the introduction of that technology back in the late 1980s. In response to a 300-ppm increase in the air's CO<sub>2</sub> concentration, rates of net photosynthesis in several C<sub>3</sub> grasses were enhanced by an average of 46 percent under conditions of ample soil nitrogen supply and by 44 percent when nitrogen was limiting to growth. With respect to above-ground biomass production, the differential was much larger, with the C<sub>3</sub> grasses wheat, rice and ryegrass experiencing an average increase of 18 percent at ample nitrogen but only 4 percent at low nitrogen; while with respect to belowground biomass production, they experienced an average increase of 70 percent at ample nitrogen and 58 percent at low nitrogen. Similarly, clover experienced a 38 percent increase in belowground biomass production at ample soil nitrogen, and a 32 percent increase at low soil nitrogen. Finally, with respect to agricultural yield, which is the bottom line in terms of food and fiber production, wheat and ryegrass experienced an average increase of 18 percent at ample nitrogen, while wheat experienced only a 10 percent increase at low nitrogen.

In light of these several results, it can be safely concluded that although there are some significant exceptions to the rule, most agricultural crops generally experience somewhat greater CO<sub>2</sub>-induced relative (percentage) increases in net photosynthesis and biomass production even when soil nitrogen concentrations are a limiting factor.

### 7.3.7.2. Fungi

Nearly all of earth's plants become involved in intimate relationships with different fungal species at one point or another in their life cycles. Among other things, the fungi commonly aid plants in the acquisition of water and important soil nutrients. In addition, fungal-plant interactions are often impacted by variations in both atmospheric CO<sub>2</sub> and soil nitrogen concentrations. In this subsection, we review how various aspects of fungal-plant interactions are influenced by elevated CO<sub>2</sub> under varying soil nitrogen regimes.

In a one-year study conducted by Walker *et al.* (1998), ponderosa pine seedlings exposed to atmospheric CO<sub>2</sub> concentrations of 525 and 700 ppm displayed total numbers of ectomycorrhizal fungi on

their roots that were 170 and 85 percent greater, respectively, than those observed on roots of ambiently grown seedlings.

In the study of Rillig *et al.* (1998), three grasses and two herbs fumigated with ambient air and air containing an extra 350 ppm CO<sub>2</sub> for four months displayed various root infection responses by arbuscular mycorrhizal fungi, which varied with soil nitrogen supply. At low soil nitrogen contents, elevated CO<sub>2</sub> increased the percent root infection by this type of fungi in all five annual grassland species. However, at high soil nitrogen contents, this trend was reversed in four of the five species.

Finally, in the study of Rillig and Allen (1998), several important observations were made with respect to the effects of elevated CO<sub>2</sub> and soil nitrogen status on fungal-plant interactions. First, after growing three-year-old shrubs at an atmospheric CO<sub>2</sub> concentration of 750 ppm for four months, they reported insignificant 19 and 9 percent increases in percent root infected by arbuscular mycorrhizal fungi at low and high soil nitrogen concentrations, respectively. However, elevated CO<sub>2</sub> significantly increased the percent root infection by arbuscules, which are the main structures involved in the symbiotic exchange of carbon and nutrients between a host plant and its associated fungi, by more than 14-fold at low soil nitrogen concentrations. In addition, the length of fungal hyphae more than doubled with atmospheric CO<sub>2</sub> enrichment in the low soil nitrogen regime. In the high soil nitrogen treatment, elevated CO<sub>2</sub> increased the percent root infection by vesicles, which are organs used by arbuscular mycorrhizal fungi for carbon storage, by approximately 2.5-fold.

In conclusion, these observations suggest that elevated CO<sub>2</sub> will indeed affect fungal-plant interactions in positive ways that often depend upon soil nitrogen status. Typically, it appears that CO<sub>2</sub>-induced stimulations of percent root infection by various fungal components is greater under lower, rather than higher, soil nitrogen concentrations. This tendency implies that elevated CO<sub>2</sub> will enhance fungal-plant interactions to a greater extent when soil nutrition is less-than-optimal for plant growth, which is the common case for most of earth's ecosystems that are not subjected to cultural fertilization practices typical of intensive agricultural production.

### 7.3.7.3. Grasses

Perennial ryegrass (*Lolium perenne* L.) has been used as a model species in many experiments to help elucidate grassland responses to atmospheric CO<sub>2</sub> enrichment and soil nitrogen availability. In the FACE study of Rogers *et al.* (1998), for example, plants exposed to 600 ppm CO<sub>2</sub> exhibited a 35 percent increase in their photosynthetic rates without regard to soil nitrogen availability. However, when ryegrass was grown in plastic ventilated tunnels at twice-ambient concentrations of atmospheric CO<sub>2</sub>, the CO<sub>2</sub>-induced photosynthetic response was about 3-fold greater in a higher, as opposed to a lower, soil nitrogen regime (Casella and Soussana, 1997). Similarly, in an open-top chamber study conducted by Davey *et al.* (1999), it was reported that an atmospheric CO<sub>2</sub> concentration of 700 ppm stimulated photosynthesis by 30 percent in this species when it was grown with moderate, but not low, soil nitrogen availability. Thus, CO<sub>2</sub>-induced photosynthetic stimulations in perennial ryegrass can be influenced by soil nitrogen content, with greater positive responses typically occurring under higher, as opposed to lower, soil nitrogen availability.

With respect to biomass production, van Ginkel and Gorissen (1998) reported that a doubling of the atmospheric CO<sub>2</sub> concentration increased shoot biomass of perennial ryegrass by 28 percent, regardless of soil nitrogen concentration. In the more revealing six-year FACE study of Daepf *et al.* (2000), plants grown at 600 ppm CO<sub>2</sub> and high soil nitrogen availability continually increased their dry matter production over that observed in ambient-

treatment plots, from 8 percent more in the first year to 25 percent more at the close of year six. When grown at a low soil nitrogen availability, however, CO<sub>2</sub>-enriched plants exhibited an initial 5 percent increase in dry matter production, which dropped to a negative 11 percent in year two; but this negative trend was thereafter turned around, and it continually rose to reach a 9 percent stimulation at the end of the study. Thus, these data demonstrate that elevated CO<sub>2</sub> increases perennial ryegrass biomass, even under conditions of low soil nitrogen availability, especially under conditions of long-term atmospheric CO<sub>2</sub> enrichment.

Lutze *et al.* (1998) reported that microcosms of the C<sub>3</sub> grass *Danthonia richardsonii* grown for four years in glasshouses fumigated with air containing 720 ppm CO<sub>2</sub> displayed total photosynthetic carbon gains that were 15-34 percent higher than those of ambiently grown microcosms, depending on the soil nitrogen concentration. In a clearer depiction of photosynthetic responses to soil nitrogen, Davey *et al.* (1999) noted that photosynthetic rates of *Agrostis capillaries* subjected to twice-ambient levels of atmospheric CO<sub>2</sub> for two years were 12 and 38 percent greater than rates measured in control plants grown at 350 ppm CO<sub>2</sub> under high and low soil nitrogen regimes, respectively. They also reported CO<sub>2</sub>-induced photosynthetic stimulations of 25 and 74 percent for *Trifolium repens* subjected to high and low soil nitrogen regimes, respectively. Thus, we see that the greatest CO<sub>2</sub>-induced percentage increase in photosynthesis can sometimes occur under the *least* favorable soil nitrogen conditions.

With respect to biomass production, Navas *et al.* (1999) reported that 60 days' exposure to 712 ppm CO<sub>2</sub> increased biomass production of *Danthonia richardsonii*, *Phalaris aquatica*, *Lotus pedunculatus*, and *Trifolium repens* across a large soil nitrogen gradient. With slightly more detail, Cotrufo and Gorissen (1997) reported average CO<sub>2</sub>-induced increases in whole-plant dry weights of *Agrostis capillaries* and *Festuca ovina* that were 20 percent greater than those of their respective controls, regardless of soil nitrogen availability. In the study of Ghannoum and Conroy (1998), three *Panicum* grasses grown for two months at twice-ambient levels of atmospheric CO<sub>2</sub> and high soil nitrogen availability displayed similar increases in total plant dry mass that were about 28 percent greater than those of their respective ambiently grown controls. At low nitrogen, however, elevated CO<sub>2</sub> had no significant effect on

the dry mass of two of the species, while it actually decreased that of the third species.

In summary, it is clear that atmospheric CO<sub>2</sub> enrichment stimulates photosynthesis and biomass production in grasses and grassland species when soil nitrogen availability is high and/or moderate. Under lower soil nitrogen conditions, it is also clear that atmospheric CO<sub>2</sub> enrichment can have the same positive effect on these parameters, but that it can also have a reduced positive effect, no effect, or (in one case) a negative effect. In light of the one long-term study that lasted six years, however, it is likely that—given enough time—grasslands have the ability to overcome soil nitrogen limitations and produce positive CO<sub>2</sub>-induced growth responses. Thus, because the rising CO<sub>2</sub> content of the air is likely to continue for a long time to come, occasional nitrogen limitations on the aerial fertilization effect of atmospheric CO<sub>2</sub> enrichment of grasslands will likely become less and less restrictive as time progresses.

Additional information on this topic, including reviews of newer publications as they become available, can be found at <http://www.co2science.org/subject/n/nitroengrass.php>.

### 7.3.7.4. Trees

#### 7.3.7.4.1. Aspen

Does a deficiency of soil nitrogen lessen the relative growth stimulation of quaking aspen (*Populus tremuloides* Michx) that is typically provided by elevated concentrations of atmospheric CO<sub>2</sub>?

In exploring this question, Kubiske *et al.* (1998) grew cuttings of four quaking aspen genotypes for five months at CO<sub>2</sub> concentrations of 380 or 720 ppm and low or high soil nitrogen in open-top chambers in the field in Michigan, USA. They found that the elevated CO<sub>2</sub> treatment significantly increased net photosynthesis, regardless of soil nitrogen content, although there were no discernible increases in above-ground growth within the five-month study period. Belowground, however, elevated CO<sub>2</sub> significantly increased fine root production, but only in the high soil nitrogen treatment.

Working at the same site, Zak *et al.* (2000) and Curtis *et al.* (2000) grew six aspen genotypes from cuttings in open-top chambers for 2.5 growing seasons at atmospheric CO<sub>2</sub> concentrations of 350 and 700 ppm on soils containing either adequate or inadequate supplies of nitrogen. Curtis *et al.* report that at the end of this period the trees growing in the doubled-CO<sub>2</sub> treatment exhibited rates of net photosynthesis that were 128 percent and 31 percent greater than those of the trees growing in the ambient-air treatment on the high- and low-nitrogen soils,

respectively, while Zak *et al.* determined the CO<sub>2</sub>-induced biomass increases of the trees in the high- and low-nitrogen soils to be 38 percent and 16 percent, respectively.

In yet another study from the Michigan site, Mikan *et al.* (2000) grew aspen cuttings for two years in open-top chambers receiving atmospheric CO<sub>2</sub> concentrations of 367 and 715 ppm in soils of low and high soil nitrogen concentrations. They report finding that elevated CO<sub>2</sub> increased the total biomass of the aspen cuttings by 50 percent and 26 percent in the high and low soil nitrogen treatments, respectively, and that it increased coarse root biomass by 78 percent and 24 percent in the same respective treatments.

Last, but again at the same site, Wang and Curtis (2001) grew cuttings of two male and two female aspen trees for about five months in open-top chambers maintained at atmospheric CO<sub>2</sub> concentrations of 380 and 765 ppm on soils of high and low nitrogen content. In the male cuttings, there was a modest difference in the CO<sub>2</sub>-induced increase in total biomass (58 percent and 66 percent in the high- and low-nitrogen soils, respectively), while in the female cuttings the difference was much greater (82 percent and 22 percent in the same respective treatments).

Considering the totality of these several observations, it would appear that the degree of soil nitrogen availability does indeed impact the aerial fertilization effect of atmospheric CO<sub>2</sub> enrichment on the growth of aspen trees by promoting a greater CO<sub>2</sub>-induced growth enhancement in soils of adequate, as opposed to insufficient, nitrogen content.

### 7.3.7.4.2. Pine

In a review of eleven of their previously published papers dealing with both loblolly pine (*Pinus taeda* L.) and ponderosa pine (*Pinus ponderosa* Dougl.), Johnson *et al.* (1998) report that when soil nitrogen levels were so low as to be extremely deficient, or so high as to be toxic, growth responses to atmospheric CO<sub>2</sub> enrichment in both species were negligible. For moderate soil nitrogen deficiencies, however, a doubling of the air's CO<sub>2</sub> content sometimes boosted growth by as much as 1,000 percent. In addition, atmospheric CO<sub>2</sub> enrichment mitigated the negative growth response of ponderosa pine to extremely high soil nitrogen concentrations.

In a second paper published by some of the same scientists in the same year, Walker *et al.* (1998) describe how they raised ponderosa pine tree seedlings for two growing seasons in open-top chambers having CO<sub>2</sub> concentrations of 350, 525 and 700 ppm on soils of low, medium and high nitrogen content. They report that elevated CO<sub>2</sub> had little effect on most growth parameters after the first growing season, the one exception being belowground biomass, which increased with both CO<sub>2</sub> and soil nitrogen. After two growing seasons, however, elevated CO<sub>2</sub> significantly increased all growth parameters, including tree height, stem diameter, shoot weight, stem volume and root volume, with the greatest responses typically occurring at the highest CO<sub>2</sub> concentration in the highest soil nitrogen treatment. Root volume at 700 ppm CO<sub>2</sub> and high soil nitrogen, for example, exceeded that of all other treatments by at least 45 percent, as did shoot volume by 42 percent. Similarly, at high CO<sub>2</sub> and soil nitrogen, coarse root and shoot weights exceeded those at ambient CO<sub>2</sub> and high nitrogen by 80 and 88 percent, respectively.

Walker *et al.* (2000) published another paper on the same trees and treatments after five years of growth. At this time, the trees exposed to the twice-ambient levels of atmospheric CO<sub>2</sub> had heights that were 43, 64 and 25 percent greater than those of the trees exposed to ambient air and conditions of high, medium and low levels of soil nitrogen, respectively. Similarly, the trunk diameters of the 700-ppm-trees were 24, 73 and 20 percent greater than the trunk diameters of the ambiently grown trees exposed to high, medium and low levels of soil nitrogen.

Switching to a different species, Entry *et al.* (1998) grew one-year-old longleaf pine seedlings for 20 months in pots of high and low soil nitrogen content within open-top chambers maintained at atmospheric CO<sub>2</sub> concentrations of 365 or 720 ppm, finding that the elevated CO<sub>2</sub> caused no overall change in whole-plant biomass at low soil nitrogen, but that at high soil nitrogen, it increased it by 42 percent. After two years of these treatments, Runion *et al.* (1999) also reported that rates of net photosynthesis were about 50 percent greater in the high CO<sub>2</sub> treatment, irrespective of soil nitrogen content ... and water content too.

Last, Finzi and Schlesinger (2003) measured and analyzed the pool sizes and fluxes of inorganic and organic nitrogen (N) in the floor and top 30 cm of mineral soil of the Duke Forest at the five-year point of a long-term FACE study, where half of the experimental plots are enriched with an extra 200 ppm of CO<sub>2</sub>. In commencing this study, they had originally hypothesized that “the increase in carbon fluxes to the microbial community under elevated CO<sub>2</sub> would increase the rate of N immobilization over mineralization,” leading to a decline in the significant CO<sub>2</sub>-induced stimulation of forest net primary production that developed over the first two years of the experiment (DeLucia *et al.*, 1999; Hamilton *et al.*, 2002). Quite to the contrary, however, they discovered “there was no statistically significant change in the cycling rate of N derived from soil organic matter under elevated CO<sub>2</sub>.” Neither was the rate of net N mineralization significantly altered by elevated CO<sub>2</sub>, nor was there any statistically significant difference in the concentration or net flux of organic and inorganic N in the forest floor and top 30-cm of mineral soil after 5 years of CO<sub>2</sub> fumigation. Hence, at this stage of the study, they could find no support for their original hypothesis, which suggests that the growth stimulation provided by elevated levels of atmospheric CO<sub>2</sub> would gradually dwindle away to something rather insignificant before the

stand reached its equilibrium biomass, although they continue to cling to this unsubstantiated belief.

Considering the totality of these several observations, it would appear that the degree of soil nitrogen availability impacts the effect of atmospheric CO<sub>2</sub> enrichment on the growth of pine trees, with greater CO<sub>2</sub>-induced growth enhancement occurring in soils of adequate, as opposed to insufficient, nitrogen content. As in the case of aspen, however, there is evidence to suggest that at some point the response to increasing soil nitrogen saturates, and beyond that point, higher N concentrations may sometimes even reduce the forest growth response to elevated CO<sub>2</sub>.

#### 7.3.7.4.3. Spruce

Egli *et al.* (1998) rooted saplings of different genotypes of Norway spruce (*Picea abies* L. Karst.) directly into calcareous or acidic soils in open-top chambers and exposed them to atmospheric CO<sub>2</sub> concentrations of 370 or 570 ppm and low or high soil nitrogen contents. They found that elevated CO<sub>2</sub> generally stimulated light-saturated rates of photosynthesis under all conditions by as much as 35 percent, regardless of genotype, which consistently led to increased above-ground biomass production, also regardless of genotype, as well as without respect to soil type or nitrogen content.

Murray *et al.* (2000) grew Sitka spruce (*Picea sitchensis* (Bong.) Carr.) seedlings for two years in pots within open-top chambers maintained at atmospheric CO<sub>2</sub> concentrations of 355 and 700 ppm. In the last year of the study, half of the seedlings received one-tenth of the optimal soil nitrogen supply recommended for this species, while the other half received twice the optimal amount. Under this protocol, the extra CO<sub>2</sub> increased the seedlings' light-saturated rates of net photosynthesis by 19 percent and 33 percent in the low- and high-nitrogen treatments, respectively, while it increased their total biomass by 0 percent and 37 percent in these same treatments. Nevertheless, Murray *et al.* note there was a reallocation of biomass from above-ground organs (leaves and stems) into roots in the low-nitrogen treatment; and they remark that this phenomenon "may provide a long-term mechanism by which Sitka spruce could utilize limited resources both more efficiently and effectively," which suggests that although low soil nitrogen precluded a short-term CO<sub>2</sub>-induced growth response in this tree species, it is possible that the negative impact of nitrogen deficiency could be overcome in the course of much longer-term atmospheric CO<sub>2</sub> enrichment.

In a related experiment, Liu *et al.* (2002) grew Sitka spruce seedlings in well-watered and fertilized pots within open-top chambers that were maintained for three years at atmospheric CO<sub>2</sub> concentrations of

either 350 or 700 ppm, after which the seedlings were planted directly into native nutrient-deficient forest soil and maintained at the same atmospheric CO<sub>2</sub> concentrations for two more years in larger open-top chambers either with or without extra nitrogen being supplied to the soil. After the first three years of the study, they determined that the CO<sub>2</sub>-enriched trees possessed 11.6 percent more total biomass than the ambient-treatment trees. At the end of the next two years, however, the CO<sub>2</sub>-enriched trees supplied with extra nitrogen had 15.6 percent more total biomass than their similarly treated ambient-air counterparts, while the CO<sub>2</sub>-enriched trees receiving no extra nitrogen had 20.5 percent more biomass than their ambient-treatment counterparts.

In light of these several observations, it would appear that the degree of soil nitrogen availability affects the growth of spruce trees by promoting a greater CO<sub>2</sub>-induced growth enhancement in soils of adequate, as opposed to insufficient, nitrogen content. As in the cases of aspen and pine, however, at some point the response of spruce trees to increasing soil nitrogen saturates, and even higher nitrogen concentrations may reduce the growth response to elevated CO<sub>2</sub> below that observed at optimal or low soil nitrogen concentrations.

## 7.3.7.4.4. Other

Maillard *et al.* (2001) grew pedunculate oak seedlings for three to four months in greenhouses maintained at atmospheric CO<sub>2</sub> concentrations of either 350 or 700 ppm under conditions of either low or high soil nitrogen concentration. The elevated CO<sub>2</sub> of their study stimulated belowground growth in the seedlings growing in the nitrogen-poor soil, significantly increasing their root-to-shoot ratios. However, it increased both the below- and above-ground biomass of seedlings growing in nitrogen-rich soil. In fact, the CO<sub>2</sub>-enriched seedlings growing in the nitrogen-rich soil produced 217 and 533 percent more stem and coarse-root biomass, respectively, than their ambient-air counterparts growing in the same fertility treatment. Overall, the doubled CO<sub>2</sub> concentration of the air in their study enhanced total seedling biomass by approximately 30 and 140 percent under nitrogen-poor and nitrogen-rich soil conditions, respectively.

Schortemeyer *et al.* (1999) grew seedlings of *Acacia melanoxylon* (a leguminous nitrogen-fixing tree native to south-eastern Australia) in hydroponic culture for six weeks in growth cabinets, where the air was maintained at CO<sub>2</sub> concentrations of either 350 or 700 ppm and the seedlings were supplied with water containing nitrogen in a number of discrete concentrations ranging from 3 to 6,400 mmol m<sup>-3</sup>. In the two lowest of these nitrogen concentration treatments, final biomass was unaffected by atmospheric CO<sub>2</sub> enrichment; but, as in the study of Maillard *et al.*, it was increased by 5- to 10-fold at the highest nitrogen concentration.

Temperton *et al.* (2003) measured total biomass production in another N<sub>2</sub>-fixing tree—*Alnus glutinosa* (the common alder)—seedlings of which had been grown for three years in open-top chambers in either ambient or elevated (ambient + 350 ppm) concentrations of atmospheric CO<sub>2</sub> and one of two soil nitrogen regimes (full nutrient solution or no fertilizer). In their study, by contrast, they found that the trees growing under low soil nutrient conditions exhibited essentially the *same* growth enhancement as that of the well-fertilized trees.

Rounding out the full gamut of growth responses, Gladow *et al.* (1998) grew eucalyptus seedlings for six months in glasshouses maintained at atmospheric CO<sub>2</sub> concentrations of either 400 or 800 ppm, fertilizing them twice daily with low or high nitrogen solutions. They found that their doubling of the air's CO<sub>2</sub> concentration increased total seedling biomass by 134 percent in the low nitrogen treatment but by a

smaller 98 percent in the high nitrogen treatment. In addition, the elevated CO<sub>2</sub> led to greater root growth in the low nitrogen treatment, as indicated by a 33 percent higher root:shoot ratio.

In conclusion, different species of trees respond differently to atmospheric CO<sub>2</sub> enrichment under conditions of low vs. high soil nitrogen fertility. The most common response is for the growth-promoting effects of atmospheric CO<sub>2</sub> enrichment to be expressed to a greater degree when soil nitrogen fertility is optimal as opposed to less-than-optimal.

## 7.3.8. High Salinity

In managed agricultural ecosystems, the buildup of soil salinity from repeated irrigations can sometimes reduce crop yields. Similarly, in natural ecosystems where exposure to brackish or salty water is commonplace, saline soils can induce growth stress in plants not normally adapted to coping with this problem. Thus, it is important to understand how rising atmospheric CO<sub>2</sub> concentrations may interact with soil salinity to affect plant growth.

In the study of Ball *et al.* (1997), it was found that two Australian mangrove species with differing tolerance to salinity exhibited increased rates of net photosynthesis in response to a doubling of the atmospheric CO<sub>2</sub> concentration, but only when exposed to salinity levels that were 25 percent, but not 75 percent, of full-strength seawater.

Mavrogianopoulos *et al.* (1999) reported that atmospheric CO<sub>2</sub> concentrations of 800 and 1200 ppm stimulated photosynthesis in parnon melons by 75 and 120 percent, respectively, regardless of soil salinity, which ranged from 0 to 50 mM NaCl. Moreover, the authors noted that atmospheric CO<sub>2</sub> enrichment partially alleviated the negative effects of salinity on melon yield, which increased with elevated CO<sub>2</sub> at all salinity levels.

Maggio *et al.* (2002) grew tomatoes at 400 and 900 ppm in combination with varying degrees of soil salinity and noted that plants grown in elevated CO<sub>2</sub> tolerated an average root-zone salinity threshold value that was about 60 percent greater than that exhibited by plants grown at 400 ppm CO<sub>2</sub> (51 vs. 32 mmol dm<sup>-3</sup> Cl).

The review of Poorter and Perez-Soba (2001) found no changes in the effect of elevated CO<sub>2</sub> on the growth responses of most plants over a wide range of soil salinities, in harmony with the earlier findings of Idso and Idso (1994).

These various studies suggest that elevated CO<sub>2</sub> concentrations have either positive or no effects on plant growth where mild to moderate stresses may be present due to high soil salinity levels. Additional information on this topic, including reviews of newer publications as they become available, can be found at [http://www.co2science.org/subject/s/salinity\\_stress.php](http://www.co2science.org/subject/s/salinity_stress.php).

## 7.3.9. Elevated Temperature

Will plants continue to exhibit CO<sub>2</sub>-induced growth increases under conditions of elevated air temperature? In this section, we review the photosynthetic and growth responses of agricultural crops, grasslands and woody species to answer this question.

### 7.3.9.1. Agricultural Crops

The optimum growth temperature for several plants has been shown to rise substantially with increasing levels of atmospheric CO<sub>2</sub> (McMurtrie and Wang, 1993; McMurtrie *et al.*, 1992; Stuhlfauth and Fock, 1990; Berry and Bjorkman, 1980). This phenomenon was predicted by Long (1991), who calculated from well-established plant physiological principles that most C<sub>3</sub> plants should increase their optimum growth temperature by approximately 5°C for a 300 ppm increase in the air's CO<sub>2</sub> content. One would thus also expect plant photosynthetic rates to rise with concomitant increases in the air's CO<sub>2</sub> concentration and temperature, as has indeed been previously shown to be true by Idso and Idso (1994). We here proceed to see if these positive CO<sub>2</sub> and temperature interactions are still being supported in the recent scientific literature.

In the study of Zhu *et al.* (1999), pineapples grown at 700 ppm CO<sub>2</sub> assimilated 15, 97 and 84 percent more total carbon than pineapples grown at the current ambient CO<sub>2</sub> concentration in day/night air temperature regimes of 30/20 (which is optimal for pineapple growth at ambient CO<sub>2</sub>), 30/25, and 35/25 °C, respectively. Similarly, Taub *et al.* (2000) demonstrated that net photosynthetic rates of cucumbers grown at twice-ambient levels of atmospheric CO<sub>2</sub> and air temperatures of 40°C were 3.2 times greater than those displayed by control

plants grown at ambient CO<sub>2</sub> and this same elevated air temperature. Thus, at air temperatures normally considered to be deleterious to plant growth, rates of photosynthesis are typically considerably greater for CO<sub>2</sub> enriched vs. ambiently grown plants.

Reddy *et al.* (1999) grew cotton plants at air temperatures ranging from 2°C below to 7°C above ambient air temperatures and reported that plants simultaneously exposed to 720 ppm CO<sub>2</sub> displayed photosynthetic rates that were 137 to 190 percent greater than those displayed by plants exposed to ambient CO<sub>2</sub> concentrations across this temperature spectrum. Similarly, Cowling and Sage (1998) reported that a 200-ppm increase in the air's CO<sub>2</sub> concentration boosted photosynthetic rates of young bean plants by 58 and 73 percent at growth temperatures of 25 and 36°C, respectively. In addition, Bunce (1998) grew wheat and barley at 350 and 700 ppm CO<sub>2</sub> across a wide range of temperatures and reported that elevated CO<sub>2</sub> stimulated photosynthesis in these species by 63 and 74 percent, respectively, at an air temperature of 10°C and by 115 and 125 percent at 30°C. Thus, the percentage increase in photosynthetic rate resulting from atmospheric CO<sub>2</sub> enrichment often increases substantially with increasing air temperature.

Elevated CO<sub>2</sub> often aids in the recovery of plants from high temperature-induced reductions in photosynthetic capacity, as noted by Ferris *et al.* (1998), who grew soybeans for 52 days under normal air temperature and soil water conditions at atmospheric CO<sub>2</sub> concentrations of 360 and 700 ppm, but then subjected them to an 8-day period of high temperature and water stress. After normal air temperature and soil water conditions were restored, the CO<sub>2</sub>-enriched plants attained photosynthetic rates that were 72 percent of their unstressed controls, while stressed plants grown at ambient CO<sub>2</sub> attained photosynthetic rates that were only 52 percent of their respective controls.

CO<sub>2</sub>-induced increases in plant growth under high air temperatures have also been observed in a number of other agricultural species. In the previously mentioned study of Cowling and Sage (1998), for example, the 200-ppm increase in the air's CO<sub>2</sub> content boosted total plant biomass for wheat and barley by a combined average of 59 and 200 percent at air temperatures of 25 and 36°C. Similarly, Ziska (1998) reported that a doubling of the atmospheric CO<sub>2</sub> concentration increased the total dry weight of soybeans by 36 and 42 percent at root zone temperatures of 25 and 30°C, respectively. Likewise,

Hakala (1998) noted that spring wheat grown at 700 ppm CO<sub>2</sub> attained total biomass values that were 17 and 23 percent greater than those attained by ambiently grown plants exposed to ambient and elevated (ambient plus 3°C) air temperatures. In addition, after inputting various observed CO<sub>2</sub>-induced growth responses of winter wheat into plant growth models, Alexandrov and Hoogenboom (2000) predicted 12 to 49 percent increases in wheat yield in Bulgaria even if air temperatures rise by as much as 4°C. Finally, in the study of Reddy *et al.* (1998), it was shown that elevated CO<sub>2</sub> (700 ppm) increased total cotton biomass by 31 to 78 percent across an air temperature range from 20 to 40°C. Thus, the beneficial effects of elevated CO<sub>2</sub> on agricultural crop yield is often enhanced by elevated air temperature.

In some cases, however, elevated CO<sub>2</sub> does not interact with air temperature to further increase the growth-promoting effects of atmospheric CO<sub>2</sub> enrichment, but simply allows the maintenance of the status quo. In the study of Demmers-Derks *et al.* (1998), for example, sugar beets grown at 700 ppm CO<sub>2</sub> attained 25 percent more biomass than ambiently grown plants, regardless of air temperature, which was increased by 3°C. Similarly, in the study of Fritschi *et al.* (1999), elevated CO<sub>2</sub> concentrations did not significantly interact with air temperature (4.5°C above ambient) to impact the growth of rhizoma peanut. Nonetheless, the 300-ppm increase in the air's CO<sub>2</sub> content increased total biomass by 52 percent, regardless of air temperature.

Finally, even if the air's CO<sub>2</sub> content were to cease rising or have no effect on plants, it is possible that temperature increases alone would promote plant growth and development. This was the case in the study of Wurr *et al.* (2000), where elevated CO<sub>2</sub> had essentially no effect on the yield of French bean. However, a 4°C increase in air temperature increased yield by approximately 50 percent.

In conclusion, the recent scientific literature continues to indicate that as the air's CO<sub>2</sub> content rises, agricultural crops will likely exhibit enhanced rates of photosynthesis and biomass production that will not be diminished by any global warming that might occur concurrently. In fact, if the ambient air temperature rises, the growth-promoting effects of atmospheric CO<sub>2</sub> enrichment will likely rise along with it.

## 7.3.9.2. Grassland Species

In the study of Lilley *et al.* (2001), swards of *Trifolium subterraneum* were grown at 380 and 690 ppm CO<sub>2</sub> in combination with simultaneous exposure to ambient and elevated (ambient plus 3.4°C) air temperature. After one year of treatment, they reported that elevated CO<sub>2</sub> increased foliage growth by 19 percent at ambient air temperature. At elevated air temperature, however, plants grown at ambient CO<sub>2</sub> exhibited a 28 percent reduction in foliage growth, while CO<sub>2</sub>-enriched plants still displayed a growth enhancement of 8 percent. Similarly, Morgan *et al.* (2001) reported that twice-ambient levels of atmospheric CO<sub>2</sub> increased above-ground biomass in native shortgrass steppe ecosystems by an average of 38 percent, in spite of an average air temperature increase of 2.6°C. Likewise, when bahiagrass was grown across a temperature gradient of 4.5°C, Fritschi *et al.* (1999) reported that a 275 ppm increase in the air's CO<sub>2</sub> content boosted photosynthesis and above-ground biomass by 22 and 17 percent, respectively,

independent of air temperature. Thus, at elevated air temperature, CO<sub>2</sub>-induced increases in rates of photosynthesis and biomass production are typically equal to or greater than what they are at ambient air temperature.

Other studies report similar results. Greer *et al.* (2000), for example, grew five pasture species at 18 and 28°C and reported that plants concomitantly exposed to 700 ppm CO<sub>2</sub> displayed average photosynthetic rates that were 36 and 70 percent greater, respectively, than average rates exhibited by control plants subjected to ambient CO<sub>2</sub> concentrations. Moreover, the average CO<sub>2</sub>-induced biomass increase for these five species rose dramatically with increasing air temperature: from only 8 percent at 18°C to 95 percent at 28°C. Thus, the beneficial effects of elevated CO<sub>2</sub> on grassland productivity is often significantly enhanced by elevated air temperature.

Finally, temperature increases alone can promote grass growth and development. Norton *et al.* (1999) found elevated CO<sub>2</sub> had essentially no effect on the growth of the perennial grass *Agrostis curtisii* after two years of fumigation; however, a 3°C increase in air temperature increased the growth of this species considerably.

In conclusion, grassland plants will likely exhibit enhanced rates of photosynthesis and biomass production as the air's CO<sub>2</sub> content rises that will not be diminished by any global warming that might occur concurrently. If the ambient air temperature rises, the growth-promoting effects of atmospheric CO<sub>2</sub> enrichment will likely rise along with it.

### 7.3.9.3. Trees

In the study of Kellomaki and Wang (2001), birch seedlings were grown at atmospheric CO<sub>2</sub> concentrations of 350 and 700 ppm in combination with ambient and elevated (ambient plus 3°C) air temperatures. After five months of treatment, the authors reported that photosynthetic rates of CO<sub>2</sub>-enriched seedlings were 21 and 28 percent greater than those displayed by their ambiently grown counterparts at ambient and elevated air temperatures, respectfully. In another study, Carter *et al.* (2000) observed that a 300 ppm increase in the air's CO<sub>2</sub> content allowed leaves of sugar maple seedlings to remain green and non-chlorotic when exposed to air temperatures 3°C above ambient air temperature. On the other hand, seedlings fumigated with ambient air exhibited severe foliar chlorosis when exposed to the same elevated air temperatures. These results thus indicate that at elevated air temperatures, rates of photosynthesis are greater and foliar health is typically better in birch and sugar maples trees in CO<sub>2</sub>-enriched as opposed to ambient air.

Other studies report similar results. Sheu *et al.* (1999) grew a sub-tropical tree at day/night temperatures of 25/20°C (ambient) and 30/25°C (elevated) for six months and reported that seedlings exposed to 720 ppm CO<sub>2</sub> displayed photosynthetic rates that were 20 and 40 percent higher, respectively, than that of their ambiently grown controls. In addition, the CO<sub>2</sub>-induced increases in total dry weight for this species were 14 and 49 percent,

respectively, at ambient and elevated air temperatures. Likewise, Maherali *et al.* (2000) observed that a 5°C increase in ambient air temperature increased the CO<sub>2</sub>-induced biomass enhancement resulting from a 750 ppm CO<sub>2</sub> enrichment of ponderosa pine seedlings from 42 to 62 percent. Wayne *et al.* (1998) reported that a 5°C increase in the optimal growth temperature of yellow birch seedlings fumigated with an extra 400 ppm CO<sub>2</sub> increased the CO<sub>2</sub>-induced increase in biomass from 60 to 227 percent. The beneficial effects of elevated CO<sub>2</sub> on tree species photosynthesis and growth can also be assessed during natural seasonal temperature changes, as documented by Hymus *et al.* (1999) for loblolly pine and Roden *et al.* (1999) for snow gum seedlings.

In some cases, however, there appear to be little interactive effects between elevated CO<sub>2</sub> and temperature on photosynthesis and growth in tree species. When Tjoelker *et al.* (1998a), for example, grew seedlings of quaking aspen, paper birch, tamarack, black spruce and jack pine at atmospheric CO<sub>2</sub> concentrations of 580 ppm, they reported average increases in photosynthetic rates of 28 percent, regardless of temperature, which varied from 18 to 30°C. After analyzing the CO<sub>2</sub>-induced increases in dry mass for these seedlings, Tjoelker *et al.* (1998b) further reported that dry mass values were about 50 and 20 percent greater for the deciduous and coniferous species, respectively, regardless of air temperature.

### 7.3.9.4. Other

In a mechanistic model study of Mediterranean shrub vegetation, Osborne *et al.* (2000) reported that increased warming and reduced precipitation would likely decrease net primary production. However, when the same model was run at twice the ambient atmospheric CO<sub>2</sub> concentration, it predicted a 25 percent increase in vegetative productivity, in spite of the increased warming and reduced precipitation. Although we tend to not review studies based on mechanistic models, it is also interesting to note that Bunce (2000) demonstrated that field-grown *Taraxacum officinale* plants exposed to 525 ppm CO<sub>2</sub> and low air temperatures (between 15 and 25°C) displayed photosynthetic rates that were 10 to 30 percent greater than what was predicted by state-of-the-art biochemical models of photosynthesis for this range of temperatures. Thus, at both high and low air temperatures, elevated CO<sub>2</sub> appears to be capable of significantly increasing the photosynthetic prowess of some plants.

In the real world, Stirling *et al.* (1998) grew five fast-growing native species at various atmospheric CO<sub>2</sub> concentrations and air temperatures, finding that twice-ambient levels of atmospheric CO<sub>2</sub> increased photosynthetic rates by 18-36 percent for all species regardless of air temperature, which was up to 3°C higher than ambient air temperature. In addition, atmospheric CO<sub>2</sub> enrichment increased average plant biomass by 25 percent, also regardless of air temperature. Likewise, in a study of vascular plants from Antarctica, Xiong *et al.* (2000) reported that a 13°C rise in air temperature increased plant biomass by 2- to 3-fold. We can only imagine what the added benefit of atmospheric CO<sub>2</sub> enrichment would do for these species.

Hamerlynck *et al.* (2000) demonstrated that the desert perennial shrub *Larrea tridentata* maintained more favorable midday leaf water potentials during a nine-day high-temperature treatment when fumigated with 700 ppm CO<sub>2</sub>, as compared to 350 ppm.

### 7.3.10. UV-B Radiation

Zhao *et al.* (2004) report that “as a result of stratospheric ozone depletion, UV-B radiation (280-320 nm) levels are still high at the Earth’s surface and are projected to increase in the near future (Madronich *et al.*, 1998; McKenzie *et al.*, 2003).” In reference to this potential development, they note that “increased levels of UV-B radiation are known to affect plant growth, development and physiological processes (Dai *et al.*, 1992; Nogués *et al.*, 1999),” stating that high UV-B levels often result in “inhibition of photosynthesis, degradation of protein and DNA, and increased oxidative stress (Jordan *et al.*, 1992; Stapleton, 1992).” In light of the above observations, it is important to clarify how the ongoing rise in the air’s CO<sub>2</sub> content might affect the deleterious effects of UV-B radiation on earth’s vegetation.

To investigate this question, Zhao *et al.* grew well watered and fertilized cotton plants in sunlit controlled environment chambers maintained at atmospheric CO<sub>2</sub> concentrations of 360 or 720 ppm from emergence until three weeks past first-flower stage under three levels of UV-B radiation (0, 8 and 16 kJ m<sup>-2</sup> d<sup>-1</sup>). On five dates between 21 and 62 days after emergence, they measured a number of plant physiological processes and parameters. Over the course of the experiment, the mean net photosynthetic rate of the upper-canopy leaves in the CO<sub>2</sub>-enriched chambers was increased—relative to that in the ambient-air chambers—by 38.3 percent in the low UV-B treatment (from 30.3 to 41.9 m m<sup>-2</sup> s<sup>-1</sup>), 41.1 percent in the medium UV-B treatment (from 28.7 to 40.5 m m<sup>-2</sup> s<sup>-1</sup>), and 51.5 percent in the high UV-B treatment (from 17.1 to 25.9 m m<sup>-2</sup> s<sup>-1</sup>). In the medium UV-B treatment, the growth stimulation from the elevated CO<sub>2</sub> was sufficient to raise net photosynthesis rates 33.7 percent above the rates experienced in the ambient air and no UV-B treatment (from 30.3 to 40.5 m m<sup>-2</sup> s<sup>-1</sup>); but in the high UV-B treatment the radiation damage was so great that even with the help of the 51.5 percent increase in net photosynthesis provided by the doubled-CO<sub>2</sub> air, the mean net photosynthesis rate of the cotton leaves was 14.5 percent less than that experienced in the

ambient air and no UV-B treatment (dropping from 30.3 to 25.9  $\text{m m}^{-2} \text{s}^{-1}$ ).

It should be noted that the medium UV-B treatment of this study was chosen to represent the intensity of UV-B radiation presently received on a clear summer day in the major cotton production region of Mississippi, USA, under current stratospheric ozone conditions, while the high UV-B treatment was chosen to represent what might be expected there following a 30 percent depletion of the ozone layer, which has been predicted to double the region's reception of UV-B radiation from 8 to 16  $\text{kJ m}^{-2} \text{d}^{-1}$ . Consequently, a doubling of the current  $\text{CO}_2$  concentration and the current UV-B radiation level would reduce the net photosynthetic rate of cotton leaves by just under 10 percent (from 28.7 to 25.9  $\text{m m}^{-2} \text{s}^{-1}$ ), whereas in the absence of a doubling of the air's  $\text{CO}_2$  content, a doubling of the UV-B radiation level would reduce cotton net photosynthesis by just over 40 percent (from 28.7 to 17.1  $\text{m m}^{-2} \text{s}^{-1}$ ).

Viewed in this light, it can be seen that a doubling the current atmospheric  $\text{CO}_2$  concentration would compensate for over three-fourths of the loss of cotton photosynthetic capacity caused by a doubling of the current UV-B radiation intensity. It may do better than that, for in the study of Zhao *et al.* (2003), it was reported that both Adamse and Britz (1992) and Rozema *et al.* (1997) found that doubled  $\text{CO}_2$  totally compensated for the negative effects of equally high UV-B radiation.

In another study (Qaderi and Reid, 2005), well watered and fertilized canola (*Brassica napus* L.) plants were grown from seed to maturity in pots within controlled environment chambers maintained at either 370 or 740 ppm  $\text{CO}_2$  with and without a daily dose of UV-B radiation in the amount of 4.2  $\text{kJ m}^{-2}$ , while a number of plant parameters were measured at various times throughout the growing season. With respect to the bottom-line result of final seed yield, this parameter was determined to be 0.98 g/plant in the control treatment (ambient  $\text{CO}_2$ , with UV-B). Doubling the  $\text{CO}_2$  concentration increased yield by 25.5 percent to 1.23 g/plant. Alternatively, removing the UV-B radiation flux increased yield by 91.8 percent to 1.88 g/plant. Doing both (doubling the  $\text{CO}_2$  concentration while simultaneously removing the UV-B flux) increased final seed yield most of all, by 175.5 percent to 2.7 g/plant. Viewed from a different perspective, doubling the air's  $\text{CO}_2$  concentration in the *presence* of the UV-B radiation flux enhanced final seed yield by 25.5 percent, while doubling  $\text{CO}_2$  in the *absence* of the UV-B radiation flux increased

seed yield by 43.6 percent. In concluding their paper, the authors note that "previous studies have shown that elevated  $\text{CO}_2$  increases biomass and seed yield, whereas UV-B decreases them (Sullivan, 1997; Teramura *et al.*, 1990)." Finding much the same thing in their study, they thus reckoned that "elevated  $\text{CO}_2$  may have a positive effect on plants by mitigating the detrimental effects caused by UV-B radiation."

Two years later in a similar study of the same plant, Qaderi *et al.* (2007) grew well watered and fertilized canola plants from the 30-day-old stage until 25 days after anthesis in 1-L pots within controlled environment chambers exposed to either 4.2  $\text{kJ m}^{-2} \text{d}^{-1}$  of UV-B radiation or no such radiation in air of either 370 or 740 ppm  $\text{CO}_2$ , in order to determine the effects of these two parameters on the photosynthetic rates and water use efficiency of the maturing husks or *siliquas* that surround the plants' seeds. Results indicated that for the plants exposed to 4.2  $\text{kJ m}^{-2} \text{d}^{-1}$  of UV-B radiation, the experimental doubling of the air's  $\text{CO}_2$  concentration led to a 29 percent increase in siliqua net photosynthesis, an 18 percent decrease in siliqua transpiration, and a 58 percent increase in siliqua water use efficiency; while for the plants exposed to no UV-B radiation, siliqua net photosynthesis was increased by a larger 38 percent, transpiration was decreased by a larger 22 percent and water use efficiency was increased by a larger 87 percent in the  $\text{CO}_2$ -enriched air.

In another noteworthy study, Deckmyn *et al.* (2001) grew white clover plants for four months in four small greenhouses, two of which allowed 88 percent of the incoming UV-B radiation to pass through their roofs and walls and two of which allowed 82 percent to pass through, while one of the two greenhouses in each of the UV-B treatments was maintained at ambient  $\text{CO}_2$  (371 ppm) and the other at elevated  $\text{CO}_2$  (521 ppm). At the mid-season point of their study, they found that the 40 percent increase in atmospheric  $\text{CO}_2$  concentration stimulated the production of flowers in the low UV-B treatment by 22 percent and in the slightly higher UV-B treatment by 43 percent; while at the end of the season, the extra  $\text{CO}_2$  was determined to have provided no stimulation of biomass production in the low UV-B treatment, but it significantly stimulated biomass production by 16 percent in the high UV-B treatment.

The results of this study indicate that the positive effects of atmospheric  $\text{CO}_2$  enrichment on flower and biomass production in white clover are greater at more realistic or natural values of UV-B radiation than those found in many greenhouses. As a result,

Deckmyn *et al.* say their results “clearly indicate the importance of using UV-B transmittant greenhouses or open-top chambers when conducting CO<sub>2</sub> studies,” for if this is not done, their work suggests that the results obtained could significantly underestimate the magnitude of the benefits that are being continuously accrued by earth’s vegetation as a result of the ongoing rise in the air’s CO<sub>2</sub> content.

In 2007, Koti *et al.* (2007) used Soil-Plant-Atmosphere-Research (SPAR) chambers at Mississippi State University (USA) to investigate the effects of doubled atmospheric CO<sub>2</sub> concentration (720 vs. 360 ppm) on the growth and development of six well watered and fertilized soybean (*Glycine max* L.) genotypes grown from seed in pots filled with fine sand and exposed to the dual stresses of high day/night temperatures (38/30°C vs. 30/22°C) and high UV-B radiation levels (10 vs. 0 kJ/m<sup>2</sup>/day). Results led this group of authors to report that “elevated CO<sub>2</sub> partially compensated [for] the damaging effects on vegetative growth and physiology caused by negative stressors such as high temperatures and enhanced UV-B radiation levels in soybean,” specifically noting, in this regard, CO<sub>2</sub>’s positive influence on the physiological parameters of plant height, leaf area, total biomass, net photosynthesis, total chlorophyll content, phenolic content and wax content, as well as relative plant injury.

In a study that did not include UV-B radiation as an experimental parameter, Estiarte *et al.* (1999) grew spring wheat in FACE plots in Arizona, USA, at atmospheric CO<sub>2</sub> concentrations of 370 and 550 ppm and two levels of soil moisture (50 and 100 percent of potential evapotranspiration). They found that leaves of plants grown in elevated CO<sub>2</sub> had 14 percent higher total flavonoid concentrations than those of plants grown in ambient air, and that soil water content did not affect the relationship. An important aspect of this finding is that one of the functions of flavonoids in plant leaves is to protect them against UV-B radiation. More studies of this nature should be conducted to see how general this beneficial response may be throughout the plant world.

In a study of UV-B and CO<sub>2</sub> effects on a natural ecosystem, which was conducted at the Abisko Scientific Research Station in Swedish Lapland, Johnson *et al.* (2002) studied plots of subarctic heath composed of open canopies of downy birch and dense dwarf-shrub layers containing scattered herbs and grasses. For a period of five years, they exposed the plots to factorial combinations of UV-B radiation—

ambient and that expected to result from a 15 percent stratospheric ozone depletion—and atmospheric CO<sub>2</sub> concentration—ambient (around 365 ppm) and enriched (around 600 ppm)—after which they determined the amounts of microbial carbon (C<sub>mic</sub>) and nitrogen (N<sub>mic</sub>) in the soils of the plots.

When the plots were exposed to the enhanced UV-B radiation, the amount of C<sub>mic</sub> in the soil was reduced to only 37 percent of what it was at the ambient UV-B level when the air’s CO<sub>2</sub> content was maintained at the ambient concentration. When the UV-B increase was accompanied by the CO<sub>2</sub> increase, however, not only was there not a decrease in C<sub>mic</sub>, there was an actual increase of 37 percent. The amount of N<sub>mic</sub> in the soil experienced a 69 percent increase when the air’s CO<sub>2</sub> content was maintained at the ambient concentration; and when the UV-B increase was accompanied by the CO<sub>2</sub> increase, N<sub>mic</sub> rose even more, by 138 percent.

These findings, in the words of Johnson *et al.*, “may have far-reaching implications ... because the productivity of many semi-natural ecosystems is limited by N (Ellenberg, 1988).” The 138 percent increase in soil microbial N observed in this study to accompany a 15 percent reduction in stratospheric ozone and a 64 percent increase in atmospheric CO<sub>2</sub> concentration (experienced in going from 365 ppm to 600 ppm) should significantly enhance the input of plant litter to the soils of these ecosystems, which phenomenon represents the first half of the carbon sequestration process, i.e., the carbon input stage. With respect to the second stage of *keeping* as much of that carbon as possible in the soil, Johnson *et al.* note that “the capacity for subarctic semi-natural heaths to act as major sinks for fossil fuel-derived carbon dioxide is [also] likely to be critically dependent on the supply of N,” as is indeed indicated to be the case in the literature review of Berg and Matzner (1997), who report that with more nitrogen in the soil, the long-term storage of carbon is significantly enhanced, as more litter is chemically transformed into humic substances when nitrogen is more readily available, and these more recalcitrant carbon compounds can be successfully stored in the soil for many millennia.

In light of these several findings, we conclude that the ongoing rise in the air’s CO<sub>2</sub> content is a powerful antidote for the deleterious biological impacts that might possibly be caused by an increase in the flux of UV-B radiation at the surface of the earth due to any further depletion of the planet’s stratospheric ozone layer.

### 7.3.11. Water Stress

As the CO<sub>2</sub> content of the air continues to rise, nearly all of earth's plants will exhibit increases in photosynthesis and biomass production. However, some experts claim that water stress will negate these benefits. In reviewing the scientific literature of the ten-year period 1983-1994, however, Idso and Idso (1994) found that water stress typically will *not*

negate the CO<sub>2</sub>-induced stimulation of plant productivity. They found that the CO<sub>2</sub>-induced percentage increase in plant biomass production was often greater under water-stressed conditions than it was when plants were well-watered. We here review some more recent scientific literature in this area for agricultural, grassland and woody plant species.

#### 7.3.11.1. Agricultural Species

During times of water stress, atmospheric CO<sub>2</sub> enrichment often stimulates plants to develop larger-than-usual and more robust root systems to probe greater volumes of soil for scarce and much-needed moisture. Wechsung *et al.* (1999), for example, observed a 70 percent increase in lateral root dry weights of water-stressed wheat grown at 550 ppm CO<sub>2</sub>, while De Luis *et al.* (1999) reported a 269 percent increase in root-to-shoot ratio of water-stressed alfalfa growing at 700 ppm CO<sub>2</sub>. Thus, elevated CO<sub>2</sub> elicits stronger-than-usual positive root responses in agricultural species under conditions of water stress.

Elevated levels of atmospheric CO<sub>2</sub> also tend to reduce the openness of stomatal pores on leaves, thus decreasing plant stomatal conductance. This phenomenon, in turn, reduces the amount of water lost to the atmosphere by transpiration and, consequently, lowers overall plant water use. Serraj *et al.* (1999) report that water-stressed soybeans grown at 700 ppm CO<sub>2</sub> reduced their total seasonal water loss by 10 percent relative to that of water-stressed control plants grown at 360 ppm CO<sub>2</sub>. In addition, Conley *et al.* (2001) noted that a 200-ppm increase in the air's CO<sub>2</sub> concentration reduced cumulative evapotranspiration in water-stressed sorghum by approximately 4 percent. Atmospheric CO<sub>2</sub> enrichment thus increases plant water acquisition, by stimulating root growth, while it reduces plant water loss, by constricting stomatal apertures; and these dual effects typically enhance plant water-use efficiency, even under conditions of less-than-optimal soil water content. But these phenomena have other implications as well.

CO<sub>2</sub>-induced increases in root development together with CO<sub>2</sub>-induced reductions in stomatal conductance often contribute to the maintenance of a more favorable plant water status during times of drought. Sgherri *et al.* (1998) reported that leaf water potential, which is a good indicator of overall plant water status, was 30 percent higher (less negative and

therefore more favorable) in water-stressed alfalfa grown at an atmospheric CO<sub>2</sub> concentration of 600 ppm CO<sub>2</sub> versus 340 ppm CO<sub>2</sub>. Wall (2001) reports that leaf water potentials were similar in CO<sub>2</sub>-enriched water-stressed plants and ambiently grown well-watered control plants, which implies a complete CO<sub>2</sub>-induced amelioration of water stress in the CO<sub>2</sub>-enriched plants. Similarly, Lin and Wang (2002) demonstrated that elevated CO<sub>2</sub> caused a several-day delay in the onset of the water stress-induced production of the highly reactive oxygenated compound H<sub>2</sub>O<sub>2</sub> in spring wheat.

If atmospheric CO<sub>2</sub> enrichment thus allows plants to maintain a better water status during times of water stress, it is only logical to expect that such plants should exhibit greater rates of photosynthesis than ambiently grown plants. And so they do. With the onset of water stress in *Brassica juncea*, for example, photosynthetic rates dropped by 40 percent in plants growing in ambient air, while plants growing in air containing 600 ppm CO<sub>2</sub> only experienced a 30 percent reduction in net photosynthesis (Rabha and Uprety, 1998). Ferris *et al.* (1998) reported that after imposing water-stress conditions on soybeans and allowing them to recover following complete rewetting of the soil, plants grown in air containing 700 ppm CO<sub>2</sub> reached pre-stressed rates of photosynthesis after six days, while plants grown in ambient air never recovered to pre-stressed rates.

Reasoning analogously, it is also to be expected that plant biomass production would be enhanced by elevated CO<sub>2</sub> concentrations under drought conditions. In exploring this idea, Ferris *et al.* (1999) reported that water-stressed soybeans grown at 700 ppm CO<sub>2</sub> attained seed yields that were 24 percent greater than those of similarly water-stressed plants grown at ambient CO<sub>2</sub> concentrations, while Hudak *et al.* (1999) reported that water-stress had no effect on yield in CO<sub>2</sub>-enriched spring wheat.

In some cases, the CO<sub>2</sub>-induced percentage biomass increase is actually greater for water-stressed plants than it is for well-watered plants. Li *et al.* (2000), for example, reported that a 180-ppm increase in the air's CO<sub>2</sub> content increased lower stem grain weights in water-stressed and well-watered spring wheat by 24 and 14 percent, respectively. Similarly, spring wheat grown in air containing an additional 280 ppm CO<sub>2</sub> exhibited 57 and 40 percent increases in grain yield under water-stressed and well-watered conditions, respectively (Schutz and Fangmeier, 2001). Likewise, Ottman *et al.* (2001) noted that elevated CO<sub>2</sub> increased plant biomass in water-

stressed sorghum by 15 percent, while no biomass increase occurred in well-watered sorghum.

In summary, the conclusions of Idso and Idso (1994) are well supported by the recent peer-reviewed scientific literature, which indicates that the ongoing rise in the air's CO<sub>2</sub> content will likely lead to substantial increases in plant photosynthetic rates and biomass production, even in the face of stressful conditions imposed by less-than-optimum soil moisture conditions.

### 7.3.11.2. Grassland Species

In the study of Leymarie *et al.* (1999), twice-ambient levels of atmospheric CO<sub>2</sub> caused significant reductions in the stomatal conductance of water-stressed *Arabidopsis thaliana*. Similarly, Volk *et al.* (2000) reported that calcareous grassland species exposed to elevated CO<sub>2</sub> concentrations (600 ppm) consistently exhibited reduced stomatal conductance, regardless of soil moisture availability. Thus, atmospheric CO<sub>2</sub> enrichment clearly reduces stomatal conductance and plant transpiration and soil water depletion in grassland ecosystems.

In the case of four grassland species comprising a pasture characteristic of New Zealand, Clark *et al.* (1999) found that leaf water potential, which is a good indicator of plant water status, was consistently higher (less negative and, therefore, less stressful) under elevated atmospheric CO<sub>2</sub> concentrations. Similarly, leaf water potentials of the water-stressed

C<sub>4</sub> grass *Panicum coloratum* grown at 1000 ppm CO<sub>2</sub> were always higher than those of their water-stressed counterparts growing in ambient air (Seneweera *et al.*, 2001). Indeed, Seneweera *et al.* (1998) reported that leaf water potentials observed in CO<sub>2</sub>-enriched water-stressed plants were an amazing three-and-a-half times greater than those observed in control plants grown at 350 ppm during drought conditions (Seneweera *et al.*, 1998).

If atmospheric CO<sub>2</sub> enrichment thus allows plants to maintain improved water status during times of water stress, it is only logical to expect that such plants will exhibit greater photosynthetic rates than similar plants growing in ambient air. In a severe test of this concept, Ward *et al.* (1999) found that extreme water stress caused 93 and 85 percent reductions in the photosynthetic rates of two CO<sub>2</sub>-enriched grassland species; yet their rates of carbon fixation were still greater than those observed under ambient CO<sub>2</sub> conditions.

In view of the fact that elevated CO<sub>2</sub> enhances photosynthetic rates during times of water stress, one would expect that plant biomass production would also be enhanced by elevated CO<sub>2</sub> concentrations under drought conditions. And so it is. On the American prairie, for example, Owensby *et al.* (1999) reported that tallgrass ecosystems exposed to twice-ambient concentrations of atmospheric CO<sub>2</sub> for eight years only exhibited significant increases in above- and below-ground biomass during years of less-than-average rainfall. Also, in the study of Derner *et al.* (2001), the authors reported that a 150-ppm increase in the CO<sub>2</sub> content of the air increased shoot biomass in two C<sub>4</sub> grasses by 57 percent, regardless of soil water content. Seneweera *et al.* (2001) reported that a 640-ppm increase in the air's CO<sub>2</sub> content increased shoot dry mass in a C<sub>4</sub> grass by 44 and 70 percent under well-watered and water-stressed conditions, respectively. Likewise, Volk *et al.* (2000) grew calcareous grassland assemblages at 360 and 600 ppm CO<sub>2</sub> and documented 18 and 40 percent CO<sub>2</sub>-induced increases in whole-community biomass under well-watered and water-stressed conditions, respectively.

In summary, the peer-reviewed scientific literature indicates that the ongoing rise in the air's CO<sub>2</sub> content will likely lead to substantial increases in plant photosynthetic rates and biomass production for grassland species even in the face of stressful environmental conditions imposed by less-than-optimum soil moisture contents.

### 7.3.11.3. Woody Species

During times of water stress, atmospheric CO<sub>2</sub> enrichment often stimulates the development of larger-than-usual and more robust root systems in woody perennial species, which allows them to probe greater volumes of soil for scarce and much-needed moisture. Tomlinson and Anderson (1998), for

example, report that greater root development in water-stressed red oak seedlings grown at 700 ppm CO<sub>2</sub> helped them effectively deal with the reduced availability of moisture. These trees eventually produced just as much biomass as well-watered controls exposed to ambient air containing 400 ppm CO<sub>2</sub>. In addition, Polley *et al.* (1999) note that water-stressed honey mesquite trees subjected to an atmospheric CO<sub>2</sub> concentration of 700 ppm produced 37 percent more root biomass than water-stressed control seedlings growing at 370 ppm.

Elevated levels of atmospheric CO<sub>2</sub> also tend to reduce the area of open stomatal pore space on leaf surfaces, thus reducing plant stomatal conductance. This phenomenon, in turn, reduces the amount of water lost to the atmosphere via transpiration. Tognetti *et al.* (1998), for example, determined that stomatal conductances of mature oak trees growing near natural CO<sub>2</sub> springs in central Italy were significantly lower than those of similar trees growing further away from the springs during periods of severe summer drought.

CO<sub>2</sub>-induced increases in root development together with CO<sub>2</sub>-induced reductions in stomatal conductance often contribute to the maintenance of a more favorable plant water status during times of drought. In the case of three Mediterranean shrubs, Tognetti *et al.* (2002) found that leaf water potential, which is a good indicator of plant water status, was consistently higher (less negative and, hence, less stressful) under twice-ambient CO<sub>2</sub> concentrations. Similarly, leaf water potentials of water-stressed mesquite seedlings grown at 700 ppm CO<sub>2</sub> were 40 percent higher than those of their water-stressed counterparts growing in ambient air (Polley *et al.*, 1999), which is comparable to values of -5.9 and -3.4 MPa observed in water-stressed evergreen shrubs (*Larrea tridentata*) exposed to 360 and 700 ppm CO<sub>2</sub>, respectively (Hamerlynck *et al.*, 2000).

Palanisamy (1999) observed water-stressed *Eucalyptus* seedlings grown at 800 ppm CO<sub>2</sub> display greater net photosynthetic rates than their ambiently grown and water-stressed counterparts. Runion *et al.* (1999) observed the CO<sub>2</sub>-induced photosynthetic stimulation of water-stressed pine seedlings grown at 730 ppm CO<sub>2</sub> to be nearly 50 percent greater than that of similar water-stressed pine seedlings grown at 365 ppm CO<sub>2</sub>. Similarly, Centritto *et al.* (1999a) found that water-stressed cherry trees grown at 700 ppm CO<sub>2</sub> displayed net photosynthetic rates that were 44 percent greater than those of water-stressed trees grown at 350 ppm CO<sub>2</sub>. And Anderson and

Tomlinson (1998) found that a 300-ppm increase in the air's CO<sub>2</sub> concentration boosted photosynthetic rates in well-watered and water-stressed red oak seedlings by 34 and 69 percent, respectively, demonstrating that the CO<sub>2</sub>-induced percentage enhancement in net photosynthesis in this species was essentially twice as great in water-stressed seedlings as in well-watered ones.

Sometimes, plants suffer drastically when subjected to extreme water stress. However, the addition of CO<sub>2</sub> to the atmosphere often gives them an edge over ambiently growing plants. Tuba *et al.* (1998), for example, reported that leaves of a water-stressed woody shrub exposed to an atmospheric CO<sub>2</sub> concentration of 700 ppm continued to maintain positive rates of net carbon fixation for a period that lasted three times longer than that observed for leaves of equally water-stressed control plants growing in ambient air. Similarly, Fernandez *et al.* (1998) discovered that herb and tree species growing near natural CO<sub>2</sub> vents in Venezuela continued to maintain positive rates of net photosynthesis during that location's dry season, while the same species growing some distance away from the CO<sub>2</sub> source displayed net losses of carbon during this stressful time. Likewise, Fernandez *et al.* (1999) noted that after four weeks of drought, the deciduous Venezuelan shrub *Ipomoea carnea* continued to exhibit positive carbon gains under elevated CO<sub>2</sub> conditions, whereas ambiently growing plants displayed net carbon losses. Polley *et al.* (2002) reported that seedlings of five woody species grown at twice-ambient CO<sub>2</sub> concentrations survived 11 days longer (on average) than control seedlings when subjected to maximum drought conditions. Thus, in some cases of water stress, enriching the air with CO<sub>2</sub> can mean the difference between life or death.

Arp *et al.* (1998) reported that six perennial plants common to the Netherlands increased their biomass under CO<sub>2</sub>-enriched conditions even when suffering from lack of water. In other cases, the CO<sub>2</sub>-induced percentage biomass increase is sometimes even greater for water-stressed plants than it is for well-watered plants. Catovsky and Bazzaz (1999), for example, reported that the CO<sub>2</sub>-induced biomass increase for paper birch was 27 percent and 130 percent for well-watered and water-stressed seedlings, respectively. Similarly, Schulte *et al.* (1998) noted that the CO<sub>2</sub>-induced biomass increase of oak seedlings was greater under water-limiting conditions than under well-watered conditions (128 percent vs. 92 percent), as did Centritto *et al.* (1999b) for basal

trunk area in cherry seedlings (69 percent vs. 22 percent).

Finally, Knapp *et al.* (2001) developed tree-ring index chronologies from western juniper stands in Oregon, USA, finding that the trees recovered better from the effects of drought in the 1990's, when the air's CO<sub>2</sub> concentration was around 340 ppm, than they did from 1900-1930, when the atmospheric CO<sub>2</sub> concentration was around 300 ppm. In a loosely related study, Osborne *et al.* (2002) looked at the warming and reduced precipitation experienced in Mediterranean shrublands over the last century and concluded that primary productivity should have been negatively impacted in those areas. However, when the concurrent increase in atmospheric CO<sub>2</sub> concentration was factored into their mechanistic model, a 25 percent increase in primary productivity was projected.

In summary, the peer-reviewed scientific literature indicates that the ongoing rise in the air's CO<sub>2</sub> content will likely lead to substantial increases in photosynthetic rates and biomass production in earth's woody species in the years and decades ahead, even in the face of stressful conditions imposed by less-than-optimal availability of soil moisture.

## 7.4. Acclimation

Plants grown in elevated CO<sub>2</sub> environments often exhibit some degree of photosynthetic acclimation or down regulation, which is typically characterized by long-term rates of photosynthesis that are somewhat lower than what would be expected on the basis of measurements made during short-term exposure to CO<sub>2</sub>-enriched air. These downward adjustments result from modest long-term decreases in the activities and/or amounts of the primary plant carboxylating enzyme rubisco. Acclimation is said to be present when the photosynthetic rates of long-term CO<sub>2</sub>-enriched plants are found to be lower than those of long-term *non*-CO<sub>2</sub>-enriched plants when the normally CO<sub>2</sub>-enriched plants are measured during brief exposures to ambient CO<sub>2</sub> concentrations. In this section, we review research that has been published on acclimation in agricultural, desert, grassland and woody species.

Additional information on this topic, including reviews on acclimation not discussed here, can be found at [http://www.co2science.org/subject/a/subject\\_a.php](http://www.co2science.org/subject/a/subject_a.php) under the heading Acclimation.

### 7.4.1. Agricultural Species

Several studies have examined the effects of elevated CO<sub>2</sub> on acclimation in agricultural crops. Ziska

(1998), for example, reported that soybeans grown at an atmospheric CO<sub>2</sub> concentration of 720 ppm initially exhibited photosynthetic rates that were 50 percent greater than those observed in control plants grown at 360 ppm. However, after the onset of photosynthetic acclimation, CO<sub>2</sub>-enriched plants displayed subsequent photosynthetic rates that were only 30 percent greater than their ambiently grown counterparts. In another study, Theobald *et al.* (1998) grew spring wheat at twice-ambient atmospheric CO<sub>2</sub> concentrations and determined that elevated CO<sub>2</sub> reduced the amount of rubisco required to sustain enhanced rates of photosynthesis, which led to a significant increase in plant photosynthetic nitrogen-use efficiency. CO<sub>2</sub>-induced increases in photosynthetic nitrogen-use efficiency have also been reported in spring wheat by Osborne *et al.* (1998).

In an interesting study incorporating both hydroponically and pot-grown wheat plants, Farage *et al.* (1998) demonstrated that low nitrogen fertilization does not lead to photosynthetic acclimation in elevated CO<sub>2</sub> environments, as long as the nitrogen supply keeps pace with the relative growth rate of the plants. Indeed, when spring wheat was grown at an atmospheric CO<sub>2</sub> concentration of 550 ppm in a free-air CO<sub>2</sub> enrichment (FACE) experiment with optimal soil nutrition and unlimited rooting volume, Garcia *et al.* (1998) could find no evidence of photosynthetic acclimation.

CO<sub>2</sub>-induced photosynthetic acclimation often results from insufficient plant sink strength, which can lead to carbohydrate accumulation in source leaves and the triggering of photosynthetic end product feedback inhibition, which reduces net photosynthetic rates. Indeed, Gesch *et al.* (1998) reported that rice plants—which have relatively limited potential for developing additional carbon sinks—grown at an atmospheric CO<sub>2</sub> concentration of 700 ppm exhibited increased leaf carbohydrate contents, which likely reduced *rbcS* mRNA levels and rubisco protein content. Similarly, Sims *et al.* (1998) reported that photosynthetic acclimation was induced in CO<sub>2</sub>-enriched soybean plants from the significant accumulation of nonstructural carbohydrates in their leaves. However, in growing several different *Brassica* species at 1,000 ppm CO<sub>2</sub>, Reekie *et al.* (1998) demonstrated that CO<sub>2</sub>-induced acclimation was avoided in species having well-developed carbon sinks (broccoli and cauliflower) and only appeared in those lacking significant sink strength (rape and mustard). Thus, acclimation does not appear to be a direct consequence of atmospheric CO<sub>2</sub> enrichment

but rather an indirect effect of low sink strength, which results in leaf carbohydrate accumulation that can trigger acclimation.

In some cases, plants can effectively increase their sink strength, and thus reduce the magnitude of CO<sub>2</sub>-induced acclimation, by forming symbiotic relationships with certain species of soil fungi. Under such conditions, photosynthetic down regulation is not triggered as rapidly, or as frequently, by end product feedback inhibition, as excess carbohydrates are mobilized out of source leaves and sent belowground to symbiotic fungi. Indeed, Louche-Tessandier *et al.* (1999) report that photosynthetic acclimation in CO<sub>2</sub>-enriched potatoes was less apparent when plants were simultaneously colonized by a mycorrhizal fungus. Thus, CO<sub>2</sub>-induced acclimation appears to be closely related to the source:sink balance that exists within plants, being triggered when sink strength falls below, and source strength rises above, critical thresholds in a species-dependent manner.

Acclimation is generally regarded as a process that reduces the amount of rubisco and/or other photosynthetic proteins, which effectively increases the amount of nitrogen available for enhancing sink development or stimulating other nutrient-limited processes. In the study of Watling *et al.* (2000), for example, the authors reported a 50 percent CO<sub>2</sub>-induced reduction in the concentration of PEP-carboxylase, the primary carboxylating enzyme in C<sub>4</sub> plants, within sorghum leaves. Similarly, Maroco *et al.* (1999) documented CO<sub>2</sub>-induced decreases in both PEP-carboxylase and rubisco in leaves of the C<sub>4</sub> crop maize.

In some cases, however, acclimation to elevated CO<sub>2</sub> is manifested by an “up-regulation” of certain enzymes. When Gesch *et al.* (2002) took rice plants from ambient air and placed them in air containing 700 ppm, for example, they noticed a significant increase in the activity of sucrose-phosphate synthase (SPS), which is a key enzyme involved in the production of sucrose. Similarly, Hussain *et al.* (1999) reported that rice plants grown at an atmospheric CO<sub>2</sub> concentration of 660 ppm displayed 20 percent more SPS activity during the growing season than did ambiently grown rice plants. Such increases in the activity of this enzyme could allow CO<sub>2</sub>-enriched plants to avoid the onset of photosynthetic acclimation by synthesizing and subsequently exporting sucrose from source leaves into sink tissues before they accumulate and trigger end product feedback inhibition.

In an interesting experiment, Gesch *et al.* (2000) took ambiently growing rice plants and placed them in an atmospheric CO<sub>2</sub> concentration of 175 ppm, which reduced photosynthetic rates by 45 percent. However, after five days exposure to this sub-ambient CO<sub>2</sub> concentration, the plants manifested an up-regulation of rubisco, which stimulated photosynthetic rates by 35 percent. Thus, plant acclimation responses can involve both an increase or decrease in specific enzymes, depending on the atmospheric CO<sub>2</sub> concentration.

In summary, many peer-reviewed studies suggest that as the CO<sub>2</sub> content of the air slowly but steadily rises, agricultural species may not necessarily exhibit photosynthetic acclimation, even under conditions of low soil nitrogen. If a plant can maintain a balance between its sources and sinks for carbohydrates at the whole-plant level, acclimation should not be necessary. Because earth’s atmospheric CO<sub>2</sub> content is rising by an average of only 1.5 ppm per year, most plants should be able to either (1) adjust their relative growth rates by the small amount that would be needed to prevent low nitrogen-induced acclimation from ever occurring, or (2) expand their root systems by the small amount that would be needed to supply the extra nitrogen required to take full advantage of the CO<sub>2</sub>-induced increase in leaf carbohydrate production. In the event a plant cannot initially balance its sources and sinks for carbohydrates at the whole-plant level, CO<sub>2</sub>-induced acclimation represents a beneficial secondary mechanism for achieving that balance through redistributing limiting resources away from the plant’s photosynthetic machinery to strengthen sink development or enhance other nutrient-limiting processes.

#### 7.4.2. Chaparral and Desert Species

Roberts *et al.* (1998) conducted a FACE experiment in southern California, USA, exposing *Adenostoma fasciculatum* shrubs to atmospheric CO<sub>2</sub> concentrations of 360 and 550 ppm while they studied the nature of gas-exchange in this chaparral species. After six months of CO<sub>2</sub> fumigation, photosynthetic acclimation occurred. However, because of reductions in stomatal conductance and transpirational water loss, the CO<sub>2</sub>-enriched shrubs exhibited leaf water potentials that were less negative (and, hence, less stressful) than those of control plants. This CO<sub>2</sub>-induced water conservation phenomenon should enable this woody perennial to better withstand the periods of drought that commonly occur in this southern California region, while the photosynthetic down regulation it exhibits should allow it to more equitably distribute the limiting resources it possesses among different essential plant physiological processes.

Huxman and Smith (2001) measured seasonal gas exchange during an unusually wet El Niño year in an annual grass (*Bromus madritensis* ssp. *rubens*) and a perennial forb (*Eriogonum inflatum*) growing within FACE plots established in the Mojave Desert, USA, which they maintained at atmospheric CO<sub>2</sub> concentrations of 350 and 550 ppm. The elevated CO<sub>2</sub> consistently increased net photosynthetic rates in the annual grass without inducing photosynthetic acclimation. In fact, even as seasonal photosynthetic rates declined post-flowering, the reduction was much less in the CO<sub>2</sub>-enriched plants. However, elevated CO<sub>2</sub> had no consistent effect on stomatal conductance in this species. By contrast, *Eriogonum* plants growing at 550 ppm CO<sub>2</sub> exhibited significant photosynthetic acclimation, especially late in the season, which led to similar rates of net photosynthesis in these plants in both CO<sub>2</sub> treatments. But in this species, elevated CO<sub>2</sub> reduced stomatal conductance over most of the growing season. Although the two desert plants exhibited different stomatal and photosynthetic responses to elevated CO<sub>2</sub>, both experienced significant CO<sub>2</sub>-induced increases in water use efficiency and biomass production, thus highlighting the existence of different, but equally effective, species-specific

mechanisms for responding positively to atmospheric CO<sub>2</sub> enrichment in a desert environment.

In another study conducted at the Mojave Desert FACE site, Hamerlynck *et al.* (2002) determined that plants of the deciduous shrub *Lycium andersonii* grown in elevated CO<sub>2</sub> displayed photosynthetic acclimation, as maximum rubisco activity in the plants growing in the CO<sub>2</sub>-enriched air was 19 percent lower than in the plants growing in ambient air. Also, the elevated CO<sub>2</sub> did not significantly impact rates of photosynthesis. Leaf stomatal conductance, on the other hand, was consistently about 27 percent lower in the plants grown in the CO<sub>2</sub>-enriched air; and during the last month of the spring growing season, the plants in the elevated CO<sub>2</sub> plots displayed leaf water potentials that were less negative than those exhibited by the control plants growing in ambient air. Hence, as the CO<sub>2</sub> content of the air increases, *Lycium andersonii* will likely respond by exhibiting significantly enhanced water use efficiency, which should greatly increase its ability to cope with the highly variable precipitation and temperature regimes of the Mojave Desert. The acclimation observed within the shrub's photosynthetic apparatus should allow it to reallocate more resources to producing and sustaining greater amounts of biomass. Thus, it is likely that future increases in the air's CO<sub>2</sub> content will favor a "greening" of the American Mojave Desert.

In summary, the few studies of the acclimation phenomenon that have been conducted on chaparral and desert plants indicate that although it can sometimes be complete, other physiological changes, such as the reductions in stomatal conductance that typically produce large increases in water use efficiency, often more than compensate for the sometimes small to negligible increases in photosynthesis.

### 7.4.3. Grassland Species

In nearly every reported case of photosynthetic acclimation in CO<sub>2</sub>-enriched plants, rates of photosynthesis displayed by grassland species grown and measured at elevated CO<sub>2</sub> concentrations are typically greater than those exhibited by control plants grown and measured at ambient CO<sub>2</sub> concentrations (Davey *et al.*, 1999; Bryant *et al.*, 1998).

As mentioned in prior sections, CO<sub>2</sub>-induced photosynthetic acclimation often results from insufficient plant sink strength, which can lead to carbohydrate accumulation in source leaves and the triggering of photosynthetic end-product feedback inhibition, which reduces rubisco activity and rates of net photosynthesis (Roumet *et al.*, 2000). As one example of this phenomenon, Rogers *et al.* (1998) reported that perennial ryegrass grown at an atmospheric CO<sub>2</sub> concentration of 600 ppm and low soil nitrogen exhibited leaf carbohydrate contents and rubisco activities that were 100 percent greater and 25 percent less, respectively, than those observed in control plants grown at 360 ppm CO<sub>2</sub>, prior to a cutting event. Following the cutting, which effectively reduced the source:sink ratio of the plants, leaf carbohydrate contents in CO<sub>2</sub>-enriched plants decreased and rubisco activities increased, completely ameliorating the photosynthetic acclimation in this species. However, at high soil nitrogen, photosynthetic acclimation to elevated CO<sub>2</sub> did not occur. Thus, photosynthetic acclimation appears to result from the inability of plants to develop adequate sinks at low soil nitrogen, and is not necessarily induced directly by atmospheric CO<sub>2</sub> enrichment.

In some cases, plants can effectively increase their sink strength and thus reduce the magnitude of CO<sub>2</sub>-induced acclimation by forming symbiotic relationships with certain species of soil fungi. Under such conditions, photosynthetic down regulation is not triggered as rapidly, or as frequently, by end-product feedback inhibition, as excess carbohydrates are mobilized out of source leaves and sent

belowground to symbiotic fungi. Staddon *et al.* (1999) reported that photosynthetic acclimation was not induced in CO<sub>2</sub>-enriched *Plantago lanceolata* plants that were inoculated with a mycorrhizal fungus, while it was induced in control plants that were not inoculated with the fungus. Thus, CO<sub>2</sub>-induced acclimation appears to be closely related to the source:sink balance that exists within plants, and is triggered when sink strength falls below, and source strength rises above, certain critical thresholds in a species-dependent manner.

As the CO<sub>2</sub> content of the air slowly but steadily rises, these peer-reviewed studies suggest that grassland species may not exhibit photosynthetic acclimation if they can maintain a balance between their sources and sinks for carbohydrates at the whole-plant level. But in the event this balancing act is not initially possible, acclimation represents a beneficial secondary mechanism for achieving that balance by redistributing limiting resources away from the plant's photosynthetic machinery to strengthen its sink development and/or nutrient-gathering activities.

### 7.4.4. Tree Species

Trees grown for long periods of time in elevated CO<sub>2</sub> environments often, but not always (Marek *et al.*, 2001; Stylinski *et al.*, 2000; Bartak *et al.*, 1999; Schortemeyer *et al.*, 1999), exhibit some degree of photosynthetic acclimation or down regulation, which is typically characterized by modestly reduced rates of photosynthesis (compared to what might be expected on the basis of short-term exposure to CO<sub>2</sub>-enriched air) that result from a long-term decrease in the activity and/or amount of the primary plant carboxylating enzyme rubisco (Kubiske *et al.*, 2002; Egli *et al.*, 1998). This acclimation response in plants accustomed to growing in CO<sub>2</sub>-enriched air is characterized by short-term reductions in their rates of net photosynthesis when measured during short-term exposure to ambient air relative to net photosynthesis rates of comparable plants that have always been grown in ambient air.

Jach and Ceulemans (2000) grew one-year-old Scots pine seedlings for two additional years at twice-ambient atmospheric CO<sub>2</sub> concentrations and reported that the elevated CO<sub>2</sub> increased the trees' mean rate of net photosynthesis by 64 percent. However, when measured during a brief return to ambient CO<sub>2</sub> concentrations, the normally CO<sub>2</sub>-enriched seedlings exhibited an approximate 21 percent reduction in average net photosynthesis rate relative to that of seedlings that had always been exposed to ambient air. Similarly, Spunda *et al.* (1998) noted that a 350-ppm increase in the air's CO<sub>2</sub> concentration boosted rates of net photosynthesis in fifteen-year-old Norway spruce trees by 78 percent; but when net photosynthesis in the normally CO<sub>2</sub>-enriched trees was measured at a temporary atmospheric CO<sub>2</sub> concentration of 350 ppm, an 18 percent reduction was observed relative to what was observed in comparable trees that had always been grown in ambient air. After reviewing the results of 15 different atmospheric CO<sub>2</sub> enrichment studies of European forest species growing in field environments maintained at twice-ambient CO<sub>2</sub> concentrations, Medlyn *et al.* (1999) found that the mean photosynthetic acclimation effect in the CO<sub>2</sub>-enriched

trees was characterized by an average reduction of 19 percent in their rates of net photosynthesis when measured at temporary ambient CO<sub>2</sub> concentrations relative to the mean rate of net photosynthesis exhibited by those trees that had always been exposed to ambient air. Nonetheless, in nearly every reported case of CO<sub>2</sub>-induced photosynthetic acclimation in trees, the photosynthetic rates of trees growing and measured in CO<sub>2</sub>-enriched air have still been much greater than those exhibited by trees growing and measured in ambient air.

CO<sub>2</sub>-induced photosynthetic acclimation, when it occurs, often results from insufficient plant sink strength, which can lead to carbohydrate accumulation in source leaves and the triggering of photosynthetic end-product feedback inhibition, which results in reduced rates of net photosynthesis. Pan *et al.* (1998), for example, reported that apple seedlings grown at an atmospheric CO<sub>2</sub> concentration of 1600 ppm had foliar starch concentrations 17-fold greater than those observed in leaves of seedlings grown at 360 ppm CO<sub>2</sub>, suggesting that this phenomenon likely triggered the reductions in leaf net photosynthesis rates they observed. Similarly, Rey and Jarvis (1998) reported that the accumulation of starch within leaves of CO<sub>2</sub>-enriched silver birch seedlings (100 percent above ambient) may have induced photosynthetic acclimation in that species. Also, in the study of Wiemken and Ineichen (2000), a 300-ppm increase in the air's CO<sub>2</sub> concentration induced seasonal acclimation in young spruce trees, where late-summer, fall and winter rates of net photosynthesis declined in conjunction with 40 to 50 percent increases in foliar glucose levels.

In some cases, trees can effectively increase their sink strength, and thus reduce the magnitude of CO<sub>2</sub>-induced photosynthetic acclimation, by forming symbiotic relationships with certain species of soil fungi. Under such conditions, photosynthetic down regulation is not triggered as rapidly, or as frequently, by end-product feedback inhibition, as excess carbohydrates are mobilized out of the trees' source leaves and sent belowground to support the growth of symbiotic fungi. Jifon *et al.* (2002), for example, reported that the degree of CO<sub>2</sub>-induced photosynthetic acclimation in sour orange tree seedlings was significantly reduced by the presence of mycorrhizal fungi, which served as sinks for excess carbohydrates synthesized by the CO<sub>2</sub>-enriched seedlings.

During acclimation to elevated CO<sub>2</sub>, the amounts and activities of rubisco and/or other photosynthetic

proteins are often reduced, which effectively increases the amount of nitrogen available for enhancing sink development or stimulating other nutrient-limited processes. As an example of this phenomenon operating in trees, in the study of Blaschke *et al.* (2001), the authors reported that a doubling of the atmospheric CO<sub>2</sub> concentration reduced foliar rubisco concentrations by 15 and 30 percent in two mature oak species growing near CO<sub>2</sub>-emitting springs. Similarly, a 200-ppm increase in the air's CO<sub>2</sub> content reduced foliar rubisco concentrations in young aspen and birch seedlings by 39 percent (Takeuchi *et al.*, 2001) and 24 percent (Tjoelker *et al.*, 1998), respectively. Also, in two *Pinus radiata* studies, seedlings fumigated with air containing 650 ppm CO<sub>2</sub> displayed 30 to 40 percent reductions in rubisco concentration and rubisco activity relative to measurements made on seedlings grown in ambient air (Griffin *et al.*, 2000; Turnbull *et al.*, 1998). Other studies of CO<sub>2</sub>-enriched Norway spruce and Scots pines have documented CO<sub>2</sub>-induced reductions in foliar chlorophyll contents of 17 percent (Spunda *et al.*, 1998) and 26 percent (Gielen *et al.*, 2000), respectively. And in the study of Gleadow *et al.* (1998), elevated CO<sub>2</sub> led to acclimation in eucalyptus seedlings, which mobilized nitrogen away from rubisco and into prunasin, a sugar-based defense compound that deters herbivory.

In another interesting experiment, Polle *et al.* (2001) germinated acorns from oak trees exposed to ambient and CO<sub>2</sub>-enriched air and subsequently grew them at ambient and twice-ambient atmospheric CO<sub>2</sub> concentrations. They discovered that seedlings derived from acorns produced on CO<sub>2</sub>-enriched trees exhibited less-pronounced photosynthetic acclimation to elevated CO<sub>2</sub> than did seedlings derived from acorns produced on ambiently grown trees, suggesting the possibility of generational adaptation to higher atmospheric CO<sub>2</sub> concentrations over even longer periods of time.

In summary, these many peer-reviewed scientific studies suggest that as the air's CO<sub>2</sub> content slowly but steadily rises, trees may be able to avoid photosynthetic acclimation if they maintain a proper balance between carbohydrate sources and sinks at the whole-tree level, which they may well be able to do in response to the current rate of rise of the air's CO<sub>2</sub> concentration (a mere 1.5 ppm per year). If a tree cannot *initially* balance its sources and sinks of carbohydrates, however, acclimation is an important and effective means of achieving that balance through redistributing essential resources away from the tree's

photosynthetic machinery in an effort to strengthen sink development, enhance various nutrient-limited processes, and increase nutrient acquisition by, for example, stimulating the development of roots and their symbiotic fungal partners. And if those adjustments are not entirely successful, it is still the case that the acclimation process is hardly ever 100 percent complete (in the studies reviewed here it was on the order of 20 percent), so that tree growth is almost always significantly enhanced in CO<sub>2</sub>-enriched air in nearly every real-world setting.

Additional information on this topic, including reviews of newer publications as they become available, can be found at <http://www.co2science.org/subject/a/acclimationtree.php>.

## 7.5. Competition

Do higher levels of atmospheric CO<sub>2</sub> favor some plants over others? Could this result in ecological changes that could be judged “bad” because of their effects on wildlife or plants that are beneficial to mankind? This section seeks to answer these questions by surveying research on the effects of CO<sub>2</sub> enhancement on C<sub>3</sub> versus C<sub>4</sub> plants, and weeds versus crops.

Additional information on this topic, including reviews on competition not discussed here, can be found at [http://www.co2science.org/subject/c/subject\\_c.php](http://www.co2science.org/subject/c/subject_c.php) under the heading Competition.

### 7.5.1. C<sub>3</sub> vs C<sub>4</sub> Plants

C<sub>3</sub> plants typically respond better to atmospheric CO<sub>2</sub> enrichment than do C<sub>4</sub> plants in terms of increasing their rates of photosynthesis and biomass production. Hence, it has periodically been suggested that in a world of rising atmospheric CO<sub>2</sub> concentration, C<sub>3</sub> plants may out-compete C<sub>4</sub> plants and displace them, thereby decreasing the biodiversity of certain ecosystems. However, the story is much more complex than what is suggested by this simple scenario.

Wilson *et al.* (1998) grew 36 species of perennial grass common to tallgrass prairie ecosystems with and without arbuscular mycorrhizal fungi, finding that the dry matter production of the C<sub>3</sub> species that were colonized by the fungi was the same as that of the non-inoculated C<sub>3</sub> species, but that the fungal-colonized C<sub>4</sub> species produced, on average, 85 percent *more* dry matter than the non-inoculated C<sub>4</sub> species. This finding is of pertinence to the relative responsiveness of C<sub>3</sub> and C<sub>4</sub> plants to atmospheric CO<sub>2</sub> enrichment; for elevated levels of atmospheric CO<sub>2</sub> tend to enhance the mycorrhizal colonization of plant roots, which is known to make soil minerals and water more available for plant growth. Hence, this CO<sub>2</sub>-induced fungal-mediated growth advantage, which from this study appears to be more readily available to C<sub>4</sub> plants, could well counter the inherently greater biomass response of C<sub>3</sub> plants relative to that of C<sub>4</sub> plants, leveling the playing field relative to their competition for space in any given ecosystem.

Another advantage that may come to C<sub>4</sub> plants as a consequence of the ongoing rise in the air's CO<sub>2</sub> content was elucidated by BassiriRad *et al.* (1998), who found that elevated CO<sub>2</sub> enhanced the ability of the perennial C<sub>4</sub> grass *Bouteloua eriopoda* to increase its uptake of NO<sub>3</sub><sup>-</sup> and PO<sub>4</sub><sup>3-</sup> considerably more than the perennial C<sub>3</sub> shrubs *Larrea tridentata* and *Prosopis glandulosa*. In an eight-year study of the effects of twice-ambient atmospheric CO<sub>2</sub> concentrations on a pristine tallgrass prairie in Kansas, Owensby *et al.* (1999) found that the elevated CO<sub>2</sub> did not affect the basal coverage of its C<sub>4</sub> species or their relative contribution to the composition of the ecosystem.

The antitranspirant effect of atmospheric CO<sub>2</sub> enrichment (Pospisilova and Catsky, 1999) is often more strongly expressed in C<sub>4</sub> plants than in C<sub>3</sub> plants and typically allows C<sub>4</sub> plants to better cope with water stress. In a study of the C<sub>3</sub> dicot *Abutilon theophrasti* and the C<sub>4</sub> dicot *Amaranthus retroflexus*, for example, Ward *et al.* (1999) found that *Amaranthus retroflexus* exhibited a greater relative recovery from drought than did the C<sub>3</sub> species, which suggests, in their words, that “the C<sub>4</sub> species would continue to be more competitive than the C<sub>3</sub> species in regions receiving more frequent and severe droughts,” which basically characterizes regions where C<sub>4</sub> plants currently exist.

Two years later, Morgan *et al.* (2001) published the results of an open-top chamber study of a native shortgrass steppe ecosystem in Colorado, USA, where

they had exposed the enclosed ecosystems to atmospheric CO<sub>2</sub> concentrations of 360 and 720 ppm for two six-month growing seasons. In spite of an average air temperature increase of 2.6°C, which was caused by the presence of the open-top chambers, the elevated CO<sub>2</sub> increased above-ground biomass production by an average of 38 percent in both years of the study; and when 50 percent of the standing green plant biomass was defoliated to simulate grazing halfway through the growing season, atmospheric CO<sub>2</sub> enrichment still increased above-ground biomass by 36 percent. It was also found that the communities enriched with CO<sub>2</sub> tended to have greater amounts of moisture in their soils than communities exposed to ambient air; and this phenomenon likely contributed to the less negative and, therefore, less stressful plant water potentials that were measured in the CO<sub>2</sub>-enriched plants. Last, the elevated CO<sub>2</sub> did not preferentially stimulate the growth of C<sub>3</sub> species over that of C<sub>4</sub> species in these communities. Elevated CO<sub>2</sub> did not significantly affect the percentage composition of C<sub>3</sub> and C<sub>4</sub> species in these grasslands; they maintained their original level of vegetative biodiversity.

This would also appear to be the conclusion of the study of Wand *et al.* (1999), who in a massive review of the scientific literature published between 1980 and 1997 analyzed nearly 120 individual responses of C<sub>3</sub> and C<sub>4</sub> grasses to elevated CO<sub>2</sub>. On average, they found photosynthetic enhancements of 33 and 25 percent, respectively, for C<sub>3</sub> and C<sub>4</sub> plants, along with biomass enhancements of 44 and 33 percent, respectively, for a doubling of the air's CO<sub>2</sub> concentration. These larger-than-expected growth responses in the C<sub>4</sub> species led them to conclude that "it may be premature to predict that C<sub>4</sub> grass species will lose their competitive advantage over C<sub>3</sub> grass species in elevated CO<sub>2</sub>."

Further support for this conclusion comes from the study of Campbell *et al.* (2000), who reviewed research work done between 1994 and 1999 by a worldwide network of 83 scientists associated with the Global Change and Terrestrial Ecosystems (GCTE) Pastures and Rangelands Core Research Project 1, which resulted in the publication of over 165 peer-reviewed scientific journal articles. After analyzing this body of research, they concluded that the "growth of C<sub>4</sub> species is about as responsive to CO<sub>2</sub> concentration as [is that of] C<sub>3</sub> species when water supply restricts growth, as is usual in grasslands containing C<sub>4</sub> species." The work of this group of scientists also provides no evidence for the suggestion

that C<sub>3</sub> plants may out-compete C<sub>4</sub> plants and thereby replace them in a high-CO<sub>2</sub> world of the future.

### 7.5.2. N-Fixers vs. Non-N-Fixers

Will nitrogen-fixing (N-fixing) plants benefit more from atmospheric CO<sub>2</sub> enrichment than non-N-fixers and thus obtain a competitive advantage over them that could lead to some non-N-fixers being excluded from certain plant communities, thereby decreasing the biodiversity of those ecosystems?

In a two-year glasshouse study of simulated low-fertility ecosystems composed of grassland species common to Switzerland, Stocklin and Korner (1999) found that atmospheric CO<sub>2</sub> enrichment gave nitrogen-fixing legumes an initial competitive advantage over non-N-fixers. However, it would be expected that, over time, a portion of the extra nitrogen fixed by these legumes would become available to neighboring non-N-fixing species, which would then be able to use it to their own advantage, thereby preserving the species richness of the ecosystem over the long haul. Indeed, in a four-year study of an established (non-simulated) high grassland ecosystem located in the Swiss Alps, Arnone (1999) found no difference between the minimal to non-existent growth responses of N-fixing and non-N-fixing species to elevated levels of atmospheric CO<sub>2</sub>.

In a study of mixed plantings of the grass *Lolium perenne* and the legume *Medicago sativa*, Matthies and Egli (1999) found that elevated CO<sub>2</sub> did not influence the competition between the two plants, either directly or indirectly via its effects upon the root hemiparasite *Rhinanthus alectorolophus*. In a study of mixed plantings of two grasses and two legumes, Navas *et al.* (1999) observed that plant responses to atmospheric CO<sub>2</sub> enrichment are more dependent upon neighboring plant density than they are upon neighboring plant identity.

In the few studies of this question that have been conducted to date, therefore, it would appear that there is little evidence to suggest that N-fixing legumes will out-compete non-N-fixing plants.

Additional information on this topic, including reviews of newer publications as they become available, can be found at <http://www.co2science.org/subject/b/biodivnfixers.php>.

### 7.5.3. Weeds vs. Non-Weeds

Elevated CO<sub>2</sub> typically stimulates the growth of nearly all plant species in monoculture, including those deemed undesirable by humans, i.e., weeds. Consequently, it is important to determine how future increases in the air's CO<sub>2</sub> content may influence relationships between weeds and non-weeds when they grow competitively in mixed-species stands.

Dukes (2002) grew model serpentine grasslands common to California, USA, in competition with the invasive forb *Centaurea solstitialis* at atmospheric CO<sub>2</sub> concentrations of 350 and 700 ppm for one year, determining that elevated CO<sub>2</sub> increased the biomass proportion of this weedy species in the community by a mere 1.2 percent, while total community biomass increased by 28 percent. Similarly, Gavazzi *et al.* (2000) grew loblolly pine seedlings for four months in competition with both C<sub>3</sub> and C<sub>4</sub> weeds at atmospheric CO<sub>2</sub> concentrations of 260 and 660 ppm, reporting that elevated CO<sub>2</sub> increased pine biomass by 22 percent while eliciting no response from either type of weed.

In a study of pasture ecosystems near Montreal, Canada, Taylor and Potvin (1997) found that elevated CO<sub>2</sub> concentrations did not influence the number of native species returning after their removal (to simulate disturbance), even in the face of the introduced presence of the C<sub>3</sub> weed *Chenopodium album*, which normally competes quite effectively with several slower-growing crops in ambient air. In fact, atmospheric CO<sub>2</sub> enrichment did not impact the growth of this weed in any measurable way.

Ziska *et al.* (1999) also studied the C<sub>3</sub> weed *C. album*, along with the C<sub>4</sub> weed *Amaranthus retroflexus*, in glasshouses maintained at atmospheric CO<sub>2</sub> concentrations of 360 and 720 ppm. They

determined that elevated CO<sub>2</sub> significantly increased the photosynthetic rate and total dry weight of the C<sub>3</sub> weed, but that it had no effect on the C<sub>4</sub> weed. Also, they found that the growth response of the C<sub>3</sub> weed to a doubling of the air's CO<sub>2</sub> content was approximately 51 percent, which is about the same as the average 52 percent growth response tabulated by Idso (1992), and that obtained by Poorter (1993) for rapidly growing wild C<sub>3</sub> species (54 percent), which finding suggests there is no enhanced dominance of the C<sub>3</sub> weed over other C<sub>3</sub> plants in a CO<sub>2</sub>-enriched environment.

Wayne *et al.* (1999) studied another agricultural weed, field mustard (*Brassica kaber*), which was sown in pots at six densities, placed in atmospheric CO<sub>2</sub> concentrations of 350 and 700 ppm, and sequentially harvested during the growing season. Early in stand development, elevated CO<sub>2</sub> increased above-ground weed biomass in a density-dependent manner, with the greatest stimulation of 141 percent occurring at the lowest density (corresponding to 20 plants per square meter) and the smallest stimulation of 59 percent occurring at the highest density (corresponding to 652 plants per square meter). However, as stands matured, the density-dependence of the CO<sub>2</sub>-induced growth response disappeared, and CO<sub>2</sub>-enriched plants exhibited an average above-ground biomass that was 34 percent greater than that of ambiently grown plants across a broad range of plant densities. This final growth stimulation was similar to that of most other herbaceous plants exposed to atmospheric CO<sub>2</sub> enrichment (30 to 50 percent biomass increases for a doubling of the air's CO<sub>2</sub> content), evidence once again that atmospheric CO<sub>2</sub> enrichment confers no undue advantage upon weeds at the expense of other plants.

In a study of a weed that affects both plants and animals, Caporn *et al.* (1999) examined bracken (*Pteridium aquilinum*), which poses a serious weed problem and potential threat to human health in the United Kingdom and other regions, growing specimens for 19 months in controlled environment chambers maintained at atmospheric CO<sub>2</sub> concentrations of 370 and 570 ppm and normal or high levels of soil fertility. They found that the high CO<sub>2</sub> treatment consistently increased rates of net photosynthesis by 30 to 70 percent, depending on soil fertility and time of year. However, elevated CO<sub>2</sub> did not increase total plant dry mass or the dry mass of any plant organ, including rhizomes, roots and fronds. In fact, the only significant effect of elevated CO<sub>2</sub> on

bracken growth was observed in the normal nutrient regime, where elevated CO<sub>2</sub> reduced mean frond area.

Finally, in a study involving two parasitic species (*Striga hermonthica* and *Striga asiatica*), Watling and Press (1997) reported that total parasitic biomass per host plant at an atmospheric CO<sub>2</sub> concentration of 700 ppm was 65 percent less than it was in ambient air. And in a related study, Dale and Press (1999) observed that the presence of a parasitic plant (*Orobanche minor*) reduced its host's biomass by 47 percent in ambient air of 360 ppm CO<sub>2</sub>, but by only 20 percent in air of 550 ppm CO<sub>2</sub>.

These several studies suggest that, contrary to what is claimed by the IPCC, the ongoing rise in the air's CO<sub>2</sub> content will not favor the growth of weedy species over that of crops and native plants. In fact, it may provide non-weeds greater protection against weed-induced decreases in their productivity and growth. Future increases in the air's CO<sub>2</sub> content may actually increase the competitiveness of non-weeds over weeds.

Additional information on this topic, including reviews of newer publications as they become available, can be found at <http://www.co2science.org/subject/b/weedsvsnonw.php>.

## 7.6. Respiration

Nearly all of earth's plants respond favorably to increases in the air's CO<sub>2</sub> concentration by exhibiting enhanced rates of net photosynthesis and biomass production during the light part of each day. In many cases, observed increases in these parameters (especially biomass production) are believed to be due, in part, to CO<sub>2</sub>-induced reductions in carbon losses via respiration during the day and especially at night (called "dark respiration"). In this summary, we examine what has been learned about this subject from experiments conducted on various herbaceous and woody plants.

Additional information on this topic, including reviews on respiration not discussed here, can be found at [http://www.co2science.org/subject/r/subject\\_r.php](http://www.co2science.org/subject/r/subject_r.php) under the heading Respiration.

### 7.6.1. Herbaceous Plants

#### 7.6.1.1. Crops

Baker *et al.* (2000) grew rice in Soil-Plant-Atmosphere Research (SPAR) units at atmospheric CO<sub>2</sub> concentrations of 350 and 700 ppm during daylight hours. Under these conditions, rates of dark respiration decreased in both CO<sub>2</sub> treatments with short-term increases in the air's CO<sub>2</sub> concentration at night. However, when dark respiration rates were

measured at the CO<sub>2</sub> growth concentrations of the plants, they were not significantly different from each other.

Cousins *et al.* (2001) grew sorghum at atmospheric CO<sub>2</sub> concentrations of 370 and 570 ppm within a free-air CO<sub>2</sub> enrichment (FACE) facility near Phoenix, Arizona, USA. Within six days of planting, the photosynthetic rates of the second leaves of the CO<sub>2</sub>-enriched plants were 37 percent greater than those of the second leaves of the ambiently grown plants. However, this CO<sub>2</sub>-induced photosynthetic enhancement slowly declined with time, stabilizing at approximately 15 percent between 23 and 60 days after planting. In addition, when measuring photosynthetic rates at a reduced oxygen concentration of 2 percent, they observed 16 and 9 percent increases in photosynthesis for the ambient and CO<sub>2</sub>-enriched plants, respectively. These observations suggest that the extra 200 ppm of CO<sub>2</sub> was reducing photorespiratory carbon losses, although this phenomenon did not account for all of the CO<sub>2</sub>-induced stimulation of photosynthesis.

Das *et al.* (2002) grew tropical nitrogen-fixing mungbean plants in open-top chambers maintained at atmospheric CO<sub>2</sub> concentrations of either 350 or 600 ppm for two growing seasons, with the extra CO<sub>2</sub> being provided between either days 0 and 20 or days 21 and 40 after germination. This work revealed that the elevated CO<sub>2</sub> decreased rates of respiration by 54-62 percent, with the greatest declines occurring during the first 20 days after germination.

Wang *et al.* (2004) grew well-watered and fertilized South American tobacco plants from seed in 8.4-liter pots (one plant per pot) filled with sand and housed in controlled-environment growth chambers maintained at atmospheric CO<sub>2</sub> concentrations of either 365 or 730 ppm for a total of nine weeks. Over this period they found that the ratio of net photosynthesis per unit leaf area (A) to dark respiration per unit leaf area (Rd) "changed dramatically." Whereas A/Rd was the same in both treatments at the beginning of the measurement period, a month later it had doubled in the CO<sub>2</sub>-enriched environment but had risen by only 58 percent in the ambient treatment. Speaking of this finding, the three researchers say that "if the dynamic relationship between A and Rd observed in *N. sylvestris* is applicable to other species, it will have important implications for carbon cycling in terrestrial ecosystems, since plants will assimilate CO<sub>2</sub> more efficiently as they mature."

Bunce (2005) grew soybeans in the field in open-top chambers maintained at atmospheric CO<sub>2</sub> concentrations of ambient and ambient +350 ppm at the Beltsville Agricultural Research Center in Maryland (USA), where net carbon dioxide exchange rate measurements were performed on a total of 16 days between 18 July and 11 September of 2000 and 2003, during the flowering to early pod-filling stages of the growing season. Averaged over the course of the study, he found that daytime net photosynthesis per unit leaf area was 48 percent greater in the plants growing in the CO<sub>2</sub>-enriched air, while nighttime respiration per unit leaf area was unaffected by elevated CO<sub>2</sub>. However, because the extra 350 ppm of CO<sub>2</sub> increased leaf dry mass per unit area by an average of 23 percent, respiration per unit of mass was significantly lower for the leaves of the soybeans growing in the CO<sub>2</sub>-enriched air.

Wang and Curtis (2002) conducted a meta-analysis of the results of 45 area-based dark respiration (Rda) and 44 mass-based dark respiration (Rdm) assessments of the effects of a doubling of the air's CO<sub>2</sub> concentration on 33 species of plants derived from 37 scientific studies. This work revealed that the mean leaf Rda of the suite of herbaceous plants studied was significantly higher (+29 percent,  $P < 0.01$ ) at elevated CO<sub>2</sub> than at ambient CO<sub>2</sub>. However, when the herbaceous plants were separated into groups that had experienced durations of CO<sub>2</sub> enrichment that were either shorter or longer than 60 days, it was found that the short-term studies exhibited a mean Rda increase of 51 percent ( $P < 0.05$ ), while the long-term studies exhibited no effect. Hence, for conditions of continuous atmospheric CO<sub>2</sub> enrichment, herbaceous plants would likely experience no change in leaf Rda. In addition, the two researchers found that plants exposed to elevated CO<sub>2</sub> for < 100 days "showed significantly less of a reduction in leaf Rdm due to CO<sub>2</sub> enrichment (-12%) than did plants exposed for longer periods (-35%,  $P < 0.01$ )." Hence, for long-term conditions of continuous atmospheric CO<sub>2</sub> enrichment, herbaceous crops would likely experience an approximate 35 percent decrease in leaf Rdm.

Bunce (2004) grew six different 16-plant batches of soybeans within a single controlled-environment chamber, one to a pot filled with 1.8 liters of vermiculite that was flushed daily with a complete nutrient solution. In three experiments conducted at day/night atmospheric CO<sub>2</sub> concentrations of 370/390 ppm, air temperatures were either 20, 25 or 30°C, while in three other experiments conducted at an air

temperature of 25°C, atmospheric CO<sub>2</sub> concentrations were either 40, 370 or 1400 ppm. At the end of the normal 16 hours of light on the 17th day after planting, half of the plants were harvested and used for the measurement of a number of physical parameters, while measurements of the plant physiological processes of respiration, translocation and nitrate reduction were made on the other half of the plants over the following 8-hour dark period.

Plotting translocation and nitrate reduction as functions of respiration, Bunce found that "a given change in the rate of respiration was accompanied by the same change in the rate of translocation or nitrate reduction, regardless of whether the altered respiration was caused by a change in temperature or by a change in atmospheric CO<sub>2</sub> concentration." As a result, and irrespective of whatever mechanisms may have been involved in eliciting the responses observed, Bunce concluded that "the parallel responses of translocation and nitrate reduction for both the temperature and CO<sub>2</sub> treatments make it unlikely that the response of respiration to one variable [CO<sub>2</sub>] was an artifact while the response to the other [temperature] was real." Hence, there is reason to believe that the oft-observed decreases in dark respiration experienced by plants exposed to elevated levels of atmospheric CO<sub>2</sub>, as per the review and analysis studies of Drake *et al.* (1999) and Wang and Curtis (2002), are indeed real and not the result of measurement system defects.

In light of these several findings, it can be concluded that the balance of evidence suggests that the growth of herbaceous crops is generally enhanced by CO<sub>2</sub>-induced decreases in respiration during the dark period.

### 7.6.1.2. Other Herbaceous Plants

In this section we review the results of studies of non-crop herbaceous plants to determine if atmospheric CO<sub>2</sub> enrichment tends to increase or decrease (or leave unaltered) their respiration rates.

Rabha and Upreti (1998) grew India mustard plants for an entire season in open-top chambers with either ambient or enriched (600 ppm) atmospheric CO<sub>2</sub> concentrations and adequate or inadequate soil moisture levels. Their work revealed that the elevated CO<sub>2</sub> concentration reduced leaf dark respiration rates by about 25 percent in both soil moisture treatments, which suggests that a greater proportion of the increased carbohydrate pool in the CO<sub>2</sub>-enriched plants remained within them to facilitate increases in growth and development.

Ziska and Bunce (1999) grew four C<sub>4</sub> plants in controlled environment chambers maintained at either full-day (24-hour) atmospheric CO<sub>2</sub> concentrations of 350 and 700 ppm or a nocturnal-only CO<sub>2</sub>

concentration of 700 ppm (with 350 ppm CO<sub>2</sub> during the day) for about three weeks. In this particular study, 24-hour CO<sub>2</sub> enrichment caused a significant increase in the photosynthesis (+13 percent) and total dry mass (+21 percent) of only one of the four C<sub>4</sub> species (*Amaranthus retroflexus*). However, there was no significant effect of nocturnal-only CO<sub>2</sub> enrichment on this species, indicating that the observed increase in biomass, resulting from 24-hour atmospheric CO<sub>2</sub> enrichment, was not facilitated by greater carbon conservation stemming from a CO<sub>2</sub>-induced reduction in dark respiration.

In an experiment that produced essentially the same result, Grunzweig and Korner (2001) constructed model grasslands representative of the Negev of Israel and placed them in growth chambers maintained at atmospheric CO<sub>2</sub> concentrations of 280, 440 and 600 ppm for five months. This study also revealed that atmospheric CO<sub>2</sub> enrichment had no effect on nighttime respiratory carbon losses.

Moving to the other end of the moisture spectrum, Van der Heijden *et al.* (2000) grew peat moss hydroponically within controlled environment chambers maintained at atmospheric CO<sub>2</sub> concentrations of 350 and 700 ppm for up to six months, while simultaneously subjecting the peat moss to three different levels of nitrogen deposition. In all cases, they found that the elevated CO<sub>2</sub> reduced rates of dark respiration consistently throughout the study by 40 to 60 percent.

In a final multi-species study, Gonzalez-Meler *et al.* (2004) reviewed the scientific literature pertaining to the effects of atmospheric CO<sub>2</sub> enrichment on plant respiration from the cellular level to the level of entire ecosystems. They report finding that “contrary to what was previously thought, specific respiration rates are generally not reduced when plants are grown at elevated CO<sub>2</sub>.” Nevertheless, they note that “whole ecosystem studies show that canopy respiration does not increase proportionally to increases in biomass in response to elevated CO<sub>2</sub>,” which suggests that respiration per unit biomass is likely somewhat reduced by atmospheric CO<sub>2</sub> enrichment. However, they also find that “a larger proportion of respiration takes place in the root system [when plants are grown in CO<sub>2</sub>-enriched air],” which once again obfuscates the issue.

The three researchers say “fundamental information is still lacking on how respiration and the processes supported by it are physiologically controlled, thereby preventing sound interpretations of what seem to be species-specific responses of

respiration to elevated CO<sub>2</sub>.” They conclude that “the role of plant respiration in augmenting the sink capacity of terrestrial ecosystems is still uncertain.”

## 7.6.2. Woody Plants

### 7.6.2.1. Coniferous Trees

Jach and Ceulemans (2000) grew three-year old Scots pine seedlings out-of-doors and rooted in the ground in open-top chambers maintained at atmospheric CO<sub>2</sub> concentrations of either 350 or 750 ppm for two years. To make the experiment more representative of the natural world, they applied no nutrients or irrigation water to the soils in which the trees grew for the duration of the study. After two years of growth under these conditions, dark respiration on a needle mass basis in the CO<sub>2</sub>-enriched seedlings was 27 percent and 33 percent lower in current-year and one-year-old needles, respectively, with the greater reduction in the older needles being thought to arise

from the greater duration of elevated CO<sub>2</sub> exposure experienced by those needles.

Hamilton *et al.* (2001) studied the short- and long-term respiratory responses of loblolly pines in a free-air CO<sub>2</sub>-enrichment (FACE) study that was established in 1996 on 13-year-old trees in a North Carolina (USA) plantation, where the CO<sub>2</sub>-enriched trees were exposed to an extra 200 ppm of CO<sub>2</sub>. This modest increase in the atmosphere's CO<sub>2</sub> concentration produced no significant short-term suppression of dark respiration rates in the trees' needles. Neither did long-term exposure to elevated CO<sub>2</sub> alter maintenance respiration, which is the amount of CO<sub>2</sub> respired to maintain existing plant tissues. However, growth respiration, which is the amount of CO<sub>2</sub> respired when constructing new tissues, was reduced by 21 percent.

McDowell *et al.* (1999) grew five-month-old seedlings of western hemlock in root boxes subjected to various root-space CO<sub>2</sub> concentrations (ranging from 90 to 7000 ppm) for periods of several hours to determine the effects of soil CO<sub>2</sub> concentration on growth, maintenance and total root respiration. In doing so, they found that although elevated CO<sub>2</sub> had no effect on growth respiration, it significantly impacted maintenance and total respiration. At a soil CO<sub>2</sub> concentration of 1585 ppm, for example, total and maintenance respiration rates of roots were 55 percent and 60 percent lower, respectively, than they were at 395 ppm. The impact of elevated CO<sub>2</sub> on maintenance respiration was so strong that it exhibited an exponential decline of about 37 percent for every doubling of soil CO<sub>2</sub> concentration. The implications of this observation are especially important because maintenance respiration comprised 85 percent of total root respiration in this study.

The results of these experiments suggest that both above and below the soil surface, coniferous trees may exhibit reductions in total respiration in a high-CO<sub>2</sub> world of the future. Three studies of three species, however, is insufficient evidence to reach a firm conclusion.

#### 7.6.2.2. Deciduous Trees

Wang and Curtis (2001) grew cuttings of two male and two female trembling aspen trees for about five months on soils containing low and high nitrogen contents in open-top chambers maintained at atmospheric CO<sub>2</sub> concentrations of 380 and 765 ppm, finding that gender had little effect on dark respiration rates, but that elevated CO<sub>2</sub> increased them, by 6 percent and 32 percent in the low and high soil nitrogen treatments, respectively. On the other hand, Karnosky *et al.* (1999) grew both O<sub>3</sub>-sensitive and O<sub>3</sub>-tolerant aspen clones for one full year in free-air CO<sub>2</sub>-enrichment (FACE) plots maintained at atmospheric CO<sub>2</sub> concentrations of 360 and 560 ppm, finding that the extra CO<sub>2</sub> decreased dark respiration rates by 24 percent.

Gielen *et al.* (2003) measured stem respiration rates of white, black and robusta poplar trees in a high-density forest plantation in the third year of a FACE experiment in which the CO<sub>2</sub> concentration of the air surrounding the trees was increased to a value of approximately 550 ppm. This study revealed, in their words, that “stem respiration rates were not affected by the FACE treatment,” and that “FACE did not influence the relationships between respiration rate and both stem temperature and relative growth rate.” In addition, they say they could find “no effect of the FACE treatment on R<sub>m</sub> [maintenance respiration, which is related to the sustaining of existing cells] and R<sub>g</sub> [growth respiration, which is related to the synthesis of new tissues].”

Hamilton *et al.* (2001) studied respiratory responses of sweetgum trees growing in the understory of a loblolly pine plantation (but occasionally reaching the top of the canopy) to an extra 200 ppm of CO<sub>2</sub> in a FACE study conducted in North Carolina, USA. As a result of their measurement program, they determined that the modest increase in atmospheric CO<sub>2</sub> concentration did

not appear to alter maintenance respiration to any significant degree, but that it reduced dark respiration by an average of 10 percent and growth respiration of leaves at the top of the canopy by nearly 40 percent.

In reviewing the results of these several deciduous tree studies, we see cases of both increases and decreases in respiration rates in response to atmospheric CO<sub>2</sub> enrichment, as well as cases of no change in respiration. More data are needed before any general conclusions may safely be drawn.

#### 7.6.2.3. Multiple Tree Studies

Amthor (2000) measured dark respiration rates of intact leaves of nine different tree species growing naturally in an American deciduous forest. Within a specially designed leaf chamber, the CO<sub>2</sub> concentration surrounding individual leaves was stabilized at 400 ppm for 15 minutes, whereupon their respiration rates were measured for 30 minutes, after which the CO<sub>2</sub> concentration in the leaf chamber was raised to 800 ppm for 15 minutes and respiration data were again recorded for the same leaves. This protocol revealed that elevated CO<sub>2</sub> had little effect on leaf dark respiration rates. The extra 400 ppm of

CO<sub>2</sub> within the measurement cuvette decreased the median respiration rate by only 1.5 percent across the nine tree species. This observation led Amthor to state that the “rising atmospheric CO<sub>2</sub> concentration has only a small direct effect on tree leaf respiration in deciduous forests;” and he calculated that it can be “more than eliminated by a 0.22°C temperature increase.” Upon this premise, he concluded that “future direct effects of increasing CO<sub>2</sub> in combination with warming could stimulate tree leaf respiration in their sum,” and that this consequence “would translate into only slight, if any, effects on the carbon balance of temperate deciduous forests in a future atmosphere containing as much as [800 ppm] CO<sub>2</sub>.”

Amthor’s conclusion is debatable, for it is based upon the extrapolation of the short-term respiratory responses of individual leaves, exposed to elevated CO<sub>2</sub> for only an hour or two, to that of entire trees, many of which will experience rising CO<sub>2</sub> levels for a century or more during their lifetimes. Trees are long-lived organisms that should not be expected to reveal the nature of their long-term responses to elevated atmospheric CO<sub>2</sub> concentrations on as short a time scale as 15 minutes. Indeed, their respiratory responses may change significantly with the passage of time as they acclimate and optimize their physiology and growth patterns to the gradually rising CO<sub>2</sub> content of earth’s atmosphere, as evidenced by the findings of the following two studies.

Wang and Curtis (2002) conducted a meta-analysis of the results of 45 area-based dark respiration (R<sub>da</sub>) and 44 mass-based dark respiration (R<sub>dm</sub>) assessments of the effects of an approximate doubling of the air’s CO<sub>2</sub> concentration on 33 species of plants (both herbaceous and woody) derived from 37 scientific publications. This effort revealed that the mean leaf R<sub>da</sub> of the woody plants they analyzed was unaffected by elevated CO<sub>2</sub>. However, there was an effect on mean leaf R<sub>dm</sub>, and it was determined to be time-dependent. The woody plants exposed to elevated CO<sub>2</sub> for < 100 days, in the reviewing scientists’ words, “showed significantly less of a reduction in leaf R<sub>dm</sub> due to CO<sub>2</sub> enrichment (-12%) than did plants exposed for longer periods (-35%, P < 0.01).” Hence, for conditions of continuous long-term atmospheric CO<sub>2</sub> enrichment, the results of Wang and Curtis’ analysis suggest woody plants may experience an approximate 35 percent decrease in leaf R<sub>dm</sub>.

Drake *et al.* (1999) also conducted a comprehensive analysis of the peer-reviewed scientific literature to determine the effects of

elevated atmospheric CO<sub>2</sub> concentrations on plant respiration rates. They found that atmospheric CO<sub>2</sub> enrichment typically decreased respiration rates in mature foliage, stems, and roots of CO<sub>2</sub>-enriched plants relative to rates measured in plants grown in ambient air; and when normalized on a biomass basis, they determined that a doubling of the atmosphere’s CO<sub>2</sub> concentration would likely reduce plant respiration rates by an average of 18 percent. To determine the potential effects of this phenomenon on annual global carbon cycling, which the twelve researchers say “will enhance the quantity of carbon stored by forests,” they input a 15 percent CO<sub>2</sub>-induced respiration reduction into a carbon sequestration model, finding that an additional 6 to 7 Gt of carbon would remain sequestered within the terrestrial biosphere each year, thus substantially strengthening the terrestrial carbon sink.

Davey *et al.* (2004) reached a different conclusion. “Averaged across many previous investigations, doubling the CO<sub>2</sub> concentration has frequently been reported to cause an instantaneous reduction of leaf dark respiration measured as CO<sub>2</sub> efflux.” However, as they continue, “no known mechanism accounts for this effect, and four recent studies [Amthor (2000); Amthor *et al.* (2001); Jahnke (2001); Jahnke and Krewitt (2002)] have shown that the measurement of respiratory CO<sub>2</sub> efflux is prone to experimental artifacts that could account for the reported response.”

Using a technique that avoids the potential artifacts of prior attempts to resolve the issue, Davey *et al.* employed a high-resolution dual channel oxygen analyzer in an open gas exchange system to measure the respiratory O<sub>2</sub> uptake of nine different species of plants in response to a short-term increase in atmospheric CO<sub>2</sub> concentration, as well as the response of seven species to long-term elevation of the air’s CO<sub>2</sub> content in four different field experiments. In doing so, they found that “over six hundred separate measurements of respiration failed to reveal any decrease in respiratory O<sub>2</sub> uptake with an instantaneous increase in CO<sub>2</sub>.” Neither could they detect any response to a five-fold increase in the air’s CO<sub>2</sub> concentration nor to the total removal of CO<sub>2</sub> from the air. They also note that “this lack of response of respiration to elevated CO<sub>2</sub> was independent of treatment method, developmental stage, beginning or end of night, and the CO<sub>2</sub> concentration at which the plants had been grown.” In the long-term field studies, however, there was a respiratory response;

but it was small (7 percent on a leaf mass basis), and it was positive, not negative.

In light of these contradictory results, the most reasonable conclusion is that atmospheric CO<sub>2</sub> enrichment may either increase or decrease woody-plant respiration, but not to any great degree, and that in the mean, the net result for the conglomerate of earth's trees would likely be something of little impact.

Additional information on this topic, including reviews of newer publications as they become available, can be found at <http://www.co2science.org/subject/r/respirationtrees.php>.

## 7.7. Carbon Sequestration

As the CO<sub>2</sub> content of the air continues to rise, nearly all of earth's plants respond by increasing their photosynthetic rates and producing more biomass. This results in more carbon being captured and stored, or sequestered, in plant fibers and soil, which counterbalances some of the CO<sub>2</sub> emissions produced by mankind's use of fossil fuels.

In this section we begin with a research review of what is known about forest and forest-species responses to atmospheric CO<sub>2</sub> enrichment and subsequent carbon sequestration. Then we survey research on how temperatures affect sequestration and whether CO<sub>2</sub> enhancement offsets the rate at which carbon is re-released from soil (decomposition).

### 7.7.1. CO<sub>2</sub> Enhancement and Carbon Sequestration

#### 7.7.1.1 Forests

The planting and preservation of forests has long been acknowledged to be an effective and environmentally friendly (indeed, *enhancing*) means for slowing climate-model-predicted CO<sub>2</sub>-induced global warming. This prescription for moderating potential climate change is based on two well-established and very straightforward facts: (1) the carbon trees use to construct their tissues comes from the air, and (2) its extraction from the atmosphere slows the rate of rise of the air's CO<sub>2</sub> content.

In an open-top chamber experiment conducted in Switzerland, Nitschelm *et al.* (1997) reported that a 71 percent increase in the atmospheric CO<sub>2</sub> concentration above white clover monocultures led to a 50 percent increase in soil organic carbon content. Related studies on wheat and soybean agroecosystems (Islam *et al.*, 1999) provided similar results, as did a free-air CO<sub>2</sub> enrichment (FACE) experiment on cotton, which documented a 10 percent increase in soil organic carbon content in plots receiving 550 ppm CO<sub>2</sub> relative to those receiving 370 ppm (Leavitt *et al.*, 1994). These phenomena will allow long-lived perennial species characteristic of forest ecosystems to sequester large amounts of carbon within their wood for extended periods of time (Chambers *et al.*, 1998).

In reviewing studies that have been conducted on individual trees, it is clear that elevated levels of atmospheric CO<sub>2</sub> increase photosynthesis and growth

in both broad-leaved and coniferous species. When broad-leaved trembling aspen (*Populus tremuloides*) were exposed to twice-ambient levels of atmospheric CO<sub>2</sub> for 2.5 years, for example, Pregitzer *et al.* (2000) reported 17 and 65 percent increases in fine root biomass at low and high levels of soil nitrogen, respectively; while Zak *et al.* (2000) observed 16 and 38 percent CO<sub>2</sub>-induced increases in total tree biomass when subjected to the same respective levels of soil nitrogen.

Similar results have been reported for coniferous trees. When branches of Sitka spruce (*Picea sitchensis*) were fumigated with air of 700 ppm CO<sub>2</sub> for four years, rates of net photosynthesis in current and second-year needles were 100 and 43 percent higher, respectively, than photosynthetic rates of needles exposed to ambient air (Barton and Jarvis, 1999). In addition, ponderosa pine (*Pinus ponderosa*) grown at 700 ppm CO<sub>2</sub> for close to 2.5 years exhibited rates of net photosynthesis in current-year needles that were 49 percent greater than those of needles exposed to air containing 350 ppm CO<sub>2</sub> (Houpis *et al.*, 1999).

Elevated CO<sub>2</sub> also enhances carbon sequestration by reducing carbon losses arising from plant respiration. Karnosky *et al.* (1999) reported that aspen seedlings grown for one year at 560 ppm CO<sub>2</sub> displayed dark respiration rates that were 24 percent lower than rates exhibited by trembling aspen grown at 360 ppm CO<sub>2</sub>. Also, elevated CO<sub>2</sub> has been shown to decrease maintenance respiration, which it did by 60 percent in western hemlock seedlings exposed to an atmospheric CO<sub>2</sub> concentration of nearly 1600 ppm (McDowell *et al.*, 1999).

In a thorough review of these topics, Drake *et al.* (1999) concluded that, on average, a doubling of the atmospheric CO<sub>2</sub> concentration reduces plant respiration rates by approximately 17 percent. This finding contrasts strikingly with the much smaller effects reported by Amthor (2000), who found an average reduction in dark respiration of only 1.5 percent for nine deciduous tree species exposed to 800 ppm CO<sub>2</sub>. The period of CO<sub>2</sub> exposure in his much shorter experiments, however, was a mere 15 minutes. If the air's CO<sub>2</sub> content doubles, plants will likely sequester something on the order of 17 percent more carbon than ambiently grown plants, solely as a consequence of CO<sub>2</sub>-induced reductions in respiration. And it is good to remember that this stored carbon is in addition to that sequestered as a result of CO<sub>2</sub>-induced increases in plant photosynthetic rates.

Based upon several different types of empirical data, a number of researchers have concluded that current rates of carbon sequestration are robust and that future rates will increase with increasing atmospheric CO<sub>2</sub> concentrations. In the study of Fan *et al.* (1998) based on atmospheric measurements, for example, the broad-leaved forested region of North America between 15 and 51°N latitude was calculated to possess a current carbon sink that can annually remove all the CO<sub>2</sub> emitted into the air from fossil fuel combustion in both Canada and the United States. On another large scale, Phillips *et al.* (1998) used data derived from tree basal area to show that average forest biomass in the tropics has increased substantially over the past 40 years and that growth in the Neotropics alone (south and central South America, the Mexican lowlands, the Caribbean islands, and southern Florida) can account for 40 percent of the missing carbon of the entire globe. And in looking to the future, White *et al.* (2000) have calculated that coniferous and mixed forests north of 50°N latitude will likely expand their northern and southern boundaries by about 50 percent due to the combined effects of increasing atmospheric CO<sub>2</sub>, rising temperature, and nitrogen deposition.

The latter of these factors, nitrogen deposition, is an important variable. As indicated in the study of White *et al.*, it can play an interactive role with increasing atmospheric CO<sub>2</sub> to increase plant growth and carbon sequestration. However, the magnitude of that role is still being debated. Nadelhoffer *et al.* (1999), for example, concluded that nitrogen deposition from human activities is "unlikely to be a major contributor" to the large CO<sub>2</sub> sink that exists in northern temperate forests. Houghton *et al.* (1998), however, feel that nitrogen deposition holds equal weight with CO<sub>2</sub> fertilization in the production of terrestrial carbon sinks; and Lloyd (1999) demonstrated that when CO<sub>2</sub> and nitrogen increase together, modeled forest productivity is greater than that predicted by the sum of the individual contributions of these two variables. Thus, anthropogenic nitrogen deposition can have anywhere from small to large positive effects on carbon sequestration, as well as everything in between.

In conclusion, as the air's CO<sub>2</sub> content continues to rise, the ability of earth's forests to sequester carbon should also rise. With more CO<sub>2</sub> in the atmosphere, trees will likely exhibit greater rates of photosynthesis and reduced rates of respiration. Together, these observations suggest that biologically fixed carbon will experience greater residency times

within plant tissues. And if this carbon is directed into wood production, which increases substantially with atmospheric CO<sub>2</sub> enrichment, some of it can be kept out of circulation for a *very* long time, possibly even a millennium or more.

Additional information on this topic, including reviews of newer publications as they become available, can be found at <http://www.co2science.org/subject/c/carbonforests.php>.

### 7.7.1.2. Old Forests

In addition to enhancing the growth and production of young forests, available research indicates that rising atmospheric CO<sub>2</sub> concentrations will also increase the productivity and growth of older forests. For most of the past century it was believed that old-growth forests, such as those of Amazonia, should be close to dynamic equilibrium. Just the opposite, however, has been repeatedly observed over the past two decades.

In one of the first studies to illuminate this reality, Phillips and Gentry (1994) analyzed the turnover rates—which are close correlates of net productivity (Weaver and Murphy, 1990)—of 40 tropical forests from all around the world. They found that the growth rates of these already highly productive forests had been rising ever higher since at least 1960, and that they had experienced an apparent acceleration in growth rate sometime after 1980. Commenting on these findings, Pimm and Sugden (1994) reported that the consistency and simultaneity of the forest growth trends that Phillips and Gentry had documented on several continents led them to conclude that “enhanced productivity induced by increased CO<sub>2</sub> is the most plausible candidate for the cause of the increased turnover.”

A few years later, Phillips *et al.* (1998) analyzed forest growth rate data for the period 1958 to 1996 for several hundred plots of mature tropical trees scattered around the world, finding that tropical forest biomass, as a whole, increased substantially over the period of record. In fact, the increase in the Neotropics was equivalent to approximately 40 percent of the missing terrestrial carbon sink of the entire globe. Consequently, they concluded that

tropical forests “may be helping to buffer the rate of increase in atmospheric CO<sub>2</sub>, thereby reducing the impacts of global climate change.” And, again, they identified the aerial fertilization effect of the ongoing rise in the air’s CO<sub>2</sub> content as one of the primary factors likely to be responsible for this phenomenon.

More recently, Laurance *et al.* (2004a) reported accelerated growth in the 1990s relative to the 1980s for the large majority (87 percent) of tree genera in 18 one-hectare plots spanning an area of about 300 km<sup>2</sup> in central Amazonia, while Laurance *et al.* (2004b) observed similarly accelerated tree community dynamics in the 1990s relative to the 1980s. In addition, Baker *et al.* (2004) reported there has been a net increase in biomass in old-growth Amazonian forests in recent decades at a rate of  $1.22 \pm 0.42$  Mg ha<sup>-1</sup> yr<sup>-1</sup>, slightly greater than that originally estimated by Phillips *et al.* And once again, it was suggested, in the words of Laurance *et al.* (2005), that these “pervasive changes in central Amazonian tree communities were most likely caused by global- or regional-scale drivers, such as increasing atmospheric CO<sub>2</sub> concentrations (Laurance *et al.*, 2004a,b).”

Expanding upon this theme, Laurance *et al.* (2005) say they “interpreted these changes as being consistent with an ecological ‘signature’ expected from increasing forest productivity (cf., Phillips and Gentry, 1994; Lewis *et al.* 2004a,b; Phillips *et al.*, 2004).” They note, however, that they have been challenged in this conclusion by Nelson (2005), and they thus go on to consider his arguments in some detail, methodically dismantling them one by one.

Evidence of increasing dynamism and productivity of intact tropical forests continued, with Lewis *et al.*, (2004a) reporting that among 50 old-growth plots scattered across tropical South America, “stem recruitment, stem mortality, and biomass growth, and loss, *all* increased significantly.” In summarizing these and other findings, Lewis (2006) reports that over the past two decades, “these forests have shown concerted changes in their ecology, becoming, on average, faster growing—more productive—and more dynamic, and showing a net increase in above-ground biomass,” all of which rates of increase are greater than the previously documented increases in the rates of these phenomena. What is more, Lewis says that “preliminary analyses also suggest the African and Australian forests are showing structural changes similar to South American forests.”

So why should we care about growth trends of old forests? People who seek to address the issue

solely on the basis of forced reductions in anthropogenic CO<sub>2</sub> emissions claim that carbon sequestration by forests is viable only when forests are young and growing vigorously. (Pearce, 1999) As forests age, as claimed by the IPCC, they gradually lose their carbon-sequestering prowess, such that forests more than one hundred years old become essentially useless for removing CO<sub>2</sub> from the air, as they claim such ancient and decrepit stands yearly lose as much CO<sub>2</sub> via respiration as they take in via photosynthesis.

Although demonstrably erroneous, with repeated telling the twisted tale actually begins to sound reasonable. After all, doesn't the metabolism of every living thing slow down as it gets older? We grudgingly admit that it does—even with trees—but some trees live a remarkably long time. In Panama (Condit *et al.*, 1995), Brazil (Chambers *et al.*, 1998; Laurance *et al.*, 2004; Chambers *et al.*, 2001), and many parts of the southwestern United States (Graybill and Idso, 1993), for example, individuals of a number of different species have been shown to live for nearly one and a half millennia. At a hundred years of age, these super-slurpers of CO<sub>2</sub> are mere youngsters. And in their really old age, their appetite for the vital gas, though diminished, is not lost. In fact, Chambers *et al.* (1998) indicate that the long-lived trees of Brazil continue to experience protracted slow growth even at 1,400 years of age. And protracted slow growth (evident in yearly increasing trunk diameters) of very old and *large* trees can absorb a huge amount of CO<sub>2</sub> out of the air each year, especially when, as noted by Chambers *et al.* (1998) with respect to the Brazilian forests in the central Amazon, about 50 percent of their above-ground biomass is contained in less than the largest 10 percent of their trees. Consequently, since the life span of these massive long-lived trees is considerably greater than the projected life span of the entire "Age of Fossil Fuels," their cultivation and preservation represents an essentially permanent, though only partial, solution to the perceived problem of the anthropogenic global warming.

Another important fact about forests and their ability to sequester carbon over long periods of time is that the forest itself is the unit of primary importance when it comes to determining the amount of carbon that can be sequestered on a unit area of land. Cary *et al.* (2001) note most models of forest carbon sequestration wrongly assume that "age-related growth trends of individual trees and even-aged, monospecific stands can be extended to natural

forests." When they compared the predictions of such models against real-world data they gathered from northern Rocky Mountain subalpine forests that ranged in age from 67 to 458 years, for example, they found that above-ground net primary productivity in 200-year-old natural stands was almost twice as great as that of modeled stands, and that the difference between the two increased linearly throughout the entire sampled age range.

So what's the explanation for the huge discrepancy? Cary *et al.* suggest that long-term recruitment and the periodic appearance of additional late-successional species (increasing biodiversity) may have significant effects on stand productivity, infusing the primary unit of concern, i.e., the ever-evolving forest super-organism, with greater vitality than would have been projected on the basis of characteristics possessed by the unit earlier in its life. They also note that by not including effects of size- or age-dependent decreases in stem and branch respiration per unit of sapwood volume in models of forest growth, respiration in older stands can be over-estimated by a factor of two to five.

How serious are these model shortcomings? For the real-world forests studied by Cary *et al.*, they produce predictions of carbon sequestration that are only a little over half as large as what is observed in nature for 200-year-old forests, while for 400-year-old forests they produce results that are only about a third as large as what is characteristic of the real world. And as the forests grow older still, the difference between reality and model projections grows with them.

Another study relevant to the ability of forests to act as long-term carbon sinks was conducted by Luo *et al.* (2003), who analyzed data obtained from the Duke Forest FACE experiment, in which three 30-meter-diameter plots within a 13-year-old forest (composed primarily of loblolly pines with sweetgum and yellow poplar trees as sub-dominants, together with numerous other trees, shrubs, and vines that occupy still smaller niches) began to be enriched with an extra 200 ppm of CO<sub>2</sub> in August 1996, while three similar plots were maintained at the ambient atmospheric CO<sub>2</sub> concentration. A number of papers describing different facets of this still-ongoing long-term study have been published; and as recounted by Luo *et al.*, they have revealed the existence of a CO<sub>2</sub>-induced "sustained photosynthetic stimulation at leaf and canopy levels [Myers *et al.*, 1999; Ellsworth, 2000; Luo *et al.*, 2001; Lai *et al.*, 2002], which resulted in sustained stimulation of wood biomass

increment [Hamilton *et al.*, 2002] and a larger carbon accumulation in the forest floor at elevated CO<sub>2</sub> than at ambient CO<sub>2</sub> [Schlesinger and Lichter, 2001].”

Based upon these findings and what they imply about rates of carbon removal from the atmosphere and its different residence times in plant, litter, and soil carbon pools, Luo *et al.* developed a model for studying the sustainability of forest carbon sequestration. Applying this model to a situation where the atmospheric CO<sub>2</sub> concentration gradually rises from a value of 378 ppm in 2000 to a value of 710 ppm in 2100, they calculated that the carbon sequestration rate of the Duke Forest would rise from an initial value of 69 g m<sup>-2</sup> yr<sup>-1</sup> to a final value of 201 g m<sup>-2</sup> yr<sup>-1</sup>, which is a far cry from the scenario promulgated by those who claim earth’s forests will have released much of the carbon they had previously absorbed as early as the year 2050 (Pearce, 1999).

Another study that supports the long-term viability of carbon sequestration by forests was conducted by Paw U *et al.* (2004), who also note that old-growth forests have generally been considered to “represent carbon sources or are neutral (Odum, 1963, 1965),” stating that “it is generally assumed that forests reach maximum productivity at an intermediate age and productivity declines in mature and old-growth stands (Franklin, 1988), presumably as dead woody debris and other respiratory demands increase.” More particularly, they report that a number of articles have suggested that “old-growth conifer forests are at equilibrium with respect to net ecosystem productivity or net ecosystem exchange (DeBell and Franklin, 1987; Franklin and DeBell, 1988; Schulze *et al.*, 1999), as an age-class end point of ecosystem development.”

To see if these claims had any merit, Paw U *et al.* used an eddy covariance technique to estimate the CO<sub>2</sub> exchange rate of the oldest forest ecosystem (500 years old) in the AmeriFlux network of carbon-flux measurement stations—the Wind River old-growth forest in southwestern Washington, USA, which is composed mainly of Douglas fir and western hemlock—over a period of 16 months, from May 1998 to August 1999. Throughout this period, the 14 scientists report “there were no monthly averages with net release of CO<sub>2</sub>,” and that the cumulative net ecosystem exchange showed “remarkable sequestration of carbon, comparable to many younger forests.” They concluded that “in contrast to frequently stated opinions, old-growth forests can be significant carbon sinks,” noting that “the old-growth forests of the Pacific Northwest can contribute to

optimizing carbon sequestration strategies while continuing to provide ecosystem services essential to supporting biodiversity.”

Binkley *et al.* (2004) revisited an aging aspen forest in the Tesuque watershed of northern New Mexico, USA—which between 1971 and 1976 (when it was between 90 and 96 years old) was thought to have had a *negative* net ecosystem production rate of -2.0 Mg ha<sup>-1</sup> yr<sup>-1</sup>—and measured the basal diameters of all trees in the central 0.01 ha of each of 27 plots arrayed across the watershed, after which they used the same regression equations employed in the earlier study to calculate live tree biomass as of 2003.

“Contrary to expectation,” as they describe it, Binkley *et al.* report that “live tree mass in 2003 [186 Mg ha<sup>-1</sup>] was significantly greater than in 1976 [149 Mg ha<sup>-1</sup>] (P = 0.02), refuting the hypothesis that live tree mass declined.” In fact, they found that the annual net increment of live tree mass was about 1.37 Mg ha<sup>-1</sup> yr<sup>-1</sup> from age 96 to age 123 years, which is only 12 percent less than the mean annual increment of live tree mass experienced over the forest’s initial 96 years of existence (149 Mg ha<sup>-1</sup> / 96 yr = 1.55 Mg ha<sup>-1</sup> yr<sup>-1</sup>). Consequently, in response to the question they posed when embarking on their study—“Do old forests gain or lose carbon?”—Binkley *et al.* concluded that “old aspen forests continue to accrue live stem mass well into their second century, despite declining current annual increments,” which, we might add, are not all that much smaller than those the forests exhibited in their younger years.

Similar results have been obtained by Hollinger *et al.* (1994) for a 300-year-old *Nothofagus* site in New Zealand, by Law *et al.* (2001) for a 250-year-old ponderosa pine site in the northwestern United States, by Falk *et al.* (2002) for a 450-year-old Douglas fir/western hemlock site in the same general area, and by Knohl *et al.* (2003) for a 250-year-old deciduous forest in Germany. In commenting on these findings, the latter investigators say they found “unexpectedly high carbon uptake rates during 2 years for an unmanaged ‘advanced’ beech forest, which is in contrast to the widely spread hypothesis that ‘advanced’ forests are insignificant as carbon sinks.” For the forest they studied, as they describe it, “assimilation is clearly not balanced by respiration, although this site shows typical characteristics of an ‘advanced’ forest at a comparatively late stage of development.”

These observations about forests are remarkably similar to recent findings regarding humans; i.e., that nongenetic interventions, even late in life, can put one

on a healthier trajectory that extends productive lifespan. So what is the global “intervention” that has put the planet’s trees on the healthier trajectory of being able to sequester significant amounts of carbon in their old age, when past theory (which was obviously based on past observations) decreed they should be in a state of no-net-growth or even negative growth? The answer is probably CO<sub>2</sub> enhancement. For any tree of age 250 years or more, the greater portion of its life (at least two-thirds of it) has been spent in an atmosphere of reduced CO<sub>2</sub> content. Up until 1920, for example, the air’s CO<sub>2</sub> concentration had never been above 300 ppm throughout the lives of such trees, whereas it is currently 375 ppm or 25 percent higher. And for older trees, even greater portions of their lives have been spent in air of even lower CO<sub>2</sub> concentration. Hence, the “intervention” that has given new life to old trees would appear to be the aerial fertilization effect produced by the CO<sub>2</sub> that resulted from the Industrial Revolution and is being maintained by its ever-expanding aftermath (Idso, 1995).

Based on these many observations, as well as the results of the study of Greenep *et al.* (2003), which strongly suggest, in their words, that “the capacity for enhanced photosynthesis in trees growing in elevated CO<sub>2</sub> is unlikely to be lost in subsequent generations,” it would appear that earth’s forests will remain strong sinks for atmospheric carbon well into the distant future. A wealth of scientific data confirms the reality of the ever-increasing productivity of earth’s older forests, especially those of Amazonia, concomitant with the rise in the air’s CO<sub>2</sub> content. An even greater wealth of laboratory and field data demonstrates that rising forest productivity is what one would expect to observe in response to the stimulus provided by the ongoing rise in the atmosphere’s CO<sub>2</sub> concentration.

### 7.7.2. Decomposition

What is the fate of the extra carbon that is stored within plant tissues as a consequence of atmospheric CO<sub>2</sub> enrichment? Is it rapidly returned to the atmosphere following tissue senescence and decomposition? Or is it locked away for long periods of time? Experiments and real-world observations reveal that atmospheric CO<sub>2</sub> enrichment typically reduces, or has no effect upon, decomposition rates of senesced plant material.

#### 7.7.2.1. Processes and Properties

Atmospheric CO<sub>2</sub> enrichment stimulates photosynthesis and growth in nearly all plants, typically producing more non-structural carbohydrates, which can be used to manufacture more carbon-based secondary compounds (CBSCs) or phenolics. This observation is important because phenolics tend to inhibit the decomposition of the organic matter in which they are found (Freeman *et al.*, 2001). If elevated levels of atmospheric CO<sub>2</sub> lead to the production of more of these decay-resistant substances, one would expect the ongoing rise in the air's CO<sub>2</sub> content to lead to the enhanced

sequestration of plant-litter-derived carbon in the world's soils, producing a negative feedback phenomenon that would tend to slow the rate of rise of the air's CO<sub>2</sub> content and thereby moderate CO<sub>2</sub>-induced global warming.

For a long time, research on this matter was rather muddled. Many studies reported the expected increases in CBSC concentrations with experimentally created increases in the air's CO<sub>2</sub> content. Others, however, could find no significant plant phenolic content changes; a few even detected CO<sub>2</sub>-induced decreases in CBSC concentrations. Penuelas *et al.* (1997) finally brought order to the issue when they identified the key role played by soil nitrogen.

In analyzing the results of several different studies, Penuelas *et al.* noticed that when soil nitrogen supply was less than adequate, some of the CBSC responses to a doubling of the air's CO<sub>2</sub> content were negative, i.e., a portion of the studies indicated that plant CBSC concentrations declined as the air's CO<sub>2</sub> content rose. When soil nutrient supply was more than adequate, however, the responses were almost all positive, with plant CBSC concentrations rising in response to a doubling of the air's CO<sub>2</sub> concentration. In addition, when the CO<sub>2</sub> content of the air was tripled, *all* CBSC responses, under both low and high soil nitrogen conditions, were positive.

The solution to the puzzle was thus fairly simple. With a tripling of the air's CO<sub>2</sub> content, nearly all plants exhibited increases in CBSC production; but with only a doubling of the atmospheric CO<sub>2</sub> concentration, adequate nitrogen is needed to ensure a positive CBSC response.

What makes these observations exciting is that atmospheric CO<sub>2</sub> enrichment, in addition to enhancing plant growth, typically stimulates nitrogen fixation in both woody (Olesniewicz and Thomas, 1999) and non-woody (Niklaus *et al.*, 1998; Dakora and Drake, 2000) legumes. As the air's CO<sub>2</sub> content continues to rise, earth's nitrogen-fixing plants should become ever more proficient in this important enterprise. In addition, some of the extra nitrogen thus introduced into earth's ecosystems will likely be shared with non-nitrogen-fixing plants. Also, since the microorganisms responsible for nitrogen fixation are found in nearly all natural ecosystems (Gifford, 1992), and since atmospheric CO<sub>2</sub> enrichment can directly stimulate the nitrogen-fixing activities of these microbes (Lowe and Evans, 1962), it can be appreciated that the ongoing rise in the air's CO<sub>2</sub> content will likely provide more nitrogen for the

production of more CBSCs in all of earth's plants. And with ever-increasing concentrations of decay-resistant materials being found throughout plant tissues, the plant-derived organic matter that is incorporated into soils should remain there for ever longer periods of time.

On the other hand, in a meta-analysis of the effects of atmospheric CO<sub>2</sub> enrichment on leaf-litter chemistry and decomposition rate that was based on a total of 67 experimental observations, Norby *et al.* (2001) found that elevated atmospheric CO<sub>2</sub> concentrations—mostly between 600 and 700 ppm—reduced leaf-litter nitrogen concentration by about 7 percent. But in experiments where plants were grown under as close to natural conditions as possible, such as in open-top chambers, free-air CO<sub>2</sub> enrichment (FACE) plots, or in the proximity of CO<sub>2</sub>-emitting springs, there were no significant effects of elevated CO<sub>2</sub> on leaf-litter nitrogen content.

In addition, based on a total of 46 experimental observations, Norby *et al.* determined that elevated atmospheric CO<sub>2</sub> concentrations increased leaf-litter lignin concentrations by an average of 6.5 percent. However, these increases in lignin content occurred in woody but not in herbaceous species. And again, the lignin concentrations of leaf litter were not affected by elevated CO<sub>2</sub> when plants were grown in open-top chambers, FACE plots, or in the proximity of CO<sub>2</sub>-emitting springs.

In an analysis of a total of 101 observations, Norby *et al.* found elevated CO<sub>2</sub> had no consistent effect on leaf-litter decomposition rate in any type of experimental setting. As the air's CO<sub>2</sub> content continues to rise, it will likely have little to no impact on leaf-litter chemistry and rates of leaf-litter decomposition. Since there will be more leaf litter produced in a high-CO<sub>2</sub> world of the future, however, that fact alone will ensure that more carbon is sequestered in the world's soils for longer periods of time.

#### 7.7.2.2. Agricultural Crops

In the study by Booker *et al.* (2000), leaves from defoliated cotton plants grown at an atmospheric CO<sub>2</sub> concentration of 720 ppm displayed significantly greater amounts of starch and soluble sugars and significantly lower concentrations of nitrogen than the leaves of plants grown in ambient air. These changes in the quality of the leaf litter produced under high CO<sub>2</sub> likely affected its subsequent decomposition rate, which was 10 to 14 percent slower than that observed for leaf litter collected from plants grown in air of normal CO<sub>2</sub> concentration. Likewise, when crop residues from soybean and sorghum plants that were raised in twice-ambient CO<sub>2</sub> environments were mixed with soils to study their decomposition rates, Torbert *et al.* (1998) noted they lost significantly less carbon – up to 40 percent less – than similarly treated crop residues from ambiently grown crops.

In contrast to the aforementioned studies, neither Van Vuuren *et al.* (2000), for spring wheat, nor Henning *et al.* (1996), for soybean and sorghum, found any significant differences in the decomposition rates of the residues of crops grown under conditions of high or normal atmospheric CO<sub>2</sub> concentration.

As the air's CO<sub>2</sub> content continues to rise, therefore, and agricultural crops grow more robustly and return greater amounts of litter to the soil, it is likely that greater amounts of carbon will be sequestered in the soil in which they grew, as crop residue decomposition rates are significantly decreased or remain unchanged.

#### 7.7.2.3. Grassland Species

In the study of Nitschelm *et al.* (1997), white clover exposed to an atmospheric CO<sub>2</sub> concentration of 600 ppm for one growing season channeled 50 percent more newly fixed carbon compounds into the soil than similar plants exposed to ambient air. In addition, the clover's roots decomposed at a rate that was 24 percent slower than that observed for roots of control plants, as has also been reported for white clover by David *et al.* (2001). These observations suggest that soil carbon sequestration under white clover ecosystems will be greatly enhanced as the air's CO<sub>2</sub> content continues to rise, as was also shown for moderately fertile sandstone grasslands (Hu *et al.*, 2001).

Similar results have been observed with mini-ecosystems comprised entirely of perennial ryegrass. Van Ginkel *et al.* (1996), for example, demonstrated that exposing this species to an atmospheric CO<sub>2</sub> concentration of 700 ppm for two months caused a 92 percent increase in root growth and 19 percent and 14 percent decreases in root decomposition rates one and two years, respectively, after incubating ground roots within soils. This work was later followed up by Van Ginkel and Gorissen (1998), who showed a 13 percent reduction in the decomposition rates of CO<sub>2</sub>-enriched perennial ryegrass roots in both disturbed and undisturbed root profiles. This and other work led the authors to calculate that CO<sub>2</sub>-induced reductions in the decomposition of perennial ryegrass litter, which enhances soil carbon sequestration, could well be large enough to remove over half of the anthropogenic CO<sub>2</sub> emissions that may be released in the next century (Van Ginkel *et al.*, 1999).

In some cases, atmospheric CO<sub>2</sub> enrichment has little or no significant effect on litter quality and subsequent rates of litter decomposition, as was the case in the study of Hirschel *et al.* (1997) for lowland

calcareous and high alpine grassland species. Similar non-effects of elevated CO<sub>2</sub> on litter decomposition have also been reported in a California grassland (Dukes and Field, 2000).

In light of these experimental findings, it would appear that as the air's CO<sub>2</sub> concentration increases, litter decomposition rates of grassland species will likely decline, increasing the amount of carbon sequestered in grassland soils. Since this phenomenon is augmented by the aerial fertilization effect of atmospheric CO<sub>2</sub> enrichment, which leads to the production of greater amounts of litter, there is thus a double reason for expecting more carbon to be removed from the atmosphere by earth's grasslands in the future.

Additional information on this topic, including reviews of newer publications as they become available, can be found at <http://www.co2science.org/subject/d/decompositiongrass.php>.

### 7.7.2.4. Woody Plants

The sequestering of carbon in the soils upon which woody plants grow has the potential to provide a powerful brake on the rate of rise of the air's CO<sub>2</sub> content if the plant litter that is incorporated into those soils does not decompose more rapidly in a CO<sub>2</sub>-enriched atmosphere than it does in current ambient air. It is important to determine if this latter constraint is true or false. In this section we review this question with respect to litter produced by conifers and deciduous trees.

Scherzel *et al.* (1998) exposed seedlings of two eastern white pine genotypes to elevated concentrations of atmospheric CO<sub>2</sub> and O<sub>3</sub> in open-top chambers for four full growing seasons, finding no changes in the decomposition rates of the litter of either genotype to the concentration increases of either of these two gases. Likewise, Kainulainen *et al.* (2003) could find no evidence that the litter of 22-year-old Scots pine trees that had been exposed to elevated concentrations of CO<sub>2</sub> and O<sub>3</sub> for three full years decomposed any faster or slower than litter produced in ambient air. In addition, Finzi and Schlesinger (2002) found that the decomposition rate of litter from 13-year-old loblolly pine trees was unaffected by elevated CO<sub>2</sub> concentrations maintained for a period of two full years in a FACE study.

In light of these observations, plus the fact that Saxe *et al.* (1998) have determined that a doubling of the air's CO<sub>2</sub> content leads to more than a doubling of the biomass production of coniferous species, it logically follows that the ongoing rise in the atmosphere's CO<sub>2</sub> concentration is increasing carbon sequestration rates in the soils upon which conifers grow and producing a significant negative feedback phenomenon that slows the rate of rise of the air's CO<sub>2</sub> content.

What about deciduous trees? Scherzel *et al.* (1998) exposed seedlings of yellow poplar trees to elevated concentrations of atmospheric CO<sub>2</sub> and O<sub>3</sub> in

open-top chambers for four full growing seasons, finding that rates of litter decomposition were similar for all treatments for the first five months of the study. Thereafter, however, litter produced in the elevated O<sub>3</sub> and CO<sub>2</sub> treatment decomposed at a significantly slower rate, such that after two years had passed, the litter from the elevated O<sub>3</sub> and CO<sub>2</sub> treatment contained approximately 12 percent more biomass than the litter from any other treatment.

Cotrufo *et al.* (1998) grew two-year-old ash and sycamore seedlings for one growing season in closed-top chambers maintained at atmospheric CO<sub>2</sub> concentrations of 350 and 600 ppm. The high-CO<sub>2</sub> air increased lignin contents in the litter produced from both tree species, which likely contributed to the decreased litter decomposition rates observed in the CO<sub>2</sub>-enriched chambers. After one year of incubation, for example, litter bags from the CO<sub>2</sub>-enriched trees of both species had about 30 percent more dry mass remaining in them than litter bags from the ambient trees. In addition, woodlouse arthropods consumed 16 percent *less* biomass when fed litter generated from seedlings grown at 600 ppm CO<sub>2</sub> than when fed litter generated from seedlings grown in ambient air.

De Angelis *et al.* (2000) constructed large open-top chambers around 30-year-old mixed stands of naturally growing Mediterranean forest species (dominated by *Quercus ilex*, *Phillyrea augustifolia*, and *Pistacia lentiscus*) near the coast of central Italy. Half of the chambers were exposed to ambient air of 350 ppm CO<sub>2</sub>, while half were exposed to air of 710 ppm CO<sub>2</sub>; and after three years, the lignin and carbon concentrations of the leaf litter of all three species were increased by 18 and 4 percent, respectively, while their nitrogen concentrations were reduced by 13 percent. These changes resulted in a 20 percent CO<sub>2</sub>-induced increase in the carbon-to-nitrogen ratio of the leaf litter, which parameter is commonly used to predict decomposition rates, where larger ratios are generally associated with less rapid decomposition than smaller ratios. This case was no exception, with 4 percent less decomposition occurring in the leaf litter gathered from beneath the CO<sub>2</sub>-enriched trees than in the litter collected from beneath the trees growing in ambient air.

Cotrufo and Ineson (2000) grew beech seedlings for five years in open-top chambers fumigated with air containing either 350 or 700 ppm CO<sub>2</sub>. Subsequently, woody twigs from each CO<sub>2</sub> treatment were collected and incubated in native forest soils for 42 months, after which they determined there was no significant effect of the differential CO<sub>2</sub> exposure

during growth on subsequent woody twig decomposition, although the mean decomposition rate of the CO<sub>2</sub>-enriched twigs was 5 percent less than that of the ambient-treatment twigs.

Conway *et al.* (2000) grew two-year-old ash tree seedlings in solardomes maintained at atmospheric CO<sub>2</sub> concentrations of 350 and 600 ppm, after which naturally senesced leaves were collected, inoculated with various fungal species, and incubated for 42 days. They found the elevated CO<sub>2</sub> significantly reduced the amount of nitrogen in the senesced leaves, thus giving the CO<sub>2</sub>-enriched leaf litter a higher carbon-to-nitrogen ratio than the litter collected from the seedlings growing in ambient air. This change likely contributed to the observed reductions in the amount of fungal colonization present on the senesced leaves from the CO<sub>2</sub>-enriched treatment, which would be expected to result in reduced rates of leaf decomposition.

King *et al.* (2001) grew aspen seedlings for five months in open-top chambers receiving atmospheric CO<sub>2</sub> concentrations of 350 and 700 ppm. At the end of this period, naturally senesced leaf litter was collected, analyzed, and allowed to decompose under ambient conditions for 111 days. Although the elevated CO<sub>2</sub> slightly lowered leaf litter nitrogen content, it had no effect on litter sugar, starch, or tannin concentrations. With little to no CO<sub>2</sub>-induced effects on leaf litter quality, there was no CO<sub>2</sub>-induced effect on litter decomposition.

Dilustro *et al.* (2001) erected open-top chambers around portions of a regenerating oak-palmetto scrub ecosystem in Florida, USA and maintained them at CO<sub>2</sub> concentrations of either 350 or 700 ppm, after which they incubated ambient- and elevated-CO<sub>2</sub>-produced fine roots for 2.2 years in the chamber soils, which were nutrient-poor and often water-stressed. They found the elevated CO<sub>2</sub> did not significantly affect the decomposition rates of the fine roots originating from either the ambient or CO<sub>2</sub>-enriched environments.

Of these seven studies of deciduous tree species, five are suggestive of slight reductions in litter decomposition rates under CO<sub>2</sub>-enriched growth conditions, while two show no effect. With deciduous trees exhibiting large growth enhancements in response to atmospheric CO<sub>2</sub> enrichment, we can expect to see large increases in the amounts of carbon they sequester in the soils on which they grow as the air's CO<sub>2</sub> content continues to rise. And this phenomenon should slow the rate of rise of the

atmosphere's CO<sub>2</sub> concentration and thereby reduce the impetus for CO<sub>2</sub>-induced global warming.

To summarize, scientific theory and empirical research show that the ongoing rise in the air's CO<sub>2</sub> content will not materially alter the rate of decomposition of the world's soil organic matter. This means the rate at which carbon is sequestered in the world's soils should continue to increase, a joint function of the rate at which the productivity of earth's plants is increased by the aerial fertilization effect of the rising atmospheric CO<sub>2</sub> concentration and the rate of expansion of the planet's vegetation into drier regions of the globe that is made possible by the concomitant CO<sub>2</sub>-induced increase in vegetative water use efficiency.

## 7.7.3. Temperature and Carbon Sequestration

### 7.7.3.1. General

It must be noted, as stated by Agren and Bosatta (2002), that "global warming has long been assumed to lead to an increase in soil respiration and, hence, decreasing soil carbon stores." Indeed, this dictum was accepted as gospel for many years, for a number of laboratory experiments seemed to suggest that nature would not allow more carbon to be sequestered in the soils of a warming world. As one non-laboratory experiment after another has recently demonstrated, however, such is not the case, and theory has been forced to change to accommodate reality.

The old-school view of things began to unravel in 1999 when two studies presented evidence refuting the long-standing orthodoxy. Abandoning the laboratory for the world of nature, Fitter *et al.* (1999) heated natural grass ecosystems by 3°C and found that the temperature increase had "no direct effect on the soil carbon store." That same year, Liski *et al.* (1999) showed that carbon storage in the soils of both high- and low-productivity boreal forests in Finland actually increased with rising temperatures along a natural temperature gradient.

The following year, Johnson *et al.* (2000) warmed natural Arctic tundra ecosystems by nearly 6°C for eight full years and found no significant effect on ecosystem respiration. Likewise, Giardina and Ryan (2000) analyzed organic carbon decomposition data derived from the forest soils of 82 different sites on five continents, reporting that "despite a 20°C gradient in mean annual temperature, soil carbon mass loss ... was insensitive to temperature."

Thornley and Cannell (2001) ventured forth with what they called “a hypothesis” concerning the matter. Specifically, they proposed the idea that warming may increase the rate of certain physico-chemical processes that transfer organic carbon from less-stable to more-stable soil organic matter pools, thereby enabling the better-protected organic matter to avoid, or more strongly resist, decomposition. Then, they developed a dynamic soil model in which they demonstrated that if their thinking were correct, long-term soil carbon storage would appear to be insensitive to a rise in temperature, even if the respiration rates of all soil carbon pools rose in response to warming, as they indeed do.

Agren and Bosatta’s 2002 paper is an independent parallel development of much the same concept, although they describe the core idea in somewhat different terms, and they upgrade the concept from what Thornley and Cannell call a “hypothesis” to what they refer to as the “continuous-quality theory.” *Quality*, in this context, refers to the degradability of soil organic matter; and *continuous quality* suggests there is a wide-ranging continuous spectrum of soil organic carbon “mini-pools” that possess differing degrees of resistance to decomposition.

The continuous quality theory states that soils from naturally higher temperature regimes will contain relatively more organic matter in carbon pools that are more resistant to degradation and are consequently characterized by lower rates of decomposition, which has been observed experimentally to be the case by Grisi *et al.* (1998). In addition, it states that this shift in the distribution of soil organic matter qualities—i.e., the higher-temperature-induced creation of more of the more-difficult-to-decompose organic matter—will counteract the decomposition-promoting influence of the higher temperatures, so that the overall decomposition rate of the totality of organic matter in a higher-temperature soil is either unaffected or reduced.

Rising CO<sub>2</sub> levels tend to maintain (Henning *et al.*, 1996) or decrease (Torbert *et al.*, 1998; Nitschelm *et al.*, 1997) CO<sub>2</sub> fluxes from agricultural soils. Consequently, these phenomena tend to increase the carbon contents of most soils in CO<sub>2</sub>-enriched atmospheres. However, it is sometimes suggested that rising air temperatures, which can accelerate the breakdown of soil organic matter and increase biological respiration rates, could negate this CO<sub>2</sub>-induced enhancement of carbon sequestration,

possibly leading to an even greater release of carbon back to the atmosphere.

Casella and Soussana (1997) grew perennial ryegrass in controlled environments receiving ambient and elevated (700 ppm) atmospheric CO<sub>2</sub> concentrations, two levels of soil nitrogen, and ambient and elevated (+3°C) air temperatures for a period of two years, finding that “a relatively large part of the additional photosynthetic carbon is stored below-ground during the two first growing seasons after exposure to elevated CO<sub>2</sub>, thereby increasing significantly the below-ground carbon pool.” At the low and high levels of soil nitrogen supply, for example, the elevated CO<sub>2</sub> increased soil carbon storage by 32 and 96 percent, respectively, “with no significant increased temperature effect.” The authors thus concluded that in spite of predicted increases in temperature, “this stimulation of the below-ground carbon sequestration in temperate grassland soils could exert a negative feed-back on the current rise of the atmospheric CO<sub>2</sub> concentration.”

Much the same conclusion was reached by Van Ginkel *et al.* (1999). After reviewing prior experimental work that established the growth and decomposition responses of perennial ryegrass to both atmospheric CO<sub>2</sub> enrichment and increased temperature, these researchers concluded that, at both low and high soil nitrogen contents, CO<sub>2</sub>-induced increases in plant growth and CO<sub>2</sub>-induced decreases in plant decomposition rate are more than sufficient to counteract any enhanced soil respiration rate that might be caused by an increase in air temperature. In addition, after reconstructing carbon storage in the terrestrial vegetation of Northern Eurasia as far back as 125,000 years ago, Velichko *et al.* (1999) determined that plants in this part of the world were more productive and efficient in sequestering carbon at higher temperatures than they were at lower temperatures. Similarly, Allen *et al.*, (1999) used sediment cores from a lake in southern Italy and from the Mediterranean Sea to conclude that, over the past 102,000 years, warmer climates have been better for vegetative productivity and carbon sequestration than have cooler climates.

In conclusion, research conducted to date strongly suggests that the CO<sub>2</sub>-induced enhancement of vegetative carbon sequestration will not be reduced by any future rise in air temperature, regardless of its cause. The rest of this section looks more closely at research regarding forests and peatlands.

### 7.7.3.2. Forests

Liski *et al.* (1999) studied soil carbon storage across a temperature gradient in a modern-day Finnish boreal forest, determining that carbon sequestration in the soil of this forest increased with temperature. In deciduous forests of the eastern United States, White *et al.* (1999) also determined that persistent increases

in growing season length (due to rising air temperatures) may lead to long-term increases in carbon storage, which tend to counterbalance the effects of increasing air temperature on respiration rates.

A data-driven analysis by Fan *et al.* (1998) suggests that the carbon-sequestering abilities of North America's forests between 15 and 51°N latitude are so robust that they can yearly remove from the atmosphere all of the CO<sub>2</sub> annually released to it by fossil fuel consumption in both the United States and Canada (and this calculation was done during a time touted as having the warmest temperatures on record). Moreover, Phillips *et al.* (1998) have shown that carbon sequestration in tropical forests has increased substantially over the past 42 years, in spite of any temperature increases that may have occurred during that time.

Similarly, King *et al.* (1999) showed that aspen seedlings increased their photosynthetic rates and biomass production as temperatures rose from 10 to 29°C, putting to rest the idea that high-temperature-induced increases in respiration rates would cause net losses in carbon fixation. White *et al.* (2000) showed that rising temperatures increased the growing season by about 15 days for 12 sites in deciduous forests located within the United States, causing a 1.6 percent increase in net ecosystem productivity per day. Thus, rather than exerting a negative influence on forest carbon sequestration, if air temperatures rise in the future they will likely have a positive effect on carbon storage in forests and their associated soils.

### 7.7.3.3. Peatlands

Putative CO<sub>2</sub>-induced global warming has long been predicted to turn boreal and tundra biomes into major sources of carbon emissions. Until just a few short years ago it was nearly universally believed that rising air temperatures would lead to the thawing of extensive areas of permafrost and the subsequent decomposition of their vast stores of organic matter, which, it was thought, would release much of the peatlands' tightly held carbon, enabling it to make its way back to the atmosphere as CO<sub>2</sub>.

Improved soil drainage and increased aridity were also envisioned to help the process along, possibly freeing enough carbon at a sufficiently rapid rate to rival the amount released to the atmosphere as CO<sub>2</sub> by all anthropogenic sources combined. The end result was claimed to be a tremendous positive feedback to the ongoing rise in the air's CO<sub>2</sub> content, which was envisioned to produce a greatly amplified atmospheric greenhouse effect that would lead to catastrophic global warming.

This scenario was always too bad to be true. Why? Because it did not begin to deal with the incredible complexity of the issue, several important neglected aspects of which have been briefly described by Weintraub and Schimel (2005).

One of the first cracks in the seemingly sound hypothesis was revealed by the study of Oechel *et al.* (2000), wherein long-term measurements of net ecosystem CO<sub>2</sub> exchange rates in wet-sedge and moist-tussock tundra communities of the Alaskan Arctic indicated that these ecosystems were gradually changing from carbon sources to carbon sinks. The transition occurred between 1992 and 1996, at the apex of a regional warming trend that culminated with the highest summer temperature and surface water deficit of the previous four decades.

How did this dramatic and unexpected biological transformation happen? The answer of the scientists who documented the phenomenon was "a previously undemonstrated capacity for ecosystems to

metabolically adjust to long-term changes in climate." Just as people can change their behavior in response to environmental stimuli, so can plants. And this ecological acclimation process is only one of several newly recognized phenomena that have caused scientists to radically revise the way they think about global change in Arctic regions.

Camill *et al.* (2001) investigated (1) changes in peat accumulation across a regional gradient of mean annual temperature in Manitoba, Canada, (2) net above-ground primary production and decomposition for major functional plant groups of the region, and (3) soil cores from several frozen and thawed bog sites that were used to determine long-term changes in organic matter accumulation following the thawing of boreal peatlands. In direct contradiction of earlier thinking on the subject, but in confirmation of the more recent findings of Camill (1999a,b), the researchers discovered that above-ground biomass and decomposition "were more strongly controlled by local succession than regional climate." In other words, they determined that over a period of several years, natural changes in plant community composition generally "have stronger effects on carbon sequestration than do simple increases in temperature and aridity." Their core-derived assessments of peat accumulation over the past two centuries demonstrated that rates of biological carbon sequestration can almost double following the melting of permafrost, in harmony with the findings of Robinson and Moore (2000) and Turetsky *et al.* (2000), who found rates of organic matter accumulation in other recently thawed peatlands to have risen by 60-72 percent.

Griffis and Rouse (2001) drew upon the findings of a number of experiments conducted over the past quarter-century at a subarctic sedge fen near Churchill, Manitoba, Canada, in order to develop an empirical model of net ecosystem CO<sub>2</sub> exchange there. The most fundamental finding of this endeavor was that "carbon acquisition is greatest during wet and warm conditions," such as is generally predicted for the world as a whole by today's most advanced climate models. However, since regional climate change predictions are not very dependable, the two scientists investigated the consequences of a 4°C increase in temperature accompanied by both a 30 percent increase and decrease in precipitation; and "in all cases," as they put it, "the equilibrium response showed substantial increases in carbon acquisition." One of the reasons behind this finding, as explained by Griffis and Rouse, is that "arctic ecosystems

photosynthesize below their temperature optimum over the majority of the growing season,” so that increasing temperatures enhance plant growth rates considerably more than they increase plant decay rates.

In summing up their findings, Griffis and Rouse say “warm surface temperatures combined with wet soil conditions in the early growing season increase above-ground biomass and carbon acquisition throughout the summer season.” Indeed, they note that “wet spring conditions can lead to greater CO<sub>2</sub> acquisition through much of the growing period even when drier conditions persist.” They thus conclude that if climate change plays out as described by current climate models—i.e., if the world becomes warmer and wetter—“northern wetlands should therefore become larger sinks for atmospheric CO<sub>2</sub>.”

In a somewhat different type of study, Mauquoy *et al.* (2002) analyzed three cores obtained from a raised peat bog in the UK (Walton Moss) and a single core obtained from a similar bog in Denmark (Lille Vildmose) for macro- and micro-fossils (pollen), bulk density, loss on ignition, carbon/nitrogen ratios, and humification, while they were <sup>14</sup>C dated by accelerator mass spectrometry. Among a variety of other things, it was determined, in their words, that “the lowest carbon accumulation values for the Walton Moss monoliths between ca. cal AD 1300 and 1800 and between ca. cal AD 1490 and 1580 for Lille Vildmose occurred during the course of Little Ice Age deteriorations,” which finding they describe as being much the same as the observation “made by Oldfield *et al.* (1997) for a Swedish ‘aapa’ mire between ca. cal AD 1400 and 1800.” They also report that carbon accumulation before this, in the Medieval Warm Period, was higher, as was also the case following the Little Ice Age, as the earth transitioned to the Modern Warm Period. Consequently, whereas the IPCC claims that warming will hasten the release of carbon from ancient peat bogs, these real-world data demonstrate that just the opposite is more likely.

In a somewhat similar study, but one that concentrated more on the role of nitrogen than of temperature, Turunen *et al.* (2004) derived recent (0-150 years) and long-term (2,000-10,000 years) apparent carbon accumulation rates for several ombrotrophic peatlands in eastern Canada with the help of <sup>210</sup>Pb- and <sup>14</sup>C-dating of soil-core materials. This work revealed that the average long-term apparent rate of C accumulation at 15 sites was  $19 \pm 8$  g C m<sup>-2</sup> yr<sup>-1</sup>, which is comparable to long-term rates observed in Finnish bogs by Tolonen and Turunen

(1996) and Turunen *et al.* (2002). Recent C accumulation rates at 23 sites, on the other hand, were much higher, averaging  $73 \pm 17$  g C m<sup>-2</sup> yr<sup>-1</sup>, which results, in their words, are also “similar to results from Finland (Tolonen and Turunen, 1996; Pitkanen *et al.*, 1999) and for boreal *Sphagnum* dominated peat deposits in North America (Tolonen *et al.*, 1988; Wieder *et al.*, 1994; Turetsky *et al.*, 2000).” Noting that recent rates of C accumulation are “strikingly higher” than long-term rates, Turunen *et al.* suggested that increased N deposition “leads to larger rates of C and N accumulation in the bogs, as has been found in European forests (Kauppi *et al.*, 1992; Berg and Matzner, 1997), and could account for some of the missing C sink in the global C budget.”

Returning to the role of temperature, Payette *et al.* (2004) quantified the main patterns of change in a subarctic peatland on the eastern coast of Canada’s Hudson Bay, which were caused by permafrost decay between 1957 and 2003, based on detailed surveys conducted in 1973, 1983, 1993 and 2003. This work revealed there was continuous permafrost thawing throughout the period of observation, such that “about 18 percent of the initial frozen peatland surface was melted in 1957,” while thereafter “accelerated thawing occurred with only 38 percent, 28 percent and 13 percent of the original frozen surface still remaining in 1983, 1993 and 2003, respectively.” This process, in their words, was one of “terrestrialization” via the establishment of fen/bog vegetation, which nearly always results in either no net loss of carbon or actual carbon sequestration. As a result, Payette *et al.* concluded that “contrary to current expectations, the melting of permafrost caused by recent climate change does *not* [our italics] transform the peatland to a carbon-source ecosystem.” Instead, they say that “rapid terrestrialization exacerbates carbon-sink conditions and tends to balance the local carbon budget.”

In a study of experimental warming of Icelandic plant communities designed to see if the warming of high-latitude tundra ecosystems would result in significant losses of species and reduced biodiversity, Jonsdottir *et al.* (2005) conducted a field experiment to learn how vegetation might respond to moderate warming at the low end of what is predicted by most climate models for a doubling of the air’s CO<sub>2</sub> content. Specifically, they studied the effects of 3-5 years of modest surface warming (1°-2°C) on two widespread but contrasting tundra plant communities, one of which was a nutrient-deficient and species-poor moss heath and the other of which was a

species-rich dwarf shrub heath. At the conclusion of the study, no changes in community structure were detected in the moss heath. In the dwarf shrub heath, on the other hand, the number of deciduous and evergreen dwarf shrubs increased more than 50 percent, bryophytes decreased by 18 percent, and canopy height increased by 100 percent, but with the researchers reporting they “detected no changes in species richness or other diversity measures in either community and the abundance of lichens did not change.” Although Jonsdottir *et al.*'s study was a relatively short-term experiment as far as ecosystem studies go, its results indicate a rise in temperature need not have a negative effect on the species diversity of high-latitude tundra ecosystems and may have a positive influence on plant growth.

In a study that included an entirely new element of complexity, Cole *et al.* (2002) constructed 48 small microcosms from soil and litter they collected near the summit of Great Dun Fell, Cumbria, England. Subsequent to “defaunating” this material by reducing its temperature to  $-80^{\circ}\text{C}$  for 24 hours, they thawed and inoculated it with native soil microbes, after which half of the microcosms were incubated in the dark at  $12^{\circ}\text{C}$  and half at  $18^{\circ}\text{C}$  for two weeks, in order to establish near-identical communities of the soils' natural complement of microflora in each microcosm. The former of these temperatures was chosen to represent mean August soil temperature at a depth of 10 cm at the site of soil collection, while the latter was picked to be “close to model predictions for soil warming that might result from a doubling of  $\text{CO}_2$  in blanket peat environments.”

Next, 10 seedlings of *Festuca ovina*, an indigenous grass of blanket peat, were planted in each of the microcosms, while 100 enchytraeid worms were added to each of half of the mini-ecosystems, producing four experimental treatments: ambient temperature, ambient temperature plus enchytraeid worms, elevated temperature, and elevated temperature plus enchytraeid worms. Then, the 48 microcosms—sufficient to destructively harvest three replicates of each treatment four different times throughout the course of the 64-day experiment—were arranged in a fully randomized design and maintained at either  $12^{\circ}$  or  $18^{\circ}\text{C}$  with alternating 12-hour light and dark periods, while being given distilled water every two days to maintain their original weights.

So what did the researchers learn? First, they found that elevated temperature reduced the ability of the enchytraeid worms to enhance the loss of carbon

from the microcosms. At the normal ambient temperature, the presence of the worms enhanced dissolved organic carbon (DOC) loss by 16 percent, while at the elevated temperature expected for a doubling of the air's  $\text{CO}_2$  content they had no effect on DOC. In addition, Cole *et al.* note that “warming may cause drying at the soil surface, forcing enchytraeids to burrow to deeper subsurface horizons;” and since the worms are known to have little influence on soil carbon dynamics below a depth of about 4 cm (Cole *et al.*, 2000), the researchers concluded that this additional consequence of warming would further reduce the ability of enchytraeids to enhance carbon loss from blanket peatlands. In summing up their findings, Cole *et al.* concluded that “the soil biotic response to warming in this study was negative,” in that it resulted in a reduced loss of carbon to the atmosphere.

But what about the effects of elevated  $\text{CO}_2$  itself on the loss of DOC from soils? Freeman *et al.* (2004) note that riverine transport of DOC has increased markedly in many places throughout the world over the past few decades (Schindler *et al.*, 1997; Freeman *et al.*, 2001; Worrall *et al.*, 2003); they suggest this phenomenon may be related to the historical increase in the air's  $\text{CO}_2$  content.

The researchers' first piece of evidence for this conclusion came from a three-year study of monoliths (11-cm diameter x 20-cm deep cores) taken from three Welsh peatlands—a bog that received nutrients solely from rainfall, a *fen* that gained more nutrients from surrounding soils and groundwater, and a riparian peatland that gained even more nutrients from nutrient-laden water transported from other terrestrial ecosystems via drainage streams—which they exposed to either ambient air or air enriched with an extra 235 ppm of  $\text{CO}_2$  within a solardome facility. This study revealed that the DOC released by monoliths from the three peatlands was significantly enhanced—by 14 percent in the bog, 49 percent in the fen, and 61 percent in the riparian peatland—by the additional  $\text{CO}_2$  to which they were exposed, which is the order of response one would expect from what we know about the stimulation of net primary productivity due to atmospheric  $\text{CO}_2$  enrichment, i.e., it is low in the face of low soil nutrients, intermediate when soil nutrient concentrations are intermediate, and high when soil nutrients are present in abundance. Consequently, Freeman *et al.* concluded that the DOC increases they observed “were induced by increased primary production and DOC exudation from plants,”

which conclusion logically follows from their findings.

Nevertheless, and to further test their hypothesis, they followed the translocation of labeled  $^{13}\text{C}$  through the plant-soil systems of the different peat monoliths for about two weeks after exposing them to ~99 percent-pure  $^{13}\text{CO}_2$  for a period of five hours. This exercise revealed that (1) the plants in the ambient-air and  $\text{CO}_2$ -enriched treatments assimilated 22.9 and 35.8 mg of  $^{13}\text{C}$  from the air, respectively, (2) the amount of DOC that was recovered from the leachate of the  $\text{CO}_2$ -enriched monoliths was 0.6 percent of that assimilated, or 0.215 mg ( $35.8 \text{ mg} \times 0.006 = 0.215 \text{ mg}$ ), and (3) the proportion of DOC in the soil solution of the  $\text{CO}_2$ -enriched monoliths that was derived from recently assimilated  $\text{CO}_2$  (the  $^{13}\text{C}$  labeled  $\text{CO}_2$ ) was 10 times higher than that of the control.

This latter observation suggests that the amount of DOC recovered from the leachate of the ambient-air monoliths was only about a tenth as much as that recovered from the leachate of the  $\text{CO}_2$ -enriched monoliths, which puts the former amount at about 0.022 mg. Hence, what really counts, i.e., the net sequestration of  $^{13}\text{C}$  experienced by the peat monoliths over the two-week period (which equals the amount that went into them minus the amount that went out), comes to 22.9 mg minus 0.022 mg = 22.878 mg for the ambient-air monoliths and 35.8 mg minus 0.215 mg = 35.585 mg for the  $\text{CO}_2$ -enriched monoliths. In the end, therefore, even though the  $\text{CO}_2$ -enriched monoliths lost 10 times more  $^{13}\text{C}$  via root exudation than did the ambient-air monoliths, they still sequestered about 55 percent more  $^{13}\text{C}$  overall, primarily in living-plant tissues.

In light of this impressive array of pertinent findings, it would appear that continued increases in the air's  $\text{CO}_2$  concentration and temperature would not result in losses of carbon from earth's peatlands. Quite to the contrary, these environmental changes—if they persist—would likely work together to enhance carbon capture by these particular ecosystems.

Additional information on this topic, including reviews of newer publications as they become available, can be found at <http://www.co2science.org/subject/c/carbonpeat.php>.

## 7.8. Other Benefits

Other benefits to plants of CO<sub>2</sub> enhancement documented in this section include superior nitrogen-use efficiency, increased nutrient acquisition, greater resistance to pathogens and parasitic plants, greater root development, greater seed and tannin production, and improved performance of transgenic plants. In addition to these benefits to plants, CO<sub>2</sub> enrichment benefits all life on earth by reducing plant emissions of isoprene, a chemical responsible for the production of tropospheric ozone.

### 7.8.1. Nitrogen-Use Efficiency

Long-term exposure to elevated atmospheric CO<sub>2</sub> concentrations often, but not always, elicits photosynthetic acclimation or down regulation in plants, which is typically accompanied by reduced amounts of rubisco and/or other photosynthetic proteins that are typically present in excess amounts in plants grown in ambient air. As a consequence, foliar nitrogen concentrations often decrease with atmospheric CO<sub>2</sub> enrichment, as nitrogen is mobilized out of leaves and into other areas of the plant to increase its availability for enhancing sink development or stimulating other nutrient-limited processes.

In reviewing the literature in this area, one quickly notices that in spite of the fact that photosynthetic acclimation has occurred, CO<sub>2</sub>-enriched plants nearly always display rates of photosynthesis that are greater than those of control plants exposed to ambient air. Consequently, photosynthetic nitrogen-use efficiency, i.e., the amount of carbon converted into sugars during the photosynthetic process per unit of leaf nitrogen, often increases dramatically in CO<sub>2</sub>-enriched plants.

In the study of Davey *et al.* (1999), for example, CO<sub>2</sub>-induced reductions in foliar nitrogen contents and concomitant increases in photosynthetic rates led to photosynthetic nitrogen-use efficiencies in the CO<sub>2</sub>-enriched (to 700 ppm CO<sub>2</sub>) grass *Agrostis capillaris* that were 27 and 62 percent greater than those observed in control plants grown at 360 ppm CO<sub>2</sub> under moderate and low soil nutrient conditions,

respectively. Similarly, elevated CO<sub>2</sub> enhanced photosynthetic nitrogen-use efficiencies in *Trifolium repens* by 66 and 190 percent under moderate and low soil nutrient conditions, respectively, and in *Lolium perenne* by 50 percent, regardless of soil nutrient status. Other researchers have found comparable CO<sub>2</sub>-induced enhancements of photosynthetic nitrogen-use efficiency in wheat (Osborne *et al.*, 1998) and in *Leucadendron* species (Midgley *et al.*, 1999).

In some cases, researchers report nitrogen-use efficiency in terms of the amount of biomass produced per unit of plant nitrogen. Niklaus *et al.* (1998), for example, reported that intact swards of CO<sub>2</sub>-enriched calcareous grasslands grown at 600 ppm CO<sub>2</sub> attained total biomass values that were 25 percent greater than those of control swards exposed to ambient air while extracting the same amount of nitrogen from the soil as ambiently grown swards. Similar results have been reported for strawberry by Deng and Woodward (1998), who noted that the growth nitrogen-use efficiencies of plants grown at 560 ppm CO<sub>2</sub> were 23 and 17 percent greater than those of ambiently grown plants simultaneously subjected to high and low soil nitrogen availability, respectively.

In conclusion, the scientific literature indicates that as the air's CO<sub>2</sub> content continues to rise, earth's plants will likely respond by reducing the amount of nitrogen invested in rubisco and other photosynthetic proteins, while still maintaining enhanced rates of photosynthesis, which consequently should increase their photosynthetic nitrogen-use efficiencies. As overall plant nitrogen-use efficiency increases, it is likely plants will grow ever better on soils containing less-than-optimal levels of nitrogen, a point addressed in more detail in Section 7.3.7 of this report.

## 7.8.2. Nutrient Acquisition

Most species of plants respond to increases in the air's CO<sub>2</sub> content by displaying enhanced rates of photosynthesis and biomass production. Oftentimes, the resulting growth stimulation is preferentially expressed belowground, thereby causing significant increases in fine-root numbers and surface area. This phenomenon tends to increase total nutrient uptake under CO<sub>2</sub>-enriched conditions, which further stimulates plant growth and development. In this summary, we review how the acquisition of plant nutrients—primarily nitrate and phosphate—is affected by atmospheric CO<sub>2</sub> enrichment. The effects of elevated CO<sub>2</sub> on nitrogen fixation are addressed elsewhere (Sections 7.3.7 and 7.8.1) and more research on the effects of CO<sub>2</sub> enhancement on roots appears in Section 7.8.5.

Smart *et al.* (1998) noted there were no differences on a per-unit-biomass basis in the total amounts of nitrogen within CO<sub>2</sub>-enriched and ambiently grown wheat seedlings after three weeks of exposure to atmospheric CO<sub>2</sub> concentrations of 360 and 1,000 ppm. Nevertheless, the CO<sub>2</sub>-enriched seedlings exhibited greater rates of soil nitrate extraction than did the ambiently grown plants. Similarly, BassiriRad *et al.* (1998) reported that a doubling of the atmospheric CO<sub>2</sub> concentration doubled the uptake rate of nitrate in the C<sub>4</sub> grass *Bouteloua eriopoda*. However, they also reported that elevated CO<sub>2</sub> had no effect on the rate of nitrate uptake in *Prosopis*, and that it decreased the rate of nitrate uptake by 55 percent in *Larrea*. Nonetheless, atmospheric CO<sub>2</sub> enrichment increased total biomass in these two species by 55 and 69 percent, respectively. Thus, although the uptake rate of this nutrient was depressed under elevated CO<sub>2</sub> conditions

in the latter species, the much larger CO<sub>2</sub>-enriched plants likely still extracted more total nitrate from the soil than did the ambiently grown plants of the experiment.

Nasholm *et al.* (1998) determined that trees, grasses and shrubs can all absorb significant amounts of organic nitrogen from soils. Thus, plants do not have to wait for the mineralization of organic nitrogen before they extract the nitrogen they need from soils to support their growth and development. Hence, the forms of nitrogen removed from soils by plants (nitrate vs. ammonium) and their abilities to remove different forms may not be as important as was once thought.

With respect to the uptake of phosphate, Staddon *et al.* (1999) reported that *Plantago lanceolata* and *Trifolium repens* plants grown at 650 ppm CO<sub>2</sub> for 2.5 months exhibited total plant phosphorus contents that were much greater than those displayed by plants grown at 400 ppm CO<sub>2</sub>, due to the fact that atmospheric CO<sub>2</sub> enrichment significantly enhanced plant biomass. Similarly, Rouhier and Read (1998) reported that enriching the air around *Plantago lanceolata* plants with an extra 190 ppm of CO<sub>2</sub> for a period of three months led to increased uptake of phosphorus and greater tissue phosphorus concentrations than were observed in plants growing in ambient air.

Greater uptake of phosphorus also can occur due to CO<sub>2</sub>-induced increases in root absorptive surface area or enhancements in specific enzyme activities. In addressing the first of these phenomena, BassiriRad *et al.* (1998) reported that a doubling of the atmospheric CO<sub>2</sub> concentration significantly increased the belowground biomass of *Bouteloua eriopoda* and doubled its uptake rate of phosphate. However, elevated CO<sub>2</sub> had no effect on uptake rates of phosphate in *Larrea* and *Prosopis*. Because the CO<sub>2</sub>-enriched plants grew so much bigger, they still removed more phosphate from the soil on a per-plant basis. With respect to the second phenomenon, phosphatase—the primary enzyme responsible for the conversion of organic phosphate into usable inorganic forms—had its activity increased by 30 to 40 percent in wheat seedlings growing at twice-ambient CO<sub>2</sub> concentrations (Barrett *et al.*, 1998).

In summary, as the CO<sub>2</sub> content of the air increases, experimental data to date suggest that much of earth's vegetation will likely extract enhanced amounts of mineral nutrients from the soils in which they are rooted.

### 7.8.3. Pathogens

As the air's CO<sub>2</sub> content continues to rise, it is natural to wonder—and important to determine—how this phenomenon may impact plant-pathogen interactions. One thing we know about the subject is that atmospheric CO<sub>2</sub> enrichment nearly always enhances photosynthesis, which commonly leads to increased plant production of carbon-based secondary compounds, including lignin and various phenolics, both of which substances tend to increase plant resistance to pathogen attack.

Enlarging upon this topic, Chakraborty and Datta (2003) report that “changes in plant physiology,

anatomy and morphology that have been implicated in increased resistance or [that] can potentially enhance host resistance at elevated CO<sub>2</sub> include: increased net photosynthesis allowing mobilization of resources into host resistance (Hibberd *et al.*, 1996a.); reduced stomatal density and conductance (Hibberd *et al.*, 1996b); greater accumulation of carbohydrates in leaves; more waxes, extra layers of epidermal cells and increased fibre content (Owensby, 1994); production of papillae and accumulation of silicon at penetration sites (Hibberd *et al.*, 1996a); greater number of mesophyll cells (Bowes, 1993); and increased biosynthesis of phenolics (Hartley *et al.*, 2000), among others.”

Chakraborty and Datta found another way atmospheric CO<sub>2</sub> enrichment may tip the scales in favor of plants in a study of the aggressiveness of the fungal anthracnose pathogen *Colletotrichum gloeosporioides*. They inoculated two isolates of the pathogen onto two cultivars of the tropical pasture legume *Stylosanthes scabra* (Fitzroy, which is susceptible to the fungal pathogen, and Seca, which is more resistant) over the course of 25 sequential infection cycles at ambient (350 ppm) and elevated (700 ppm) atmospheric CO<sub>2</sub> concentrations in controlled environment chambers. This protocol revealed that “at twice-ambient CO<sub>2</sub> the overall level of aggressiveness of the two [pathogen] isolates was significantly reduced on both [host] cultivars.” In addition, they say that “as shown previously (Chakraborty *et al.*, 2000), the susceptible Fitzroy develops a level of resistance to anthracnose at elevated CO<sub>2</sub>, but resistance in Seca remains largely unchanged.” Simultaneously, however, pathogen fecundity was found to increase at twice-ambient CO<sub>2</sub>. Of this finding, they report that their results “concur with the handful of studies that have demonstrated increased pathogen fecundity at elevated CO<sub>2</sub> (Hibberd *et al.*, 1996a; Klironomos *et al.*, 1997; Chakraborty *et al.*, 2000).” How this happened in the situation they investigated, as they describe it, is that the overall increase in fecundity at high CO<sub>2</sub> “is a reflection of the altered canopy environment,” wherein “the 30 percent larger *S. scabra* plants at high CO<sub>2</sub> (Chakraborty *et al.*, 2000) makes the canopy microclimate more conducive to anthracnose development.”

In view of the opposing changes induced in pathogen behavior by elevated levels of atmospheric CO<sub>2</sub> in this specific study—reduced aggressiveness but increased fecundity—it is difficult to know the outcome of atmospheric CO<sub>2</sub> enrichment for the

pathogen-host relationship. More research, especially under realistic field conditions, will be needed to clarify the situation; and, of course, different results are likely to be observed for different pathogen-host associations. Results also could differ under different climatic conditions. Nevertheless, the large number of ways in which elevated CO<sub>2</sub> has been demonstrated to increase plant resistance to pathogen attack suggests that plants may well gain the advantage over pathogens as the air’s CO<sub>2</sub> content continues to climb in the years ahead.

McElrone *et al.* (2005) “assessed how elevated CO<sub>2</sub> affects a foliar fungal pathogen, *Phyllosticta minima*, of *Acer rubrum* [red maple] growing in the understory at the Duke Forest free-air CO<sub>2</sub> enrichment experiment in Durham, North Carolina, USA ... in the 6th, 7th, and 8th years of the CO<sub>2</sub> exposure.” Surveys conducted in those years, in their words, “revealed that elevated CO<sub>2</sub> [to 200 ppm above ambient] significantly reduced disease incidence, with 22%, 27% and 8% fewer saplings and 14%, 4%, and 5% fewer leaves infected per plant in the three consecutive years, respectively.” In addition, they report that the elevated CO<sub>2</sub> “also significantly reduced disease severity in infected plants in all years (e.g. mean lesion area reduced 35%, 50%, and 10% in 2002, 2003, and 2004, respectively).”

With respect to identifying the underlying mechanism or mechanisms that produced these beneficent consequences, thinking it could have been a direct deleterious effect of elevated CO<sub>2</sub> on the fungal pathogen, McElrone *et al.* performed some side experiments in controlled environment chambers. However, they found that the elevated CO<sub>2</sub> benefited the fungal pathogen as well as the red maple saplings, observing that “exponential growth rates of *P. minima* were 17% greater under elevated CO<sub>2</sub>.” And they obtained similar results when they repeated the *in vitro* growth analysis two additional times in different growth chambers.

Taking another tack when “scanning electron micrographs verified that conidia germ tubes of *P. minima* infect *A. rubrum* leaves by entering through the stomata,” the researchers turned their attention to the pathogen’s mode of entry into the saplings’ foliage. In this investigation they found that both stomatal size and density were unaffected by atmospheric CO<sub>2</sub> enrichment, but that “stomatal conductance was reduced by 21-36% under elevated CO<sub>2</sub>, providing smaller openings for infecting germ tubes.” They concluded that reduced disease severity under elevated CO<sub>2</sub> was likely due to altered leaf

chemistry, as elevated CO<sub>2</sub> increased total leaf phenolic concentrations by 15 percent and tannin concentrations by 14 percent.

Because the phenomena they found to be important in reducing the amount and severity of fungal pathogen infection (leaf spot disease) of red maple have been demonstrated to be operative in most other plants as well, McElrone *et al.* say these CO<sub>2</sub>-enhanced leaf defensive mechanisms “may be prevalent in many plant pathosystems where the pathogen targets the stomata.” They state their results “provide concrete evidence for a potentially generalizable mechanism to predict disease outcomes in other pathosystems under future climatic conditions.”

Malmstrom and Field (1997) grew individual oat plants for two months in pots within phytocells maintained at CO<sub>2</sub> concentrations of 350 and 700 ppm, while a third of each CO<sub>2</sub> treatment’s plants were infected with the barley yellow dwarf virus (BYDV), which plagues more than 150 plant species worldwide, including all major cereal crops. They found that the elevated CO<sub>2</sub> stimulated net photosynthesis rates in all plants, but with the greatest increase occurring in diseased individuals (48 percent vs. 34 percent). In addition, atmospheric CO<sub>2</sub> enrichment decreased stomatal conductance by 34 percent in healthy plants, but by 50 percent in infected ones, thus reducing transpirational water losses more in infected plants. Together, these two phenomena contributed to a CO<sub>2</sub>-induced doubling of the instantaneous water-use efficiency of healthy control plants, but to a much larger 2.7-fold increase in diseased plants. Thus, although BYDV infection did indeed reduce overall plant biomass production, the growth response to elevated CO<sub>2</sub> was greatest in the diseased plants. After 60 days of CO<sub>2</sub> enrichment, for example, total plant biomass increased by 36 percent in infected plants, while it increased by only 12 percent in healthy plants. In addition, while elevated CO<sub>2</sub> had little effect on root growth in healthy plants, it increased root biomass in infected plants by up to 60 percent. In their concluding remarks, therefore, Malmstrom and Field say that CO<sub>2</sub> enrichment “may reduce losses of infected plants to drought” and “may enable diseased plants to compete better with healthy neighbors.”

Tiedemann and Firsching (2000) grew spring wheat from germination to maturity in controlled environment chambers maintained at either ambient (377 ppm) or enriched (612 ppm) atmospheric CO<sub>2</sub> concentrations and either ambient (20 ppb) or

enriched (61 ppb) atmospheric ozone (O<sub>3</sub>) concentrations, while half of the plants in each of the four resulting treatments were inoculated with a leaf rust-causing pathogen. These procedures revealed that the percent of leaf area infected by rust in inoculated plants was largely unaffected by atmospheric CO<sub>2</sub> enrichment but strongly reduced by elevated O<sub>3</sub>. With respect to photosynthesis, elevated CO<sub>2</sub> increased rates in inoculated plants by 20 and 42 percent at ambient and elevated O<sub>3</sub> concentrations, respectively. Although inoculated plants produced lower yields than non-inoculated plants, atmospheric CO<sub>2</sub> enrichment still stimulated yield in infected plants, increasing it by fully 57 percent at high O<sub>3</sub>. Consequently, the beneficial effects of elevated CO<sub>2</sub> on wheat photosynthesis and yield continued to be expressed in the presence of both O<sub>3</sub> and pathogenic stresses.

In another joint CO<sub>2</sub>/O<sub>3</sub> study, Percy *et al.* (2002) grew the most widely distributed North American tree species—trembling aspen—in twelve 30-m-diameter free-air CO<sub>2</sub> enrichment (FACE) rings near Rhinelander, Wisconsin, USA in air maintained at ambient CO<sub>2</sub> and O<sub>3</sub> concentrations, ambient O<sub>3</sub> and elevated CO<sub>2</sub> (560 ppm during daylight hours), ambient CO<sub>2</sub> and elevated O<sub>3</sub> (46.4-55.5 ppb during daylight hours), and elevated CO<sub>2</sub> and O<sub>3</sub> over the period of each growing season from 1998 through 2001. Throughout this experiment they assessed a number of the young trees’ growth characteristics, as well as their responses to poplar leaf rust (*Melampsora medusae*), which they say “is common on aspen and belongs to the most widely occurring group of foliage diseases.” Their work revealed that elevated CO<sub>2</sub> alone did not alter rust occurrence, but that elevated O<sub>3</sub> alone increased it by nearly fourfold. When applied together, however, elevated CO<sub>2</sub> reduced the enhancement of rust development caused by elevated O<sub>3</sub> from nearly fourfold to just over twofold.

Jwa and Walling (2001) grew tomato plants in hydroponic culture for eight weeks in controlled environment chambers maintained at atmospheric CO<sub>2</sub> concentrations of 350 and 700 ppm. At week five of their study, half of the plants growing in each CO<sub>2</sub> concentration were infected with the fungal pathogen *Phytophthora parasitica*, which attacks plant roots and induces water stress that decreases plant growth and yield. This infection procedure reduced total plant biomass by nearly 30 percent at both atmospheric CO<sub>2</sub> concentrations. However, the elevated CO<sub>2</sub> treatment increased the total biomass of healthy and

infected plants by the same percentage, so that infected tomato plants grown at 700 ppm CO<sub>2</sub> exhibited biomass values similar to those of healthy tomato plants grown at 350 ppm CO<sub>2</sub>. Consequently, atmospheric CO<sub>2</sub> enrichment completely counterbalanced the negative effects of *Phytophthora parasitica* infection on tomato productivity.

Pangga *et al.* (2004) grew well-watered and fertilized pencilflower (cultivar Fitzroy) seedlings—an important legume crop susceptible to anthracnose disease caused by *Colletotrichum gloeosporioides*—within a controlled environment facility maintained at atmospheric CO<sub>2</sub> concentrations of either 350 or 700 ppm, where they inoculated six-, nine- and twelve-week-old plants with conidia of *C. gloeosporioides*. Then, ten days after inoculation, they counted the anthracnose lesions on the plants and classified them as either resistant or susceptible. In doing so, they found that “the mean number of susceptible, resistant, and total lesions per leaf averaged over the three plant ages was significantly ( $P < 0.05$ ) greater at 350 ppm than at 700 ppm CO<sub>2</sub>, reflecting the development of a level of resistance in susceptible cv. Fitzroy at high CO<sub>2</sub>.” With respect to plants inoculated at twelve weeks of age, they say that those grown “at 350 ppm had 60 and 75 percent more susceptible and resistant lesions per leaf, respectively, than those [grown] at 700 ppm CO<sub>2</sub>.” The Australian scientists say their work “clearly shows that at 350 ppm overall susceptibility of the canopy increases with increasing age because more young leaves are produced on secondary and tertiary branches of the more advanced plants.” However, “at 700 ppm CO<sub>2</sub>, infection efficiency did not increase with increasing plant age despite the presence of many more young leaves in the enlarged canopy,” which finding, in their words, “points to reduced pathogen efficiency or an induced partial resistance to anthracnose in Fitzroy at 700 ppm CO<sub>2</sub>.”

Finally, according to Plesl *et al.* (2007), “potato late blight caused by the oomycete *Phytophthora infestans* (Mont.) de Bary is the most devastating disease of potato worldwide,” adding that “infection occurs through leaves and tubers followed by a rapid spread of the pathogen finally causing destructive necrosis.” In an effort to ascertain the effects of atmospheric CO<sub>2</sub> enrichment on this pathogen, Plesl *et al.* grew individual well watered and fertilized plants of the potato cultivar Indira in 3.5-liter pots filled with a 1:2 mixture of soil and “Fruhstorfer T-Erde” in controlled-environment chambers maintained at atmospheric CO<sub>2</sub> concentrations of

either 400 or 700 ppm. Four weeks after the start of the experiment, the first three fully developed pinnate leaves were cut from the plants and inoculated with zoospores of *P. infestans* in Petri dishes containing water-agar, after which their symptoms were evaluated daily via comparison with control leaves that were similarly treated but unexposed to the pathogen.

Results of the German researchers analysis revealed that the 300 ppm increase in CO<sub>2</sub> “dramatically reduced symptom development,” including extent of necrosis (down by 44 percent four days after inoculation and 65 percent five days after inoculation), area of sporulation (down by 100 percent four days after inoculation and 61 percent five days after inoculation), and sporulation intensity (down by 73 percent four days after inoculation and 17 percent five days after inoculation). Plesl *et al.* conclude that their results “clearly demonstrated that the potato cultivar Indira, which under normal conditions shows a high susceptibility to *P. infestans*, develops resistance against this pathogen after exposure to 700 ppm CO<sub>2</sub>,” noting that “this finding agrees with results from Ywa *et al.* (1995), who reported an increased tolerance of tomato plants to *Phytophthora* root rot when grown at elevated CO<sub>2</sub>.” These similar observations bode well for both potato and tomato cultivation in a CO<sub>2</sub>-enriched world of the future.

In conclusion, the balance of evidence obtained to date demonstrates an enhanced ability of plants to withstand pathogen attacks in CO<sub>2</sub>-enriched as opposed to ambient-CO<sub>2</sub> air. As the atmosphere’s CO<sub>2</sub> concentration continues to rise in the years to come, earth’s vegetation should fare ever better in its battle against myriad debilitating plant diseases.

### 7.8.4. Parasitic Plants

Parasitic plants obtain energy, water and nutrients from their host plants and cause widespread reductions in harvestable crop yields around the globe. Hence, it is important to understand how rising atmospheric CO<sub>2</sub> levels may impact the growth of parasitic plants and the relationships between them and their hosts.

Matthies and Egli (1999) grew *Rhinanthus alectorolophus* (a widely distributed parasitic plant of Central Europe) for a period of two months on the grass *Lolium perenne* and the legume *Medicago sativa* in pots placed within open-top chambers maintained at atmospheric CO<sub>2</sub> concentrations of 375 and 590 ppm, half of which pots were fertilized to produce an optimal soil nutrient regime and half of which were unfertilized. At low nutrient supply, they found that atmospheric CO<sub>2</sub> enrichment decreased mean parasite biomass by an average of 16 percent, while at high nutrient supply it increased parasite biomass by an average of 123 percent. Nevertheless, the extra 215 ppm of CO<sub>2</sub> increased host plant biomass in both situations: by 29 percent under high soil nutrition and by 18 percent under low soil nutrition.

Dale and Press (1999) infected white clover (*Trifolium repens*) plants with *Orobancha minor* (a parasitic weed that primarily infects leguminous crops in the United Kingdom and the Middle East) and exposed them to atmospheric CO<sub>2</sub> concentrations of either 360 or 550 ppm for 75 days in controlled-environment growth cabinets. The elevated CO<sub>2</sub> in this study had no effect on the total biomass of parasite per host plant, nor did it impact the number of parasites per host plant or the time to parasitic attachment to host roots. On the other hand, whereas infected host plants growing in ambient air produced 47 percent less biomass than uninfected plants growing in ambient air, infected plants growing at 550 ppm CO<sub>2</sub> exhibited final dry weights that were only 20 percent less than those displayed by

uninfected plants growing in the CO<sub>2</sub>-enriched air, indicative of a significant CO<sub>2</sub>-induced partial alleviation of parasite-induced biomass reductions in the white clover host plants.

Watling and Press (1997) infected several C<sub>4</sub> sorghum plants with *Striga hermonthica* and *Striga asiatica* (parasitic C<sub>3</sub> weeds of the semi-arid tropics that infest many grain crops) and grew them, along with uninfected control plants, for approximately two months in controlled-environment cabinets maintained at atmospheric CO<sub>2</sub> concentrations of 350 and 700 ppm. In the absence of parasite infection, the extra 350 ppm of CO<sub>2</sub> increased sorghum biomass by approximately 36 percent. When infected with *S. hermonthica*, however, the sorghum plants grown at ambient and elevated CO<sub>2</sub> concentrations only produced 32 and 43 percent of the biomass displayed by their respective uninfected controls. Infection with *S. asiatica* was somewhat less stressful and led to host biomass production that was about half that of uninfected controls in both ambient and CO<sub>2</sub>-enriched air. The end result was that the doubling of the air's CO<sub>2</sub> content employed in this study increased sorghum biomass by 79 percent and 35 percent in the C<sub>4</sub> sorghum plants infected with *S. hermonthica* and *S. asiatica*, respectively.

Hwangbo *et al.* (2003) grew Kentucky Bluegrass (*Poa pratensis* L.) with and without infection by the C<sub>3</sub> chlorophyllous parasitic angiosperm *Rhinanthus minor* L. (a facultative hemiparasite found in natural and semi-natural grasslands throughout Europe) for eight weeks in open-top chambers maintained at ambient and elevated (650 ppm) CO<sub>2</sub> concentrations. At the end of the study, the parasite's biomass (when growing on its host) was 47 percent greater in the CO<sub>2</sub>-enriched chambers, while its host exhibited only a 10 percent CO<sub>2</sub>-induced increase in biomass in the parasite's absence but a nearly doubled 19 percent increase when infected by it.

Watling and Press (2000) grew upland rice (*Oryza sativa* L.) in pots in controlled-environment chambers maintained at 350 and 700 ppm CO<sub>2</sub> in either the presence or absence of the root parasite *S. hermonthica* for a period of 80 days after sowing, after which time the plants were harvested and weighed. In ambient air, the presence of the parasite reduced the biomass of the rice to only 35 percent of what it was in the absence of the parasite; whereas in air enriched with CO<sub>2</sub> the presence of the parasite reduced the biomass of infected plants to but 73 percent of what it was in the absence of the parasite.

In summary, these several observations suggest that the rising CO<sub>2</sub> content of the air can have wide and variable effects on parasitic plants, ranging from negative to positive growth responses, depending upon soil nutrition and host plant specificity. With respect to the infected host plants, elevated CO<sub>2</sub> generally tends to reduce the negative effects of parasitic infection, so that infected host plants continue to exhibit positive growth responses to elevated CO<sub>2</sub>. It is likely that whatever the scenario with regard to parasitic infection, host plants will fare better under higher atmospheric CO<sub>2</sub> conditions than they do currently.

Additional information on this topic, including reviews of newer publications as they become available, can be found at <http://www.co2science.org/subject/p/parasites.php>.

### 7.8.5. Roots

In reviewing the scientific literature pertaining to atmospheric CO<sub>2</sub> enrichment effects on belowground plant growth and development, Weihong *et al.* (2000) briefly summarize what is known about this subject. They report that atmospheric CO<sub>2</sub> enrichment

typically enhances the growth rates of roots, especially those of fine roots, and that CO<sub>2</sub>-induced increases in root production eventually lead to increased carbon inputs to soils, due to enhanced root turnover and exudation of various organic carbon compounds, which can potentially lead to greater soil carbon sequestration. In addition, they note that increased soil carbon inputs stimulate the growth and activities of soil microorganisms that utilize plant-derived carbon as their primary energy source; and they report that subsequently enhanced activities of fungal and bacterial plant symbionts often lead to increased plant nutrient acquisition.

In a much more narrowly focused study, Crookshanks *et al.* (1998) sprouted seeds of the small and fast-growing *Arabidopsis thaliana* plant on agar medium in Petri dishes and grew the resulting immature plants in controlled environment chambers maintained at atmospheric CO<sub>2</sub> concentrations of either 355 or 700 ppm. Visual assessments of root growth were made after emergence of the roots from the seeds, while microscopic investigations of root cell properties were also conducted. The scientists learned that the CO<sub>2</sub>-enriched plants directed a greater proportion of their newly produced biomass into root, as opposed to shoot, growth. In addition, the young plants produced longer primary roots and more and longer lateral roots. These effects were found to be related to the CO<sub>2</sub>-induced stimulation of mitotic activity, accelerated cortical cell expansion, and increased cell wall plasticity.

Gouk *et al.* (1999) grew an orchid plantlet, Mokara Yellow, in plastic bags flushed with 350 and 10,000 ppm CO<sub>2</sub> for three months to study the effects of elevated CO<sub>2</sub> on this epiphytic CAM species. They determined that the super-elevated CO<sub>2</sub> of their experiment enhanced the total dry weight of the orchid plantlets by more than two-fold, while increasing the growth of existing roots and stimulating the induction of new roots from internodes located on the orchid stems. Total chlorophyll content was also increased by elevated CO<sub>2</sub>—by 64 percent in young leaves and by 118 percent in young roots. This phenomenon permitted greater light harvesting during photosynthesis and likely led to the tissue starch contents of the CO<sub>2</sub>-enriched plantlets rising nearly 20-fold higher than those of the control-plantlets. In spite of this large CO<sub>2</sub>-induced accumulation of starch, however, no damage or disruption of chloroplasts was evident in the leaves and roots of the CO<sub>2</sub>-enriched plants.

A final question that has periodically intrigued researchers is whether plants take up carbon through their roots in addition to through their leaves. Although a definitive answer eludes us, various aspects of the issue have been described by Idso (1989), who we quote as follows.

“Although several investigators have claimed that plants should receive little direct benefit from dissolved CO<sub>2</sub> (Stolwijk *et al.*, 1957; Skok *et al.*, 1962; Splittstoesser, 1966), a number of experiments have produced significant increases in root growth (Erickson, 1946; Leonard and Pinckard, 1946; Geisler, 1963; Yorgalevitch and Janes, 1988), as well as yield itself (Kursanov *et al.*, 1951; Grinfeld, 1954; Nakayama and Bucks, 1980; Baron and Gorski, 1986), with CO<sub>2</sub>-enriched irrigation water. Early on, Misra (1951) suggested that this beneficent effect may be related to CO<sub>2</sub>-induced changes in soil nutrient availability; and this hypothesis may well be correct. Arteca *et al.* (1979), for example, have observed K, Ca and Mg to be better absorbed by potato roots when the concentration of CO<sub>2</sub> in the soil solution is increased; while Mauney and Hendrix (1988) found Zn and Mn to be better absorbed by cotton under such conditions, and Yurgalevitch and Janes (1988) found an enhancement of the absorption of Rb by tomato roots. In all cases, large increases in either total plant growth or yield accompanied the enhanced uptake of nutrients. Consequently, as it has been suggested that CO<sub>2</sub> concentration plays a major role in determining the porosity, plasticity and charge of cell membranes (Jackson and Coleman, 1959; Mitz, 1979), which could thereby alter ion uptake and organic acid production (Yorgalevitch and Janes, 1988), it is possible that some such suite of mechanisms may well be responsible for the plant productivity increases often observed to result from enhanced concentrations of CO<sub>2</sub> in the soil solution.”

In the next two sections we survey the scientific literature on root responses to atmospheric CO<sub>2</sub> enrichment for crops and then trees.

#### 7.8.5.1. Crops

Hodge and Millard (1998) grew narrowleaf plantain (*Plantago lanceolata*) seedlings for a period of six weeks in controlled environment growth rooms maintained at atmospheric CO<sub>2</sub> concentrations of either 400 or 800 ppm. By the end of this period, the plants in the 800-ppm air exhibited increases in shoot and root dry matter production that were 159 percent and 180 percent greater, respectively, than the corresponding dry matter increases experienced by the plants growing in 400-ppm air, while the amount of plant carbon recovered from the potting medium (sand) was 3.2 times greater in the elevated-CO<sub>2</sub> treatment. Thus, these investigators found that the belowground growth stimulation provided by atmospheric CO<sub>2</sub> enrichment was greater than that experienced above-ground.

Wechsung *et al.* (1999) grew spring wheat (*Triticum aestivum*) in rows in a FACE study employing atmospheric CO<sub>2</sub> concentrations of 370 and 550 ppm and irrigation treatments that periodically replaced either 50 percent or 100 percent of prior potential evapotranspiration in an effort to determine the effects of elevated CO<sub>2</sub> and water stress on root growth. They found that elevated CO<sub>2</sub> increased in-row root dry weight by an average of 22 percent during the growing season under both the wet and dry irrigation regimes. In addition, during the vegetative growth phase, atmospheric CO<sub>2</sub> enrichment increased inter-row root dry weight by 70 percent, indicating that plants grown in elevated CO<sub>2</sub> developed greater lateral root systems than plants grown at ambient CO<sub>2</sub>. During the reproductive growth phase, elevated CO<sub>2</sub> stimulated the branching

of lateral roots into inter-row areas, but only when water was limiting to growth. In addition, the CO<sub>2</sub>-enriched plants tended to display greater root dry weights at a given depth than did ambiently grown plants.

In a comprehensive review of all prior FACE experiments conducted on agricultural crops, Kimball *et al.* (2002) determined that for a 300-ppm increase in atmospheric CO<sub>2</sub> concentration, the root biomass of wheat, ryegrass and rice experienced an average increase of 70 percent at ample water and nitrogen, 58 percent at low nitrogen and 34 percent at low water, while clover experienced a 38 percent increase at ample water and nitrogen, plus a 32 percent increase at low nitrogen. Outdoing all of the other crops was cotton, which exhibited a 96 percent increase in root biomass at ample water and nitrogen.

Zhao *et al.* (2000) germinated pea (*Pisum sativum*) seeds and exposed the young plants to various atmospheric CO<sub>2</sub> concentrations in controlled environment chambers to determine if elevated CO<sub>2</sub> impacts root border cells, which are major contributors of root exudates in this and most other agronomic plants. They found that elevated CO<sub>2</sub> increased the production of root border cells in pea seedlings. In going from ambient air to air enriched to 3,000 and 6,000 ppm CO<sub>2</sub>, border-cell numbers increased by over 50 percent and 100 percent, respectively. Hence, as the CO<sub>2</sub> content of the air continues to rise, peas (and possibly many other crop plants) will likely produce greater numbers of root border cells, which should increase the amounts of root exudations occurring in their rhizospheres, which further suggests that associated soil microbial and fungal activities will be stimulated as a result of the increases in plant-derived carbon inputs that these organisms require to meet their energy needs.

Van Ginkel *et al.* (1996) grew perennial ryegrass (*Lolium perenne*) plants from seed in two growth chambers for 71 days under continuous <sup>14</sup>CO<sub>2</sub>-labeling of the atmosphere at CO<sub>2</sub> concentrations of 350 and 700 ppm at two different soil nitrogen levels. At the conclusion of this part of the experiment, the plants were harvested and their roots dried, pulverized and mixed with soil in a number of one-liter pots that were placed within two wind tunnels in an open field, one of which had ambient air of 361 ppm CO<sub>2</sub> flowing through it, and one of which had air of 706 ppm CO<sub>2</sub> flowing through it. Several of the containers were then seeded with more *Lolium perenne*, others were similarly seeded the following year, and still others were kept bare for two years. Then, at the ends

of the first and second years, the different degrees of decomposition of the original plant roots were assessed.

It was determined, first, that shoot and root growth were enhanced by 13 and 92 percent, respectively, by the extra CO<sub>2</sub> in the initial 71-day portion of the experiment, once again demonstrating the significant benefits that are often conferred upon plant roots by atmospheric CO<sub>2</sub> enrichment. Secondly, it was found that the decomposition of the high-CO<sub>2</sub>-grown roots in the high-CO<sub>2</sub> wind tunnel was 19 percent lower than that of the low-CO<sub>2</sub>-grown roots in the low-CO<sub>2</sub> wind tunnel at the end of the first year, and that it was 14 percent lower at the end of the second year in the low-nitrogen-grown plants but equivalent in the high-nitrogen-grown plants. It was also determined that the presence of living roots reduced the decomposition rate of dead roots below the dead-root-only decomposition rate observed in the bare soil treatment. Based on these findings, van Ginkel *et al.* conclude that “the combination of higher root yields at elevated CO<sub>2</sub> combined with a decrease in root decomposition will lead to a longer residence time of C in the soil and probably to a higher C storage.”

In conclusion, as the CO<sub>2</sub> content of the air continues to rise, many crops will likely develop larger and more extensively branching root systems that may help them to better cope with periods of reduced soil moisture availability. This chain of events should make the soil environment even more favorable for plant growth and development in a high-CO<sub>2</sub> world of the future.

#### 7.8.5.2. Trees

Janssens *et al.* (1998) grew three-year-old Scots pine seedlings for a period of six months in open-top chambers maintained at ambient and 700 ppm atmospheric CO<sub>2</sub>, finding that the extra CO<sub>2</sub> increased total root length by 122 percent and total root dry mass by 135 percent. In a similar study that employed close to the same degree of enhancement of the air's CO<sub>2</sub> content, Pritchard *et al.* (2001a) grew idealized ecosystems representative of regenerating longleaf pine forests of the southeastern USA for a period of 18 months in large soil bins located within open-top chambers. The above-ground parts of these seedlings experienced a growth enhancement of 20 percent. The root biomass of the trees, however, was increased by more than three times as much (62 percent).

Working with FACE technology, Pritchard *et al.* (2001b) studied 14-year-old loblolly pine trees after a year of exposure to an extra 200 ppm of CO<sub>2</sub>, finding that total standing root length and root numbers were 16 and 34 percent greater, respectively, in the CO<sub>2</sub>-enriched plots than in the ambient-air plots. In addition, the elevated CO<sub>2</sub> increased the diameter of living and dead roots by 8 and 6 percent, respectively, while annual root production was found to be 26 percent greater in the CO<sub>2</sub>-enriched plots. For the degree of CO<sub>2</sub> enrichment employed in the prior two studies, this latter enhancement corresponds to a root biomass increase of approximately 45 percent.

In an open-top chamber study of a model ecosystem composed of a mixture of spruce and beech seedlings, Wiemken *et al.* (2001) investigated the effects of a 200 ppm increase in the air's CO<sub>2</sub> concentration that prevailed for a period of four years. On nutrient-poor soils, the extra CO<sub>2</sub> led to a 30 percent increase in fine-root biomass, while on nutrient-rich soils it led to a 75 percent increase. These numbers correspond to increases of about 52 percent and 130 percent, respectively, for atmospheric

CO<sub>2</sub> enhancements on the order of those employed by Janssens *et al.* (1998) and Pritchard *et al.* (2001a).

Another interesting aspect of the Wiemken *et al.* study was their finding that the extra CO<sub>2</sub> increased the amount of symbiotic fungal biomass associated with the trees' fine roots by 31 percent on nutrient-poor soils and by 100 percent on nutrient-rich soils, which for the degree of atmospheric CO<sub>2</sub> enrichment used in the studies of Janssens *et al.* (1998) and Pritchard *et al.* (2001a) translate into increases of about 52 percent and 175 percent, respectively.

Berntsen and Bazzaz (1998) removed intact chunks of soil from the Hardwood-White Pine-Hemlock forest region of New England and placed them in plastic containers within controlled environment glasshouses maintained at either 375 or 700 ppm CO<sub>2</sub> for a period of two years in order to study the effects of elevated CO<sub>2</sub> on the regeneration of plants from seeds and rhizomes present in the soil. At the conclusion of the study, total mesocosm plant biomass (more than 95 percent of which was supplied by yellow and white birch tree seedlings) was found to be 31 percent higher in the elevated CO<sub>2</sub> treatment than in ambient air, with a mean enhancement of 23 percent above-ground and 62 percent belowground. The extra CO<sub>2</sub> also increased the mycorrhizal colonization of root tips by 45 percent in white birch and 71 percent in yellow birch; and the CO<sub>2</sub>-enriched yellow birch seedlings exhibited 322 percent greater root length and 305 percent more root surface area than did the yellow birch seedlings growing in ambient air.

Kubiske *et al.* (1998) grew cuttings of four quaking aspen genotypes in open-top chambers for five months at atmospheric CO<sub>2</sub> concentrations of either 380 or 720 ppm and low or high soil nitrogen concentrations. They found, surprisingly, that the cuttings grown in elevated CO<sub>2</sub> displayed no discernible increases in above-ground growth. However, the extra CO<sub>2</sub> significantly increased fine-root length and root turnover rates at high soil nitrogen by increasing fine-root production, which would logically be expected to produce benefits (not the least of which would be a larger belowground water- and nutrient-gathering system) that would eventually lead to enhanced above-ground growth as well.

Expanding on this study, Pregitzer *et al.* (2000) grew six quaking aspen genotypes for 2.5 growing seasons in open-top chambers maintained at atmospheric CO<sub>2</sub> concentrations of 350 and 700 ppm with both adequate and inadequate supplies of soil

nitrogen. This work demonstrated that the trees exposed to elevated CO<sub>2</sub> developed thicker and longer roots than the trees growing in ambient air, and that the fine-root biomass of the CO<sub>2</sub>-enriched trees was enhanced by 17 percent in the nitrogen-poor soils and by 65 percent in the nitrogen-rich soils.

Yet another study of quaking aspen conducted by King *et al.* (2001) demonstrated that trees exposed to an atmospheric CO<sub>2</sub> concentration 560 ppm in a FACE experiment produced 133 percent more fine-root biomass than trees grown in ambient air of 360 ppm, which roughly equates to 233 percent more fine-root biomass for the degree of CO<sub>2</sub> enrichment employed in the prior study of Pregitzer *et al.* And when simultaneously exposed to air of 1.5 times the normal ozone concentration, the degree of fine-root biomass stimulation produced by the extra CO<sub>2</sub> was still as great as 66 percent, or roughly 115 percent when extrapolated to the greater CO<sub>2</sub> enrichment employed by Pregitzer *et al.*

In a final quaking aspen study, King *et al.* (1999) grew four clones at two different temperature regimes (separated by 5°C) and two levels of soil nitrogen (N) availability (high and low) for 98 days, while measuring photosynthesis, growth, biomass allocation, and root production and mortality. They found that the higher of the two temperature regimes increased rates of photosynthesis by 65 percent and rates of whole-plant growth by 37 percent, while it simultaneously enhanced root production and turnover. It was thus their conclusion that “trembling aspen has the potential for substantially greater growth and root turnover under conditions of warmer soil at sites of both high and low N-availability” and that “an immediate consequence of this will be greater inputs of C and nutrients to forest soils.”

In light of these several findings pertaining to quaking aspen trees, it is evident that increases in atmospheric CO<sub>2</sub> concentration, air temperature and soil nitrogen content all enhance their belowground growth, which positively impacts their above-ground growth.

Turning our attention to other deciduous trees, Gleadow *et al.* (1998) grew eucalyptus seedlings for six months in glasshouses maintained at atmospheric CO<sub>2</sub> concentrations of either 400 or 800 ppm, fertilizing them twice daily with low or high nitrogen solutions. The elevated CO<sub>2</sub> of their experiment increased total plant biomass by 98 and 134 percent relative to plants grown at ambient CO<sub>2</sub> in the high and low nitrogen treatments, respectively. In addition, in the low nitrogen treatment, elevated CO<sub>2</sub>

stimulated greater root growth, as indicated by a 33 percent higher root:shoot ratio.

In a more complex study, Day *et al.* (1996) studied the effects of elevated CO<sub>2</sub> on fine-root production in open-top chambers erected over a regenerating oak-palmetto scrub ecosystem in Florida, USA, determining that a 350-ppm increase in the atmosphere's CO<sub>2</sub> concentration increased fine-root length densities by 63 percent while enhancing the distribution of fine roots at both the soil surface (0-12 cm) and at a depth of 50-60 cm. These findings suggest that the ongoing rise in the atmosphere's CO<sub>2</sub> concentration will likely increase the distribution of fine roots near the soil surface, where the greatest concentrations of nutrients are located, and at a depth that coincides with the upper level of the site's water table, both of which phenomena should increase the trees' ability to acquire the nutrients and water they will need to support CO<sub>2</sub>-enhanced biomass production in the years ahead.

In another study that employed CO<sub>2</sub>, temperature and nitrogen as treatments, Uselman *et al.* (2000) grew seedlings of the nitrogen-fixing black locust tree for 100 days in controlled environments maintained at atmospheric CO<sub>2</sub> concentrations of 350 and 700 ppm and air temperatures of 26°C (ambient) and 30°C, with either some or no additional nitrogen fertilization, finding that the extra CO<sub>2</sub> increased total seedling biomass by 14 percent, the elevated temperature increased it by 55 percent, and nitrogen fertilization increased it by 157 percent. With respect to root exudation, a similar pattern was seen. Plants grown in elevated CO<sub>2</sub> exuded 20 percent more organic carbon compounds than plants grown in ambient air, while elevated temperature and fertilization increased root exudation by 71 and 55 percent, respectively. Hence, as the air's CO<sub>2</sub> content continues to rise, black locust trees will likely exhibit enhanced rates of biomass production and exudation of dissolved organic compounds from their roots. Moreover, if air temperature also rises, even by as much as 4°C, its positive effect on biomass production and root exudation will likely be even greater than that resulting from the increasing atmospheric CO<sub>2</sub> concentration. The same would appear to hold true for anthropogenic nitrogen deposition, reinforcing what was learned about the impacts of these three environmental factors on the growth of quaking aspen trees.

In light of these several experimental findings, it can confidently be concluded that the ongoing rise in the air's CO<sub>2</sub> content, together with possible

concurrent increases in air temperature and nitrogen deposition, will likely help earth's woody plants increase their root mass and surface area to become ever more robust and productive.

### 7.8.6. Seeds

Elevated CO<sub>2</sub> levels are known to have effects on seeds that are different from their effects on total biomass, roots, and other dimensions examined so far. In this section we survey the scientific literature on this topic regarding crops, grasslands, and trees.

Additional information on this topic, including reviews on seeds not discussed here, can be found at [http://www.co2science.org/subject/s/subject\\_s.php](http://www.co2science.org/subject/s/subject_s.php) under the heading Seeds.

#### 7.8.6.1. Crops

In a greenhouse study of the various components of seed biomass production, Palta and Ludwig (2000) grew narrow-leaved lupin in pots filled with soil within Mylar-film tunnels maintained at either 355 or 700 ppm CO<sub>2</sub>. They found that the extra CO<sub>2</sub> increased (1) the final number of pods and (2) the number of pods that filled large seeds, while it (3) reduced to zero the number of pods that had small seeds, (4) reduced the number of pods with unfilled seeds from 16 to 1 pod per plant, and increased (5) pod set and (6) dry matter accumulation on the developing branches. These several CO<sub>2</sub>-induced improvements to key physiological processes resulted in 47 to 56 percent increases in dry matter per plant, which led to increases of 44 to 66 percent in seed yield per plant.

Sanhewe *et al.* (1996) grew winter wheat in polyethylene tunnels maintained at atmospheric CO<sub>2</sub> concentrations of 380 and 680 ppm from the time of

seed germination to the time of plant maturity, while maintaining a temperature gradient of approximately 4°C in each tunnel. In addition to the elevated CO<sub>2</sub> increasing seed yield per unit area, they found it also increased seed weight, but not seed survival or germination. Increasing air temperature, on the other hand, increased seed longevity across the entire range of temperatures investigated (14 to 19°C).

Thomas *et al.* (2003) grew soybean plants to maturity in sunlit controlled-environment chambers under sinusoidally varying day/night-max/min temperatures of 28/18, 32/22, 36/26, 40/30 and 44/34°C and two levels of atmospheric CO<sub>2</sub> concentration (350 and 700 ppm). They determined, in their words, that the effect of temperature on seed composition and gene expression was “pronounced,” but that “there was no effect of CO<sub>2</sub>.” In this regard, however, they note that “Heagle *et al.* (1998) observed a positive significant effect of CO<sub>2</sub> enrichment on soybean seed oil and oleic acid concentration,” the latter of which parameters Thomas *et al.* found to increase with rising temperature all the way from 28/18 to 44/34°C.

In another soybean study, Ziska *et al.* (2001) grew one modern and eight ancestral genotypes in glasshouses maintained at atmospheric CO<sub>2</sub> concentrations of 400 and 710 ppm, finding that the extra CO<sub>2</sub> increased photosynthetic rates by an average of 75 percent. This enhancement in photosynthetic sugar production led to increases in seed yield that averaged 40 percent for all cultivars, except for one ancestral variety that exhibited an 80 percent increase in seed yield. Hence, if plant breeders were to utilize the highly CO<sub>2</sub>-responsive ancestral cultivar identified in this study in their breeding programs, it is possible that soybean seed yields could be made to rise even faster and higher in the days and years ahead.

### 7.8.6.2. Grasslands

Steinger *et al.* (2000) collected seeds from *Bromus erectus* plants that had been grown at atmospheric CO<sub>2</sub> concentrations of 360 and 650 ppm and germinated some of both groups of seeds under those same two sets of conditions. They found the elevated CO<sub>2</sub> treatment increased individual seed mass by about 9 percent and increased seed carbon-to-nitrogen ratio by almost 10 percent. However, they also learned that these changes in seed properties had little impact on subsequent seedling growth. In fact, when the seeds produced by ambient or CO<sub>2</sub>-enriched plants were germinated and grown in ambient air, there was no significant size difference between the two groups of resultant seedlings after a period of 19 days. Likewise, when the seeds produced from ambient or CO<sub>2</sub>-enriched plants were germinated and grown in the high CO<sub>2</sub> treatment, there was also no significant difference between the sizes of the seedlings derived from the two groups of seeds. However, the CO<sub>2</sub>-enriched seedlings produced from both groups of seeds were almost 20 percent larger than the seedlings produced from *both* groups of seeds grown in ambient air, demonstrating that the direct effects of elevated atmospheric CO<sub>2</sub> concentration on seedling growth and development were more important than the differences in seed characteristics produced by the elevated atmospheric CO<sub>2</sub> concentration in which their parent plants grew.

In another study conducted about the same time, Edwards *et al.* (2001) utilized a FACE experiment where daytime atmospheric CO<sub>2</sub> concentrations above a sheep-grazed pasture in New Zealand were increased by 115 ppm to study the effects of elevated CO<sub>2</sub> on seed production, seedling recruitment and

species compositional changes. In the two years of their study, the extra daytime CO<sub>2</sub> increased seed production and dispersal in seven of the eight most abundant species, including the grasses *Anthoxanthum odoratum*, *Lolium perenne* and *Poa pratensis*, the legumes *Trifolium repens* and *T. subterranean*, and the herbs *Hypochaeris radicata* and *Leontodon saxatilis*. In some of these plants, elevated CO<sub>2</sub> increased the number of seeds per reproductive structure, while all of them exhibited CO<sub>2</sub>-induced increases in the number of reproductive structures per unit of ground area. In addition, they determined that the CO<sub>2</sub>-induced increases in seed production contributed in a major way to the increase in the numbers of species found within the CO<sub>2</sub>-enriched plots.

In a five-year study of a nutrient-poor calcareous grassland in Switzerland, Thurig *et al.* (2003) used screen-aided CO<sub>2</sub> control (SACC) technology (Leadley *et al.*, 1997) to enrich the air over half of their experimental plots with an extra 300 ppm of CO<sub>2</sub>, finding that “the effect of elevated CO<sub>2</sub> on the number of flowering shoots (+24%) and seeds (+29%) at the community level was similar to above ground biomass response.” In terms of species functional groups, there was a 42 percent increase in the mean seed number of graminoids and a 33 percent increase in the mean seed number of forbs, but no change in legume seed numbers. In most species, mean seed weight also tended to be greater in plants grown in CO<sub>2</sub>-enriched air (+12 percent); and Thurig *et al.* say it is known from many studies that heavier seeds result in seedlings that “are more robust than seedlings from lighter seeds (Baskin and Baskin, 1998).”

Wang and Griffin (2003) grew dioecious white cockle plants from seed to maturity in sand-filled pots maintained at optimum moisture and fertility conditions in environmentally controlled growth chambers in which the air was continuously maintained at CO<sub>2</sub> concentrations of either 365 or 730 ppm. In response to this doubling of the air’s CO<sub>2</sub> content, the vegetative mass of both male and female plants rose by approximately 39 percent. Reproductive mass, on the other hand, rose by 82 percent in male plants and by 97 percent in females. In the female plants, this feat was accomplished, in part, by increases of 36 percent and 44 percent in the number and mass of seeds per plant, and by a 15 percent increase in the mass of individual seeds, in harmony with the findings of Jablonski *et al.* (2002), which they derived from a meta-analysis of the results

of 159 CO<sub>2</sub> enrichment experiments conducted on 79 species of agricultural and wild plants. Because dioecious plants comprise nearly half of all angiosperm families, we may expect to see a greater proportion of plant biomass allocated to reproduction in a high-CO<sub>2</sub> world of the future, which result should bode well for the biodiversity of earth’s many ecosystems.

### 7.8.6.3. Trees

How does enriching the air with carbon dioxide impact the reproductive capacity of trees? LaDeau and Clark (2001) determined the reproductive response of loblolly pine trees to atmospheric CO<sub>2</sub> enrichment at Duke Forest in the Piedmont region of

North Carolina, USA, where in August of 1996 three 30-m-diameter FACE rings began to enrich the air around the 13-year-old trees they encircled to 200 ppm above the atmosphere's normal background concentration, while three other FACE rings served as control plots. Because the trees were not mature at the start of the experiment they did not produce any cones until a few rare ones appeared in 1998. By the fall of 1999, however, the two scientists found that, compared to the trees growing in ambient air, the CO<sub>2</sub>-enriched trees were twice as likely to be reproductively mature, and they produced three times more cones per tree. Similarly, the trees growing in the CO<sub>2</sub>-enriched air produced 2.4 times more cones in the fall of 2000; and from August 1999 through July 2000, they collected three times as many seeds in the CO<sub>2</sub>-fertilized FACE rings as in the control rings.

Also working on this aspect of the Duke Forest FACE study were Hussain *et al.* (2001), who report that (1) seeds collected from the CO<sub>2</sub>-enriched trees were 91 percent heavier than those collected from the trees growing in ambient air, (2) the CO<sub>2</sub>-enriched seeds had a lipid content that was 265 percent greater than that of the seeds produced on the ambient-treatment trees, (3) the germination success for seeds developed under atmospheric CO<sub>2</sub> enrichment was more than three times greater than that observed for control seeds developed at ambient CO<sub>2</sub>, regardless of germination CO<sub>2</sub> concentration, (4) seeds from the CO<sub>2</sub>-enriched trees germinated approximately five days earlier than their ambiently produced counterparts, again regardless of germination CO<sub>2</sub> concentration, and (5) seedlings developing from seeds collected from CO<sub>2</sub>-enriched trees displayed significantly greater root lengths and needle numbers than seedlings developing from trees exposed to ambient air, also regardless of growth CO<sub>2</sub> concentration.

The propensity for elevated levels of atmospheric CO<sub>2</sub> to hasten the production of more plentiful seeds on the trees of this valuable timber species bodes well for naturally regenerating loblolly pine stands of the southeastern United States, where LaDeau and Clark report the trees "are profoundly seed-limited for at least 25 years." As the air's CO<sub>2</sub> content continues to climb, they conclude that "this period of seed limitation may be reduced." In addition, the observations of Hussain *et al.* suggest that loblolly pine trees in a CO<sub>2</sub>-enriched world of the future will likely display significant increases in their photosynthetic rates. Enhanced carbohydrate supplies resulting from this phenomenon will likely be used to

increase seed weight and lipid content. Such seeds should consequently exhibit significant increases in germination success, and their enhanced lipid supplies will likely lead to greater root lengths and needle numbers in developing seedlings. Consequently, when CO<sub>2</sub>-enriched loblolly pine seedlings become photosynthetically active, they will likely produce biomass at greater rates than those exhibited by seedlings growing under current CO<sub>2</sub> concentrations.

Five years later, LaDeau and Clark (2006a) conducted a follow-up study that revealed "carbon dioxide enrichment affected mean cone production both through early maturation and increased fecundity," so that "trees in the elevated CO<sub>2</sub> plots produced twice as many cones between 1998 and 2004 as trees in the ambient plots." They also determined that the trees grown in elevated CO<sub>2</sub> "made the transition to reproductive maturation at smaller [trunk] diameters," and that they "not only reached reproductive maturation at smaller diameters, but also at younger ages." By 2004, for example, they say that "roughly 50% of ambient trees and 75% of fumigated trees [had] produced cones." In addition, they observed that "22% of the trees in high CO<sub>2</sub> produced between 40 and 100 cones during the study, compared with only 9% of ambient trees."

"In this 8-year study," in the words of the two researchers, "we find that previous short-term responses indeed persist." In addition, they note that "*P. taeda* trees that produce large seed crops early in their life span tend to continue to be prolific producers (Schultz, 1997)," and they conclude that this fact, together with their findings, suggests that "individual responses seen in this young forest may be sustained over their life span."

In a concurrent report, LaDeau and Clark (2006b) analyzed the seed and pollen responses of the loblolly pines to atmospheric CO<sub>2</sub> enrichment, finding that the "trees grown in high-CO<sub>2</sub> plots first began producing pollen while younger and at smaller sizes relative to ambient-grown trees," and that cone pollen and airborne pollen grain abundances were significantly greater in the CO<sub>2</sub>-enriched stands. More specifically, they found that "by spring 2005, 63% of all trees growing in high CO<sub>2</sub> had produced both pollen and seeds vs. only 36% of trees in the ambient plots." The researchers say precocious pollen production "could enhance the production of viable seeds by increasing the percentage of fertilized ovules," and that "more pollen disseminated from multiple-source trees may also increase rates of gene flow among stands, and could further reduce rates of self-pollination,

indirectly enhancing the production of viable seeds.” They also say “pine pollen is not a dangerous allergen for the public at large.”

Another major study of the reproductive responses of trees to elevated levels of atmospheric CO<sub>2</sub> was conducted at the Kennedy Space Center, Florida, USA, where in 1996 three species of scrub-oak (*Quercus myrtifolia*, *Q. chapmanii*, and *Q. geminata*) were enclosed within sixteen open-top chambers, half of which were maintained at 379 ppm CO<sub>2</sub> and half at 704 ppm. Five years later—in August, September and October of 2001—Stiling *et al.* (2004) counted the numbers of acorns on randomly selected twigs of each species, while in November of that year they counted the numbers of fallen acorns of each species within equal-size quadrates of ground area, additionally evaluating mean acorn weight, acorn germination rate, and degree of acorn infestation by weevils. They found acorn germination rate and degree of predation by weevils were unaffected by elevated CO<sub>2</sub>, while acorn size was enhanced by a small amount: 3.6 percent for *Q. myrtifolia*, 7.0 percent for *Q. chapmanii*, and 7.7 percent for *Q. geminata*. Acorn number responses, on the other hand, were enormous, but for only two of the three species, as *Q. geminata* did not register any CO<sub>2</sub>-induced increase in reproductive output, in harmony with its unresponsive overall growth rate. For *Q. myrtifolia*, however, Stiling *et al.* report “there were four times as many acorns per 100 twigs in elevated CO<sub>2</sub> as in ambient CO<sub>2</sub> and for *Q. chapmanii* the increase was over threefold.” On the ground, the enhancement was greater still, with the researchers reporting that “the number of *Q. myrtifolia* acorns per meter squared in elevated CO<sub>2</sub> was over seven times greater than in ambient CO<sub>2</sub> and for *Q. chapmanii*, the increase was nearly sixfold.”

Stiling *et al.* say these results lead them to believe “there will be large increases in seedling production in scrub-oak forests in an atmosphere of elevated CO<sub>2</sub>,” noting that “this is important because many forest systems are ‘recruitment-limited’ (Ribbens *et al.*, 1994; Hubbell *et al.*, 1999),” which conclusion echoes that of LaDeau and Clark with respect to loblolly pines.

A third major study of CO<sub>2</sub> effects on seed production in trees has been conducted at the FACE facility near Rhinelander, Wisconsin (USA), where young paper birch (*Betula papyrifera* Marsh.) seedlings were planted in 1997 and have been growing since 1998 in open-top chambers maintained at atmospheric CO<sub>2</sub> concentrations of either 360 or

560 ppm, as well as at atmospheric ozone (O<sub>3</sub>) concentrations of either ambient or 1.5 times ambient. There, Darbah *et al.* (2007) collected many types of data pertaining to flowering, seed production, seed germination and new seedling growth and development over the 2004-2006 growing seasons; and as they describe it, “elevated CO<sub>2</sub> had significant positive effect[s] on birch catkin size, weight, and germination success rate.” More specifically, they note that “elevated CO<sub>2</sub> increased germination rate of birch by 110%, compared to ambient CO<sub>2</sub> concentrations, decreased seedling mortality by 73%, increased seed weight by 17% [and] increased [new seedling] root length by 59%.”

In conclusion, research on a variety of tree species finds that CO<sub>2</sub> enhancement increases the production of viable seeds and seedlings, meaning these species should flourish as CO<sub>2</sub> levels continue to rise. Additional information on this topic, including reviews of newer publications as they become available, can be found at <http://www.co2science.org/subject/s/seedstrees.php>.

### 7.8.7. Tannins

Condensed tannins are naturally occurring secondary carbon compounds produced in the leaves of a number of different plants that often act to deter herbivorous insects. How do condensed tannin concentrations in the leaves and roots of trees respond to atmospheric CO<sub>2</sub> enrichment?

Additional information on this topic, including reviews on tannins not discussed here, can be found at [http://www.co2science.org/subject/t/subject\\_t.php](http://www.co2science.org/subject/t/subject_t.php) under the heading Tannins.

#### 7.8.7.1. Aspen Trees

King *et al.* (2001) grew aspen seedlings for five months in open-top chambers maintained at atmospheric CO<sub>2</sub> concentrations of either 350 or 700 ppm. At the end of this period, naturally senesced leaf litter was collected and analyzed; and it was found that the elevated CO<sub>2</sub> of this particular study had no effect on leaf litter tannin concentration.

A substantially different result was obtained in an earlier study of aspen leaves that was conducted by McDonald *et al.* (1999), who grew aspen seedlings in controlled environment greenhouses that were maintained at either ambient (387 ppm) or elevated (696 ppm) CO<sub>2</sub> concentrations under conditions of either low or high light availability (half and full sunlight, respectively) for 31 days after the mean date of bud break. In this case it was determined that under low light conditions, the CO<sub>2</sub>-enriched seedlings exhibited an increase of approximately 15 percent in leaf condensed tannin concentration, while under high light conditions the CO<sub>2</sub>-induced increase in leaf condensed tannin concentration was 175 percent.

In a much more complex study than either of the two preceding ones, Agrell *et al.* (2005) examined the

effects of ambient and elevated concentrations of atmospheric CO<sub>2</sub> (360 ppm and 560 ppm, respectively) and O<sub>3</sub> (35-60 ppb and 52-90 ppb, respectively) on the foliar chemistry of more mature aspen trees of two different genotypes (216 and 259) growing out-of-doors at the Aspen Free Air CO<sub>2</sub> Enrichment (FACE) facility near Rhinelander, Wisconsin, USA, as well as the impacts of these effects on the host plant preferences of forest tent caterpillar larvae.

In reporting the results of the study, Agrell *et al.* say that “the only chemical component showing a somewhat consistent covariation with larval preferences was condensed tannins,” noting that “the tree becoming relatively less preferred as a result of CO<sub>2</sub> or O<sub>3</sub> treatment was in general also the one for which average levels of condensed tannins were most positively (or least negatively) affected by that treatment.” The mean condensed tannin concentrations of the aspen 216 and 259 genotypes were 25 percent and 57 percent higher, respectively, under the elevated CO<sub>2</sub> and O<sub>3</sub> combination treatment compared to the ambient CO<sub>2</sub> and O<sub>3</sub> combination treatment.

In light of these findings, it is logical to presume that as atmospheric concentrations of CO<sub>2</sub> and O<sub>3</sub> continue to rise, the increase in condensed tannin concentration likely to occur in the foliage of aspen trees should lead to their leaves becoming less preferred for consumption by the forest tent caterpillar.

Additional information on this topic, including reviews of newer publications as they become available, can be found at <http://www.co2science.org/subject/t/tanninsaspen.php>.

## 7.8.7.2. Birch Trees

How do condensed tannin concentrations in the leaves and roots of paper birch (*Betula papyrifera* Marsh.) and silver birch (*Betula pendula* Roth) trees respond to atmospheric CO<sub>2</sub> enrichment with and without concomitant increases in atmospheric temperature and ozone concentrations? We here briefly summarize the findings of several studies that have broached one or more parts of this question.

McDonald *et al.* (1999) grew paper birch seedlings in controlled environment greenhouses that were maintained at either ambient (387 ppm) or elevated (696 ppm) CO<sub>2</sub> concentrations under conditions of either low or high light availability (half and full sunlight, respectively) for 31 days after the mean date of bud break. In doing so, they determined that under low light conditions the CO<sub>2</sub>-enriched seedlings exhibited an increase of approximately 15 percent in leaf condensed tannin concentration, while under high light conditions the CO<sub>2</sub>-induced tannin increase was a whopping 175 percent.

Peltonen *et al.* (2005) studied the impacts of doubled atmospheric CO<sub>2</sub> and O<sub>3</sub> concentrations on the accumulation of 27 phenolic compounds, including soluble condensed tannins, in the leaves of two European silver birch clones in seven-year-old soil-grown trees that were exposed in open-top chambers for three growing seasons to ambient and twice-ambient atmospheric CO<sub>2</sub> and O<sub>3</sub> concentrations singly and in combination. This work, which was carried out in central Finland, revealed that elevated CO<sub>2</sub> increased the concentration of soluble condensed tannins in the leaves of the trees by 19 percent. In addition, they found that the elevated CO<sub>2</sub> protected the leaves from elevated O<sub>3</sub> because, as they describe it, “all the O<sub>3</sub>-derived effects on the leaf phenolics and traits were prevented by elevated CO<sub>2</sub>.”

Kuokkanen *et al.* (2003) grew two-year-old silver birch seedlings in ambient air of 350 ppm CO<sub>2</sub> or air enriched to a CO<sub>2</sub> concentration of 700 ppm under conditions of either ambient temperature or ambient temperature plus 3°C for one full growing season in the field in closed-top chambers at the Mekrijarvi Research Station of the University of Joensuu in eastern Finland. Then, during the middle of the summer, when carbon-based secondary compounds of birch leaves are fairly stable, they picked several leaves from each tree and determined their condensed tannin concentrations, along with the concentrations of a number of other physiologically important substances. This work revealed that the concentration

of total phenolics, condensed tannins and their derivatives significantly increased in the leaves produced in the CO<sub>2</sub>-enriched air, as has also been observed by Lavola and Julkunen-Titto (1994), Williams *et al.* (1994), Kinney *et al.* (1997), Bezemer and Jones (1998) and Kuokkanen *et al.* (2001). In fact, the extra 350 ppm of CO<sub>2</sub> nearly tripled condensed tannin concentrations in the ambient-temperature air, while it increased their concentrations in the elevated-temperature air by a factor in excess of 3.5.

In a study of roots, Parsons *et al.* (2003) grew two-year-old paper birch saplings in well-watered and fertilized 16-L pots from early May until late August in glasshouse rooms maintained at either 400 or 700 ppm CO<sub>2</sub>. This procedure revealed that the concentration of condensed tannins in the fine roots of the saplings was increased by 27 percent in the CO<sub>2</sub>-enriched treatment; and in regard to this finding, the researchers say “the higher condensed tannin concentrations that were present in the birch fine roots may offer these tissues greater protection against soil-borne pathogens and herbivores.”

Parsons *et al.* (2004) collected leaf litter samples from early September to mid-October beneath paper birch trees growing in ambient and CO<sub>2</sub>-enriched (to 200 ppm above ambient) FACE plots in northern Wisconsin, USA, which were also maintained under ambient and O<sub>3</sub>-enriched (to 19 ppb above ambient) conditions, after which the leaf mass produced in each treatment was determined, sub-samples of the leaves were assessed for a number of chemical constituents. The researchers learned that condensed tannin concentrations were 64 percent greater in the CO<sub>2</sub>-enriched plots. Under CO<sub>2</sub>- and O<sub>3</sub>-enriched conditions, condensed tannin concentrations were 99 percent greater.

In conclusion, it appears that elevated concentrations of atmospheric CO<sub>2</sub> tend to increase leaf and fine-root tannin concentrations of birch trees, and that this phenomenon tends to protect the trees' foliage from predation by voracious insect herbivores and protect the trees' roots from soil-borne pathogens and herbivores.

## 7.8.7.3. Oak Trees

Dury *et al.* (1998) grew four-year-old pedunculate oak trees (*Quercus robur* L.) in pots within greenhouses maintained at ambient and twice-ambient atmospheric CO<sub>2</sub> concentrations in combination with ambient and elevated (ambient plus 3°C) air

temperatures for approximately one year. This work revealed that elevated CO<sub>2</sub> had only minor and contrasting direct effects on leaf palatability: a temporary increase in foliar phenolic concentrations and decreases in leaf toughness and nitrogen content. The elevated temperature treatment, on the other hand, significantly reduced leaf palatability, because oak leaf toughness increased as a consequence of temperature-induced increases in condensed tannin concentrations. As a result, the researchers concluded that “a 3°C rise in temperature might be expected to result in prolonged larval development, increased food consumption, and reduced growth” for herbivores feeding on oak leaves in a CO<sub>2</sub>-enriched and warmer world of the future.

Cornelissen *et al.* (2003) studied fluctuating asymmetry in the leaves of two species of sclerophyllous oaks—myrtle oak (*Quercus myrtifolia*) and sand live oak (*Quercus geminata*)—that dominate a native scrub-oak community at the Kennedy Space Center, Titusville, Florida (USA). Fluctuating asymmetry is the term used to describe small variations from perfect symmetry in otherwise bilaterally symmetrical characters in an organism (Moller and Swaddle, 1997), which asymmetry is believed to arise as a consequence of developmental instabilities experienced during ontogeny that may be caused by various stresses, including both genetic and environmental factors (Moller and Shykoff, 1999).

Based on measurements of (1) distances from the leaf midrib to the left and right edges of the leaf at its widest point and (2) leaf areas on the left and right sides of the leaf midrib, Cornelissen *et al.* determined that “asymmetric leaves were less frequent in elevated CO<sub>2</sub>, and, when encountered, they were less asymmetric than leaves growing under ambient CO<sub>2</sub>.” In addition, they found that “*Q. myrtifolia* leaves under elevated CO<sub>2</sub> were 15.0% larger than in ambient CO<sub>2</sub> and *Q. geminata* leaves were 38.0 percent larger in elevated CO<sub>2</sub> conditions.” They also determined that “elevated CO<sub>2</sub> significantly increased tannin concentration for both *Q. myrtifolia* and *Q. geminata* leaves” and that “asymmetric leaves contained significantly lower concentrations of tannins than symmetric leaves for both *Q. geminata* and *Q. myrtifolia*.” Specifically, they found induced increases in tanning concentrations of approximately 35 percent for *Q. myrtifolia* and 43 percent for *Q. geminata*. In commenting on their primary findings of reduced percentages of leaves experiencing asymmetry in the presence of elevated levels of atmospheric CO<sub>2</sub> and the lesser degree of asymmetry

exhibited by affected leaves in the elevated CO<sub>2</sub> treatment, Cornelissen *et al.* say that “a possible explanation for this pattern is the fact that, by contrast to other environmental stresses, which can cause negative effects on plant growth, the predominant effect of elevated CO<sub>2</sub> on plants is to promote growth with consequent reallocation of resources (Docherty *et al.*, 1996).” Another possibility they discuss “is the fact that CO<sub>2</sub> acts as a plant fertilizer,” and, as a result, that “elevated CO<sub>2</sub> ameliorates plant stress compared with ambient levels of CO<sub>2</sub>.”

In a subsequent study conducted at the Kennedy Space Center’s scrub-oak community, Hall *et al.* (2005b) evaluated foliar quality and herbivore damage in three oaks (*Q. myrtifolia*, *Q. chapmanii* and *Q. geminata*) plus the nitrogen-fixing legume *Galactia elliottii* at three-month intervals from May 2001 to May 2003, at which times samples of undamaged leaves were removed from each of the four species in all chambers and analyzed for various chemical constituents, while 200 randomly selected leaves of each species in each chamber were scored for the presence of six types of herbivore damage. Analyses of the data thereby obtained indicated that for condensed tannins, hydrolyzable tannins, total phenolics and lignin, in all four species there were always greater concentrations of all four leaf constituents in the CO<sub>2</sub>-enriched leaves, with across-species mean increases of 6.8 percent for condensed tannins, 6.1 percent for hydrolyzable tannins, 5.1 percent for total phenolics and 4.3 percent for lignin. In addition, there were large CO<sub>2</sub>-induced decreases in all leaf damage categories among all species: chewing (-48 percent), mines (-37 percent), eye spot gall (-45 percent), leaf tier (-52 percent), leaf mite (-23 percent) and leaf gall (-16 percent). Hall *et al.* thus concluded that the changes they observed in leaf chemical constituents and herbivore damage “suggest that damage to plants may decline as atmospheric CO<sub>2</sub> levels continue to rise.”

Last, and largely overlapping the investigation of Hall *et al.* (2005b), was the study of Hall *et al.* (2005a), who evaluated the effects of the Kennedy Space Center experiment’s extra 350 ppm of CO<sub>2</sub> on litter quality, herbivore activity, and their interactions, over the three-year-period 2000-2002. This endeavor indicated, in their words, that “changes in litter chemistry from year to year were far larger than effects of CO<sub>2</sub> or insect damage, suggesting that these may have only minor effects on litter decomposition.” The one exception to this finding was that “condensed tannin concentrations increased under elevated CO<sub>2</sub>

regardless of species, herbivore damage, or growing season,” rising by 11 percent in 2000, 18 percent in 2001 and 41 percent in 2002 as a result of atmospheric CO<sub>2</sub> enrichment, as best we can determine from the researchers’ bar graphs. Also, the five scientists report that “lepidopteran larvae can exhibit slower growth rates when feeding on elevated CO<sub>2</sub> plants (Fajer *et al.*, 1991) and become more susceptible to pathogens, parasitoids, and predators (Lindroth, 1996; Stiling *et al.*, 1999),” noting further that at their field site, “which hosts the longest continuous study of the effects of elevated CO<sub>2</sub> on insects, herbivore populations decline markedly under elevated CO<sub>2</sub> (Stiling *et al.*, 1999, 2002, 2003; Hall *et al.*, 2005b).”

In conclusion, it would appear CO<sub>2</sub>-enriched air produces a large and continuous enhancement of condensed tannin concentrations in oak tree foliage, which causes marked declines in herbivore populations observed in CO<sub>2</sub>-enriched open-top-chamber studies.

### 7.8.8. Transgenic Plants

Toxins produced by *Bacillus thuringiensis* (Bt) supplied to crops via foliar application have been used as a means of combating crop pests for well over half a century. More recently, the Bt gene for producing the toxin has been artificially inserted in some species of plants, producing transgenic plants that are pest resistant. The effectiveness of this management technique depends primarily upon the amount of Bt-produced toxins that are ingested by targeted insects. Another kind of transgenic plant is wheat that has been made heat resistant by the introduction into its gene code of heat shock protein (HSP) or plastidial EF-Tu (protein synthesis elongation factor). How does atmospheric CO<sub>2</sub> enrichment affect transgenic plants?

If soil nitrogen levels are low, foliar nitrogen concentrations in plants grown in enhanced CO<sub>2</sub> environments are generally reduced from what they are at the current atmospheric CO<sub>2</sub> concentration, which suggests that insects would have to eat more

foliage to get their normal requirement of nitrogen for proper growth and development in CO<sub>2</sub>-enriched air. But by eating more foliage, the insects would also ingest more Bt-produced toxins, and they would be more severely impacted by those substances.

To test this hypothesis, Coviella and Trumble (2000) grew cotton plants in each of six Teflon-film chambers in a temperature-controlled greenhouse, where three of the chambers were maintained at an atmospheric CO<sub>2</sub> concentration of 370 ppm, and three were maintained at 900 ppm CO<sub>2</sub>. In addition, half of the plants in each chamber received high levels of nitrogen (N) fertilization, while half received low levels (30 vs. 130 mg N/kg soil/week). After 45 days of growth under these conditions, leaves were removed from the plants and dipped in a Bt solution, after which known amounts of treated leaf material were fed to *Spodoptera exigua* larvae and their responses measured and analyzed.

By these means, the two researchers determined that the plants grown in the elevated CO<sub>2</sub> chambers did indeed have significantly lower foliar nitrogen concentrations than the plants grown in the ambient CO<sub>2</sub> chambers under the low N fertilization regime; but this was not the case under the high N regime. They also discovered that older larvae fed with foliage grown in elevated CO<sub>2</sub> with low N fertilization consumed significantly more plant material than insects fed with foliage grown in ambient CO<sub>2</sub>; but, again, no differences were observed with high N fertilization. Last, and “consistent with the effect of higher Bt toxin intake due to enhanced consumption,” they found that “insects fed on low N plants had significantly higher mortality in elevated CO<sub>2</sub>.” Yet, again, no such effect was evident in the high N treatment. Consequently, with respect to pest management using Bt-produced toxins supplied to crops via foliar application, Coviella and Trumble concluded that “increasing atmospheric CO<sub>2</sub> is making the foliar applications more efficacious.”

Coviella *et al.* (2000), in an analogous experiment to that of Coviella and Trumble, grew cotton plants in 12 Teflon-film chambers in a temperature-controlled greenhouse, where six chambers were maintained at an atmospheric CO<sub>2</sub> concentration of 370 ppm and six were maintained at 900 ppm CO<sub>2</sub>. Half of the cotton plants in each of these chambers were of a transgenic line containing the Bt gene for the production of the Cry1Ac toxin, which is mildly toxic for *Spodoptera exigua*, while the other half were of a near isogenic line without the Bt gene. In addition, and as before,

half of the plants in each chamber received the same low and high levels of N fertilization; and between 40 and 45 days after emergence, leaves were removed from the plants and fed to the *S. exigua* larvae, after which a number of larval responses were measured and analyzed, along with various leaf properties.

This work revealed that the low-N plants in the elevated CO<sub>2</sub> treatment had lower foliar N concentrations than did the low-N plants in the ambient CO<sub>2</sub> treatment, and that the transgenic plants from the low-N, high CO<sub>2</sub> treatment produced lower levels of Bt toxin than did the transgenic plants from the low-N, ambient CO<sub>2</sub> treatment. In addition, the high level of N fertilization only partially compensated for this latter high-CO<sub>2</sub> effect. In the ambient CO<sub>2</sub> treatment there was also a significant increase in days to pupation for insects fed transgenic plants; but this difference was not evident in elevated CO<sub>2</sub>. In addition, pupal weight in ambient CO<sub>2</sub> was significantly higher in non-transgenic plants; and, again, this difference was not observed in elevated CO<sub>2</sub>.

In discussing their findings, the three researchers wrote that “these results support the hypothesis that the lower N content per unit of plant tissue caused by the elevated CO<sub>2</sub> will result in lower toxin production by transgenic plants when nitrogen supply to the plants is a limiting factor.” They also note that “elevated CO<sub>2</sub> appears to eliminate differences between transgenic and non-transgenic plants for some key insect developmental/fitness variables including length of the larval stage and pupal weight.”

These findings suggest that in the case of inadvertent Bt gene transference to wild relatives of transgenic crop lines, elevated levels of atmospheric CO<sub>2</sub> will tend to negate certain of the negative effects the wayward genes might otherwise inflict on the natural world. Hence, the ongoing rise in the air’s CO<sub>2</sub> content could be said to constitute an “insurance policy” against this potential outcome.

On the other hand, Coviella *et al.*’s results also suggest that transgenic crops designed to produce Bt-type toxins may become less effective in carrying out the objectives of their design as the air’s CO<sub>2</sub> content continues to rise. Coupling this possibility with the fact that the *foliar* application of *Bacillus thuringiensis* to crops should become even more effective in a higher-CO<sub>2</sub> world, as found by Coviella and Trumble, one could argue that the implantation of toxin-producing genes in crops is not the way to go in the face of the ongoing rise in the air’s CO<sub>2</sub> content, which reduces that technique’s effectiveness at the

same time that it increases the effectiveness of direct foliar applications.

In a study of three different types of rice—a wild type (WT) and two transgenic varieties, one with 65 percent wild-type Rubisco (AS-77) and one with 40 percent wild-type Rubisco (AS-71)—Makino *et al.* (2000) grew plants from seed for 70 days in growth chambers maintained at 360 and 1000 ppm CO<sub>2</sub>, after which they harvested the plants and determined their biomass. In doing so, they found that the mean dry weights of the WT, AS-77 and AS-71 varieties grown in air of 360 ppm were, respectively, 5.75, 3.02 and 0.83 g, while in air of 1000 ppm CO<sub>2</sub>, corresponding mean dry weights were 7.90, 7.40 and 5.65 g. Consequently, although the growth rates of the genetically engineered rice plants were inferior to that of the wild type when grown in normal air of 360 ppm CO<sub>2</sub> (with AS-71 producing less than 15 percent as much biomass as the wild type), when grown in air of 1000 ppm CO<sub>2</sub> they experienced greater CO<sub>2</sub>-induced increases in growth: a 145 percent increase in the case of AS-77 and a 581 percent increase in the case of AS-71. Hence, whereas the transgenic plants were highly disadvantaged in normal air of 360 ppm CO<sub>2</sub> (with AS-71 plants attaining a mean dry weight of only 0.83 g while the WT plants attained a mean dry weight of 5.75 g), they were found to be pretty much on an equal footing in highly CO<sub>2</sub>-enriched air (with AS-71 plants attaining a mean dry weight of 5.65 g while the WT plants attained a mean dry weight of 7.90 g). This finding bodes well for the application of this type of technology to rice crops in a future world of higher atmospheric CO<sub>2</sub> content.

Returning to cotton, Chen *et al.* (2005) grew well watered and fertilized plants of two varieties—one expressing Cry1A (c) genes from *Bacillus thuringiensis* and a non-transgenic cultivar from the same recurrent parent—in pots placed within open-top chambers maintained at either 375 or 750 ppm CO<sub>2</sub> in Sanhe County, Hebei Province, China, from planting in mid-May to harvest in October, throughout which period several immature bolls were collected and analyzed for various chemical characteristics, while others were stored under refrigerated conditions for later feeding to cotton bollworm larvae, whose growth characteristics were closely monitored. In pursuing this protocol, the five researchers found that the elevated CO<sub>2</sub> treatment increased immature boll concentrations of condensed tannins by approximately 22 percent and 26 percent in transgenic and non-transgenic cotton, respectively (see Tannins in Section 7.8.7. for a

discussion of the significance of this observation). In addition, they found that elevated CO<sub>2</sub> slightly decreased the body biomass of the cotton bollworms and reduced moth fecundity. The Bt treatment was even more effective in this regard, and in the combined Bt-high-CO<sub>2</sub> treatment, the negative cotton bollworm responses were expressed most strongly of all. Chen *et al.* concluded that the expected higher atmospheric CO<sub>2</sub> concentrations of the future will “either not change or only slightly enhance the efficacy of Bt technology against cotton bollworms.”

Two years later, Chen *et al.* (2007) reported growing the same two cultivars under the same conditions from the time of planting on 10 May 2004 until the plants were harvested in October, after which egg masses of the cotton bollworms were reared in a growth chamber under ambient-CO<sub>2</sub> conditions, while three successive generations of them were fed either transgenic or non-transgenic cotton bolls from plants grown in either ambient or twice-ambient atmospheric CO<sub>2</sub> concentrations, during which time a number of physiological characteristics of the cotton bollworms were periodically assessed. This work revealed, in the words of Chen *et al.*, that “both elevated CO<sub>2</sub> and transgenic Bt cotton increased larval lifespan,” but that they decreased “pupal weight, survival rate, fecundity, frass output, relative and mean relative growth rates, and the efficiency of conversion of ingested and digested food.” As a result, they say that “transgenic Bt cotton significantly decreased the population-trend index compared to non-transgenic cotton for the three successive bollworm generations, *especially at elevated CO<sub>2</sub>* [our italics].”

Based on these findings, the four researchers concluded that the negative effects of elevated CO<sub>2</sub> on cotton bollworm physiology and population dynamics “may intensify through successive generations,” in agreement with the findings of Brooks and Whittaker (1998, 1999) and Wu *et al.* (2006). They additionally concluded that “both elevated CO<sub>2</sub> and transgenic Bt cotton are adverse environmental factors for cotton bollworm long-term population growth,” and that the combination of the two factors may intensify their adverse impact on the population performance of the cotton bollworm, which would be good news for cotton growers.

Fu *et al.* (2008) note that “heat stress is a major constraint to wheat production and negatively impacts grain quality, causing tremendous economic losses, and may become a more troublesome factor due to global warming.” Consequently, as they describe it,

they “introduced into wheat the maize gene coding for plastidal EF-Tu [protein synthesis elongation factor],” in order to assess “the expression of the transgene, and its effect on thermal aggregation of leaf proteins in transgenic plants,” as well as “the heat stability of photosynthetic membranes (thylakoids) and the rate of CO<sub>2</sub> fixation in young transgenic plants following exposure to heat stress.” These operations led, in their words, “to improved protection of leaf proteins against thermal aggregation, reduced damage to thylakoid membranes and enhanced photosynthetic capability following exposure to heat stress,” which results “support the concept that EF-Tu ameliorates negative effects of heat stress by acting as a molecular chaperone.”

Fu *et al.* describe their work as “the first demonstration that a gene other than HSP [heat shock protein] gene can be used for improvement of heat tolerance,” noting it also indicates that the improvement is possible in a species that has a complex genome, such as hexaploid wheat. They conclude by stating their results “strongly suggest that heat tolerance of wheat, and possibly other crop plants, can be improved by modulating expression of plastidal EF-Tu and/or by selection of genotypes with increased endogenous levels of this protein.”

In summary, genetic alterations to crop plants enable them to better withstand the assaults of insects pests or increases in seasonal maximum air temperatures. Elevated CO<sub>2</sub> either improves or does not change the effectiveness of genetic alternatives to achieve these objectives, while it simultaneously reduces the severity of possible negative effects that could arise from the escape of transplanted genes into the natural environment.

Additional information on this topic, including reviews of newer publications as they become available, can be found at <http://www.co2science.org/subject/t/summaries/transgenicplants.php>.

### 7.8.9. Isoprene

Isoprene (C<sub>5</sub>H<sub>8</sub> or 2-methyl-1,3-butadiene) is a highly reactive non-methane hydrocarbon (NMHC) that is emitted in copious quantities by vegetation and is responsible for the production of vast amounts of tropospheric ozone (Chameides *et al.*, 1988; Harley *et al.*, 1999), which is a debilitating scourge of plant and animal life alike. Poisson *et al.* (2000) calculate that current levels of NMHC emissions—the vast majority of which are isoprene, accounting for more than twice as much as all other NMHCs combined—may increase surface ozone concentrations by up to 40 percent in the marine boundary-layer and 50-60 percent over land. They further estimate that the current tropospheric ozone content extends the atmospheric lifetime of methane—one of the world's

most powerful greenhouse gases—by approximately 14 percent. Consequently, it can be appreciated that reducing isoprene emissions from vegetation is to be desired.

Although a few experiments conducted on certain plant species have suggested that elevated concentrations of atmospheric CO<sub>2</sub> have little to no effect on their emissions of isoprene (Buckley, 2001; Baraldi *et al.*, 2004; Rapparini *et al.*, 2004), a much larger number of other experiments are suggestive of substantial CO<sub>2</sub>-induced reductions in isoprene emissions, as demonstrated by the work of Monson and Fall (1989), Loreto and Sharkey (1990), Sharkey *et al.* (1991) and Loreto *et al.* (2001).

Rosentiel *et al.* (2003) studied three 50-tree cottonwood plantations growing in separate mesocosms within the forestry section of the Biosphere 2 facility near Oracle, Arizona, USA, one of which mesocosms was maintained at an atmospheric CO<sub>2</sub> concentration of 430 ppm, while the other two were enriched to concentrations of 800 and 1200 ppm for one entire growing season. Integrated over that period, the total above-ground biomass of the trees in the latter two mesocosms was increased by 60 percent and 82 percent, respectively, while their production of isoprene was decreased by 21 percent and 41 percent, respectively.

Scholefield *et al.* (2004) measured isoprene emissions from *Phragmites australis* plants (one of the world's most important natural grasses) growing at different distances from a natural CO<sub>2</sub> spring in central Italy. At the specific locations they chose to make their measurements, atmospheric CO<sub>2</sub> concentrations of approximately 350, 400, 550 and 800 ppm had likely prevailed for the entire lifetimes of the plants. Across this CO<sub>2</sub> gradient, plant isoprene emissions dropped ever lower as the air's CO<sub>2</sub> concentration rose ever higher. Over the first 50-ppm CO<sub>2</sub> increase, isoprene emissions were reduced to approximately 65 percent of what they were at ambient CO<sub>2</sub>, while for CO<sub>2</sub> increases of 200 and 450 ppm, they were reduced to only about 30 percent and 7 percent of what they were in the 350-ppm-CO<sub>2</sub> air. The researchers note that these reductions were likely caused by reductions in leaf isoprene synthase, which was observed to be highly correlated with isoprene emissions, leading them to conclude that “elevated CO<sub>2</sub> generally inhibits the expression of isoprenoid synthesis genes and isoprene synthase activity which may, in turn, limit formation of every chloroplast-derived isoprenoid.” They state that the “basal

emission rate of isoprene is likely to be reduced under future elevated CO<sub>2</sub> levels.”

Centritto *et al.* (2004) grew hybrid poplar saplings for one full growing season in a FACE facility located at Rapolano, Italy, where the air's CO<sub>2</sub> concentration was increased by approximately 200 ppm. Their study demonstrated that “isoprene emission is reduced in elevated CO<sub>2</sub>, in terms of both maximum values of isoprene emission rate and isoprene emission per unit of leaf area averaged across the total number of leaves per plant,” which in their case amounted to a reduction of approximately 34 percent. When isoprene emission was summed over the entire plant profile, however, the reduction was not nearly so great (only 6 percent), because of the greater number of leaves on the CO<sub>2</sub>-enriched saplings. “However,” as they state, “Centritto *et al.* (1999), in a study with potted cherry seedlings grown in open-top chambers, and Gielen *et al.* (2001), in a study with poplar saplings exposed to FACE, showed that the stimulation of total leaf area in response to elevated CO<sub>2</sub> was a transient effect, because it occurred only during the first year of growth.” Hence, they concluded “it may be expected that with similar levels of leaf area, the integrated emission of isoprene would have been much lower in elevated CO<sub>2</sub>.” Indeed, they say that their data, “as well as that reported by Scholefield *et al.* (2004), in a companion experiment on *Phragmites* growing in a nearby CO<sub>2</sub> spring, mostly confirm that isoprene emission is inversely dependent on CO<sub>2</sub> [concentration] when this is above ambient, and suggests that a lower fraction of C will be re-emitted in the atmosphere as isoprene by single leaves in the future.”

Working at another FACE facility, the Aspen FACE facility near Rhinelander, Wisconsin, USA, Calfapietra *et al.* (2008) measured emissions of isoprene from sun-exposed upper-canopy leaves of an O<sub>3</sub>-tolerant clone and an O<sub>3</sub>-sensitive clone of trembling aspen (*Populus tremuloides* Michx.) trees that were growing in either normal ambient air, air enriched with an extra 190-200 ppm CO<sub>2</sub>, air with 1.5 times the normal ozone concentration, or air simultaneously enriched with the identical concentrations of both of these atmospheric trace gases. Results of their analysis showed that for the trees growing in air of ambient ozone concentration, the extra 190 ppm of CO<sub>2</sub> decreased the mean isoprene emission rate by 11.7 percent in the O<sub>3</sub>-tolerant aspen clone and by 22.7 percent in the O<sub>3</sub>-sensitive clone, while for the trees growing in air with 1.5 times the ambient ozone concentration, the extra

CO<sub>2</sub> also decreased the mean isoprene emission rate by 10.4 percent in the O<sub>3</sub>-tolerant clone and by 32.7 percent in the O<sub>3</sub>-sensitive clone. At the same time, and in the same order, net photosynthesis rates were increased by 34.9 percent, 47.4 percent, 31.6 percent and 18.9 percent.

Possell *et al.* (2004) grew seedlings of English oak (*Quercus robur*), one to a mesocosm (16 cm diameter, 60 cm deep), in either fertilized or unfertilized soil in *soldardomes* maintained at atmospheric CO<sub>2</sub> concentrations of either ambient or ambient plus 300 ppm for one full year, at the conclusion of which period they measured rates of isoprene emissions from the trees' foliage together with their rates of photosynthesis. In the unfertilized trees, this work revealed that the 300-ppm increase in the air's CO<sub>2</sub> concentration reduced isoprene emissions by 63 percent on a leaf area basis and 64 percent on a biomass basis, while in the fertilized trees the extra CO<sub>2</sub> reduced isoprene emissions by 70 percent on a leaf area basis and 74 percent on a biomass basis. In addition, the extra CO<sub>2</sub> boosted leaf photosynthesis rates by 17 percent in the unfertilized trees and 13 percent in the fertilized trees.

Possell *et al.* (2005) performed multiple three-week-long experiments with two known isoprene-emitting herbaceous species (*Mucuna pruriens* and *Arundo donax*), which they grew in controlled environment chambers that were maintained at two different sets of day/night temperatures (29/24°C and 24/18°C) and atmospheric CO<sub>2</sub> concentrations characteristic of glacial (180 ppm), pre-industrial (280 ppm) and current (366 ppm) conditions, where canopy isoprene emission rates were measured on the final day of each experiment. They obtained what they describe as “the first empirical evidence for the enhancement of isoprene production, on a unit leaf area basis, by plants that grew and developed in [a] CO<sub>2</sub>-depleted atmosphere,” which results, in their words, “support earlier findings from short-term studies with woody species (Monson and Fall, 1989; Loreto and Sharkey, 1990).” Then, combining their emission rate data with those of Rosenstiel *et al.* (2003) for *Populus deltoides*, Centritto *et al.* (2004) for *Populus x euroamericana* and Scholefield *et al.* (2004) for *Phragmites australis*, they developed a single downward-trending isoprene emissions curve that stretches all the way from 180 to 1200 ppm CO<sub>2</sub>, where it asymptotically approaches a value that is an order of magnitude less than what it is at 180 ppm.

Working at the Biosphere 2 facility near Oracle, Arizona, USA, in enclosed ultraviolet light-depleted

mesocosms (to minimize isoprene depletion by atmospheric oxidative reactions such as those involving OH), Pegoraro *et al.* (2005) studied the effects of atmospheric CO<sub>2</sub> enrichment (1200 ppm compared to an ambient concentration of 430 ppm) and drought on the emission of isoprene from cottonwood (*Populus deltoides* Bartr.) foliage and its absorption by the underlying soil for both well-watered and drought conditions. In doing so, they found that “under well-watered conditions in the agriforest stands, gross isoprene production (i.e., the total production flux minus the soil uptake) was inhibited by elevated CO<sub>2</sub> and the highest emission fluxes of isoprene were attained in the lowest CO<sub>2</sub> treatment.” In more quantitative terms, it was determined that the elevated CO<sub>2</sub> treatment resulted in a 46 percent reduction in gross isoprene production. In addition, it was found that drought suppressed the isoprene sink capacity of the soil beneath the trees, but that “the full sink capacity of dry soil was recovered within a few hours upon rewetting.”

Putting a slightly negative slant on their findings, Pegoraro *et al.* suggested that “in future, potentially hotter, drier environments, higher CO<sub>2</sub> may not mitigate isoprene emission as much as previously suggested.” However, we note that climate models generally predict an intensification of the hydrologic cycle in response to rising atmospheric CO<sub>2</sub> concentrations, and that the anti-transpirant effect of atmospheric CO<sub>2</sub> enrichment typically leads to increases in the moisture contents of soils beneath vegetation. Also, we note that over the latter decades of the twentieth century, when the IPCC claims the earth warmed at a rate and to a level that were unprecedented over the past two millennia, soil moisture data from all around the world tended to display upward trends. Robock *et al.* (2000), for example, developed a massive collection of soil moisture data from over 600 stations spread across a variety of climatic regimes, including the former Soviet Union, China, Mongolia, India and the United States, determining that “In contrast to predictions of summer desiccation with increasing temperatures, for the stations with the longest records, summer soil moisture in the top 1 m has increased while temperatures have risen.” And in a subsequent study of “45 years of gravimetrically observed plant available soil moisture for the top 1 m of soil, observed every 10 days for April-October for 141 stations from fields with either winter or spring cereals from the Ukraine for 1958-2002,” Robock *et al.* (2005) discovered that these real-world

observations “show a positive soil moisture trend for the entire period of observation,” noting that “even though for the entire period there is a small upward trend in temperature and a downward trend in summer precipitation, the soil moisture still has an upward trend for both winter and summer cereals.” Consequently, in a CO<sub>2</sub>-enriched world of the future, we likely will have the best of both aspects of isoprene activity: less production by vegetation and more consumption by soils.

Finally, we address the issue of how well models predict the response of isoprene emission to future global change. According to Monson *et al.* (2007) such predictions “probably contain large errors,” which clearly need to be corrected. The reason for the errors, write the twelve researchers who conducted the study, is that “the fundamental logic of such models is that changes in NPP [net primary production] will produce more or less biomass capable of emitting isoprene, and changes in climate will stimulate or inhibit emissions per unit of biomass.” They continue, “these models tend to ignore the discovery that there are direct effects of changes in the atmospheric CO<sub>2</sub> concentration on isoprene emission that tend to work in the opposite direction to that of stimulated NPP,” as has been indicated in the research studies described above. Their results showed, in their words, “that growth in an atmosphere of elevated CO<sub>2</sub> inhibited the emission of isoprene at levels that completely compensate for possible increases in emission due to increases in aboveground NPP.”

In lamenting this sorry state of global-change modeling, Monson *et al.* say that, “to a large extent, the modeling has ‘raced ahead’ of our mechanistic understanding of how isoprene emissions will respond to the fundamental drivers of global change,” and that “without inclusion of these effects in the current array of models being used to predict changes in atmospheric chemistry due to global change, one has to question the relevance of the predictions.”

A year later, Arneth *et al.* (2008) used a mechanistic isoprene-dynamic vegetation model of European woody vegetation to “investigate the interactive effects of climate and CO<sub>2</sub> concentration on forest productivity, species composition, and isoprene emissions for the periods 1981-2000 and 2081-2100,” which included a parameterization of the now-well-established direct CO<sub>2</sub>-isoprene inhibition phenomenon we have described in the papers above. The study found that “across the model domain,” the CO<sub>2</sub>-isoprene inhibition effect “has the potential to

offset the stimulation of [isoprene] emissions that could be expected from warmer temperatures and from the increased productivity and leaf area of emitting vegetation.”

In view of these findings, it appears the ongoing rise in the atmosphere's CO<sub>2</sub> concentration will lead to ever greater reductions in atmospheric isoprene concentrations. As noted in the introductory paragraph of this section, such a consequence would be welcome news for man and nature.

### 7.8.10. Microorganisms

Plants grown in CO<sub>2</sub>-enriched atmospheres nearly always exhibit increased photosynthetic rates and biomass production. Due to this productivity enhancement, more plant material is typically added to soils from root growth, turnover and exudation, as well as from leaves and stems following their abscission and falling to the ground during senescence. Such additions of carbon onto and into soils often serve as the only carbon source for supporting the development and growth of microorganisms in terrestrial habitats. Thus, it is important to understand how CO<sub>2</sub>-induced increases in plant growth affect microorganisms, a topic omitted from discussion by the IPCC.

Several studies have shown that atmospheric CO<sub>2</sub> enrichment does not significantly impact soil microorganisms. Zak *et al.* (2000), for example, observed no significant differences in soil microbial biomass beneath aspen seedlings grown at 350 and 700 ppm CO<sub>2</sub> after 2.5 years of differential treatment. Likewise, in the cases of Griffiths *et al.* (1998) and Insam *et al.* (1999), neither research team reported any changes in microbial community structure beneath ryegrass and artificial tropical ecosystems, respectively, after subjecting them to atmospheric CO<sub>2</sub> enrichment.

Other studies, however, have found that elevated CO<sub>2</sub> can significantly affect soil microorganisms. Van Ginkel and Gorissen (1998) observed that three months of elevated CO<sub>2</sub> exposure (700 ppm) increased soil microbial biomass beneath ryegrass

plants by 42 percent relative to that produced under ambient CO<sub>2</sub> conditions, as did Van Ginkel *et al.* (2000). Likewise, soil microbial biomass was reported to increase by 15 percent beneath agricultural fields subjected to a two-year wheat-soybean crop rotation (Islam *et al.*, 2000). In a study by Marilley *et al.* (1999), atmospheric CO<sub>2</sub> enrichment significantly increased bacterial numbers in the rhizospheres beneath ryegrass and white clover monocultures. Similarly, Lussenhop *et al.* (1998) reported CO<sub>2</sub>-induced increases in the amounts of bacteria, protozoa, and microarthropods in soils that had supported regenerating poplar tree cuttings for five months. In addition, Hungate *et al.* (2000) reported that twice-ambient CO<sub>2</sub> concentrations significantly increased the biomass of active fungal organisms and flagellated protozoa beneath serpentine and sandstone grasslands after four years of treatment exposure.

In taking a closer look at the study of Marilley *et al.* (1999), it is evident that elevated CO<sub>2</sub> caused shifts in soil microbial populations. In soils beneath their leguminous white clover, for example, elevated CO<sub>2</sub> favored shifts towards *Rhizobium* bacterial species, which likely increased nitrogen availability—via nitrogen fixation—to support enhanced plant growth. However, in soils beneath non-leguminous ryegrass monocultures, which do not form symbiotic relationships with *Rhizobium* species, elevated CO<sub>2</sub> favored shifts towards *Pseudomonas* species, which likely acquired nutrients to support enhanced plant growth through mechanisms other than nitrogen fixation. Nonetheless, in both situations, the authors observed CO<sub>2</sub>-induced shifts in bacterial populations that would likely optimize nutrient acquisition for specific host plant species.

In an unrelated study, Montealegre *et al.* (2000) reported that elevated CO<sub>2</sub> acted as a selective agent among 120 different isolates of *Rhizobium* growing beneath white clover plants. Specifically, when bacterial strains favored by ambient and elevated CO<sub>2</sub> concentrations were mixed together and grown with white clover at an atmospheric CO<sub>2</sub> concentration of 600 ppm, 17 percent more root nodules were formed by isolates previously determined to be favored by elevated CO<sub>2</sub>.

Hu *et al.* (2001) subjected fertile sandstone grasslands to five years of twice-ambient CO<sub>2</sub> concentrations and found they exhibited increased soil microbial biomass while simultaneously enhancing plant nitrogen uptake. The net effect of these phenomena reduced nitrogen availability for

microbial use, which consequently decreased microbial respiration and, hence, microbial decomposition. Consequently, these ecosystems displayed CO<sub>2</sub>-induced increases in net carbon accumulation. Similarly, Williams *et al.* (2000) reported that microbial biomass carbon increased by 4 percent in a tallgrass prairie after five years exposure to twice-ambient CO<sub>2</sub> concentrations, which contributed to a total soil carbon enhancement of 8 percent.

In summation, as the CO<sub>2</sub> content of the air continues to rise, earth's vegetation will likely respond with increasing photosynthetic rates and biomass production, returning more organic carbon to the soil where it will be utilized by microbial organisms to maintain or increase their population numbers, biomass and heterotrophic activities (Weihong *et al.*, 2000; Arnone and Bohlen, 1998). Shifts in microbial community structure may occur that will favor the intricate relationships that currently exist between leguminous and non-leguminous plants and the specific microorganisms upon which they depend.

### 7.8.11. Worms

Perhaps the best known worm in the world is the common earthworm. How will it be affected as the air's CO<sub>2</sub> content continues to climb, and how will its various responses affect the biosphere? What about other worms? How will they fare in a CO<sub>2</sub>-enriched world of the future, and what will be the results of their responses?

“Earthworms,” in the words of Edwards (1988), “play a major role in improving and maintaining the fertility, structure, aeration and drainage of agricultural soils.” As noted by Sharpley *et al.* (1988), “by ingestion and digestion of plant residue and subsequent egestion of cast material, earthworms can redistribute nutrients in a soil and enhance enzyme activity, thereby increasing plant availability of both soil and plant residue nutrients,” as others have also demonstrated (Bertsch *et al.*, 1988; McCabe *et al.*, 1988; Zachmann and Molina, 1988). Kemper (1988) describes how “burrows opened to the surface by surface-feeding worms provide drainage for water accumulating on the surface during intense rainfall,” noting that “the highly compacted soil surrounding the expanded burrows has low permeability to water which often allows water to flow through these holes for a meter or so before it is sorbed into the surrounding soil.”

Hall and Dudas (1988) report that the presence of earthworms appears to mitigate the deleterious effects of certain soil toxins. Logsdon and Linden (1988) describe a number of other beneficial effects of earthworms, including (1) enhancement of soil aeration, since under wet conditions earthworm channels do not swell shut as many soil cracks do, (2) enhancement of soil water uptake, since roots can explore deeper soil layers by following earthworm channels, and (3) enhancement of nutrient uptake, since earthworm casts and channel walls have a more neutral pH and higher available nutrient level than bulk soil. Hence, we should care about what happens to earthworms as the air’s CO<sub>2</sub> content rises because of the many important services they provide for earth’s plant life.

Edwards (1988) says “the most important factor in maintaining good earthworm populations in agricultural soils is that there be adequate availability of organic matter,” while Hendrix *et al.* (1988) and Kladvko (1988) report that greater levels of plant productivity promote greater levels of earthworm activity. Consequently, since the most ubiquitous and powerful effect of atmospheric CO<sub>2</sub> enrichment is its stimulation of plant productivity, which leads to enhanced organic matter delivery to soils, it logically follows that this aerial fertilization effect of the ongoing rise in the air’s CO<sub>2</sub> content should increase earthworm populations and amplify the many beneficial services they provide for plants.

The second most significant and common effect of atmospheric CO<sub>2</sub> enrichment on plants is its antitranspirant effect, whereby elevated levels of

atmospheric CO<sub>2</sub> reduce leaf stomatal apertures and slow the rate of evaporative water loss from the vast bulk of earth’s vegetation. Both growth chamber studies and field experiments that have studied this phenomenon provide voluminous evidence that it often leads to increased soil water contents in many terrestrial ecosystems, which also benefits earthworm populations.

Zaller and Arnone (1997) fumigated open-top and -bottom chambers in a calcareous grassland near Basal, Switzerland with air of either 350 or 600 ppm CO<sub>2</sub> for an entire growing season. They found that the mean annual soil moisture content in the CO<sub>2</sub>-enriched chambers was 10 percent greater than that observed in the ambient-air chambers, and because rates of surface cast production by earthworms are typically positively correlated with soil moisture content, they found that cumulative surface cast production after only one year was 35 percent greater in the CO<sub>2</sub>-enriched chambers than in the control chambers. In addition, because earthworm casts are rich in organic carbon and nitrogen, the cumulative amount of these important nutrients on a per-land-area basis was found to be 28 percent greater in the CO<sub>2</sub>-enriched chambers than it was in the ambient-air chambers. In a subsequent study of the same grassland, Zaller and Arnone (1999) found that plants growing in close proximity to the earthworm casts produced more biomass than similar plants growing further away from them. They also found that the CO<sub>2</sub>-induced growth stimulation experienced by the various grasses was also greater for those plants growing nearer the earthworm casts.

These various observations suggest that atmospheric CO<sub>2</sub> enrichment sets in motion a self-enhancing cycle of positive biological phenomena, whereby increases in the air’s CO<sub>2</sub> content (1) stimulate plant productivity and (2) reduce plant evaporative water loss, which results in (3) more organic matter entering the soil and (4) a longer soil moisture retention time and/or greater soil water contents, all of which factors lead to (5) the development of larger and more active earthworm populations, which (6) enhance many important soil properties, including fertility, structure, aeration and drainage, which improved properties (7) further enhance the growth of the plants whose CO<sub>2</sub>-induced increase in productivity was the factor that started the whole series of processes in the first place.

More earthworms also can increase soil’s ability to sequester carbon. As Jongmans *et al.* (2003) point out, “the rate of organic matter decomposition can be

decreased in worm casts compared to bulk soil aggregates (Martin, 1991; Haynes and Fraser, 1998).” On the basis of these studies and their own micro-morphological investigation of structural development and organic matter distribution in two calcareous marine loam soils on which pear trees had been grown for 45 years (one of which soils exhibited little to no earthworm activity and one of which exhibited high earthworm activity, due to different levels of heavy metal contamination of the soils as a consequence of the prior use of different amounts of fungicides), they concluded that “earthworms play an important role in the intimate mixing of organic residues and fine mineral soil particles and the formation of organic matter-rich micro-aggregates and can, therefore, contribute to physical protection of organic matter, thereby slowing down organic matter turnover and increasing the soil’s potential for carbon sequestration.” Put more simply, atmospheric CO<sub>2</sub> enrichment that stimulates the activity of earthworms also leads to more—and more secure—sequestration of carbon in earth’s soils.

Don *et al.* (2008) studied the effects of anecic earthworms—which generally inhabit a single vertical burrow throughout their entire lives that can be as much as five meters in depth, but is generally in the range of one to two meters—on soil carbon stocks and turnover via analyses of enzyme activity, stable isotopes, nuclear magnetic resonance spectroscopy, and the <sup>14</sup>C age of their burrow linings. The results of their study indicated that “the carbon distribution in soils is changed by anecic earthworms’ activity with more carbon stored in the subsoil where earthworms slightly increase the carbon stocks.” In this regard they also state that “the translocation of carbon from [the] organic layer to the subsoil will decrease the carbon vulnerability to mineralization,” since “carbon in the organic layer and the surface soil is much more prone to disturbances with rapid carbon loss than subsoil carbon.”

Bossuyt *et al.* (2005) conducted a pair of experiments designed to investigate “at what scale and how quickly earthworms manage to protect SOM [soil organic matter].” In the first experiment, soil aggregate size distribution together with total C and <sup>13</sup>C were measured in three treatments—control soil, soil + <sup>13</sup>C-labeled sorghum leaf residue, and soil + <sup>13</sup>C-labeled residue + earthworms—after a period of 20 days incubation, where earthworms were added after the eighth day. In the second experiment, they determined the protected C and <sup>13</sup>C pools inside the newly formed casts and macro- and micro-soil-

aggregates. Results indicated that the proportion of large water-stable macroaggregates was on average 3.6 times greater in the soil-residue samples that contained earthworms than in those that lacked earthworms, and that the macroaggregates in the earthworm treatment contained approximately three times more sequestered carbon. What is more, the earthworms were found to form “a significant pool of protected C in microaggregates within large macroaggregates after 12 days of incubation,” thereby demonstrating the rapidity with which earthworms perform their vital function of sequestering carbon in soils when plant residues become available to them.

Cole *et al.* (2002) report that “in the peatlands of northern England, which are classified as blanket peat, it has been suggested that the potential effects of global warming on carbon and nutrient dynamics will be related to the activities of dominant soil fauna, and especially enchytraeid worms.” In harmony with these ideas, Cole *et al.* say they “hypothesized” that warming would lead to increased enchytraeid worm activity, which would lead to higher grazing pressure on microbes in the soil; and since enchytraeid grazing has been observed to enhance microbial activity (Cole *et al.*, 2000), they further hypothesized that more carbon would be liberated in dissolved organic form, “supporting the view that global warming will increase carbon loss from blanket peat ecosystems.”

The scientists next describe how they constructed small microcosms from soil and litter they collected near the summit of Great Dun Fell, Cumbria, England. Subsequent to “defaunating” this material by reducing its temperature to -80°C for 24 hours, they thawed and inoculated it with native soil microbes, after which half of the microcosms were incubated in the dark at 12°C and half at 18°C, the former of which temperatures was approximately equal to mean August soil temperature at a depth of 10 cm at the site of soil collection, while the latter was said by them to be “close to model predictions for soil warming that might result from a doubling of CO<sub>2</sub> in blanket peat environments.”

Ten seedlings of an indigenous grass of blanket peat were then transplanted into each of the microcosms, while 100 enchytraeid worms were added to each of half of the mini-ecosystems. These procedures resulted in the creation of four experimental treatments: ambient temperature, ambient temperature + enchytraeid worms, elevated temperature, and elevated temperature + enchytraeid worms. The resulting 48 microcosms—sufficient to destructively harvest three replicates of each

treatment four different times throughout the course of the 64-day experiment—were arranged in a fully randomized design and maintained at either 12 or 18°C with alternating 12-hour light and dark periods. In addition, throughout the entire course of the study, the microcosms were given distilled water every two days to maintain their original weights.

So what did the researchers find? First, and contrary to their hypothesis, elevated temperature reduced the ability of the enchytraeid worms to enhance the loss of carbon from the microcosms. At the normal ambient temperature, for example, the presence of the worms enhanced dissolved organic carbon (DOC) loss by 16 percent, while at the elevated temperature expected for a doubling of the air's CO<sub>2</sub> content, the worms had no effect at all on DOC. In addition, Cole *et al.* note that “warming may cause drying at the soil surface, forcing enchytraeids to burrow to deeper subsurface horizons.” Hence, since the worms are known to have little influence on soil carbon dynamics below a depth of 4 cm (Cole *et al.*, 2000), they concluded that this additional consequence of warming would further reduce the ability of enchytraeids to enhance carbon loss from blanket peatlands.

In summarizing their findings, Cole *et al.* say that “the soil biotic response to warming in this study was negative.” That is, it was of such a nature that it resulted in a reduced loss of carbon to the atmosphere, which would tend to slow the rate of rise of the air's CO<sub>2</sub> content, just as was suggested by the results of the study of Jongmans *et al.*

Yeates *et al.* (2003) report results from a season-long FACE study of a 30-year-old New Zealand pasture, where three experimental plots had been maintained at the ambient atmospheric CO<sub>2</sub> concentration of 360 ppm and three others at a concentration of 475 ppm (a CO<sub>2</sub> enhancement of only 32 percent) for a period of four to five years. The pasture contained about twenty species of plants, including C<sub>3</sub> and C<sub>4</sub> grasses, legumes and forbs. Nematode, or “roundworm,” populations increased significantly in response to the 32 percent increase in the air's CO<sub>2</sub> concentration. Of the various feeding groups studied, Yeates *et al.* report that the relative increase “was lowest in bacterial-feeders (27%), slightly higher in plant (root) feeders (32%), while those with delicate stylets (or narrow lumens; plant-associated, fungal-feeding) increased more (52% and 57%, respectively).” The greatest nematode increases were recorded among omnivores (97 percent) and predators (105 percent). Most dramatic of all, root-

feeding populations of the *Longidorus* nematode taxon rose by 330 percent. Also increasing in abundance were earthworms: *Aporrectodea caliginosa* by 25 percent and *Lumbricus rubellus* by 58 percent. Enchytraeids, on the other hand, decreased in abundance, by approximately 30 percent.

With respect to earthworms, Yeates *et al.* note that just as was found in the studies cited in the first part of this review, the introduction of lumbricids has been demonstrated to improve soil conditions in New Zealand pastures (Stockdill, 1982), which benefits pasture plants. Hence, the CO<sub>2</sub>-induced increase in earthworm numbers observed in Yeates *et al.*'s study would be expected to do more of the same, while the reduced abundance of enchytraeids they documented in the CO<sub>2</sub>-enriched pasture would supposedly lead to less carbon being released to the air from the soil, as per the known ability of enchytraeids to promote carbon loss from British peat lands under current temperatures.

In summary, the lowly earthworm and still lowlier soil nematodes respond to increases in the air's CO<sub>2</sub> content via a number of plant-mediated phenomena in ways that further enhance the positive effects of atmospheric CO<sub>2</sub> enrichment on plant growth and development, while at the same time helping to sequester more carbon more securely in the soil.

## 7.9. Greening of the Earth

More than two decades ago, Idso (1986) published a small item in *Nature* advancing the idea that the aerial fertilization effect of the CO<sub>2</sub> that is liberated by the burning of coal, gas and oil was destined to dramatically enhance the productivity of earth's vegetation. In a little book he had published four years earlier (Idso, 1982), he had predicted that "CO<sub>2</sub> effects on both the managed and unmanaged biosphere will be overwhelmingly positive." In a monograph based on a lecture he gave nine years later (Idso, 1995), he said "we appear to be experiencing the initial stages of what could truly be called a *rebirth of the biosphere*, the beginnings of a biological rejuvenation that is without precedent in all of human history."

In light of the fact that Idso's worldview is nearly the exact opposite of the apocalyptic vision promulgated by the IPCC, it is instructive to see what real-world observations reveal about the matter. In this section we review studies that show a CO<sub>2</sub>-induced greening of Africa, Asia, Europe, North America, the oceans, and the entire globe.

Additional information on this topic, including reviews not discussed here, can be found at [http://www.co2science.org/subject/g/subject\\_g.php](http://www.co2science.org/subject/g/subject_g.php) under the heading Greening of the Earth.

### 7.9.1. Africa

In an article by Fred Pearce that was posted on the website of *New Scientist* magazine on 16 September 2002 titled “Africa’s deserts are in ‘spectacular’ retreat,” we were told the story of vegetation reclaiming great tracts of barren land across the entire southern edge of the Sahara. This information likely came as a bit of a surprise to many, since the United Nations Environment Program had reported to the World Summit on Sustainable Development in Johannesburg, South Africa in August of that year that over 45 percent of the continent was experiencing severe desertification. The world of nature, however, told a vastly different story.

Pearce began by stating “the southern Saharan desert is in retreat, making farming viable again in what were some of the most arid parts of Africa,” noting that “Burkina Faso, one of the West African countries devastated by drought and advancing deserts 20 years ago, is growing so much greener that families who fled to wetter coastal regions are starting to go home.”

The good news was not confined to Burkina Faso. “Vegetation,” according to Pearce, “is ousting sand across a swathe of land stretching from Mauritania on the shores of the Atlantic to Eritrea 6000 kilometers away on the Red Sea coast.” Besides being widespread in space, the greening was widespread in time, having been happening since at least the mid-1980s.

Quoting Chris Reij of the Free University of Amsterdam, Pearce wrote that “aerial photographs taken in June show ‘quite spectacular regeneration of vegetation’ in northern Burkina Faso.” The data indicated the presence of more trees for firewood and more grassland for livestock. In addition, a survey that Reij was collating showed, according to Pearce, “a 70% increase in yields of local cereals such as sorghum and millet in one province in recent years.” Also studying the area was Kjeld Rasmussen of the University of Copenhagen, who reported that since the 1980s there had been a “steady reduction in bare ground” with “vegetation cover, including bushes and trees, on the increase on the dunes.”

Pearce also reported on the work of a team of geographers from Britain, Sweden and Denmark that had spent much of the prior summer analyzing archived satellite images of the Sahel. Citing Andrew Warren of University College London as a source of information on this study, he said the results showed “that ‘vegetation seems to have increased

significantly’ in the past 15 years, with major regrowth in southern Mauritania, northern Burkina Faso, north-western Niger, central Chad, much of Sudan and parts of Eritrea.”

Should these findings take us by surprise? Not in the least, as Nicholson *et al.* (1998) reported in a study of a series of satellite images of the Central and Western Sahel that were taken from 1980 to 1995, they could find no evidence of any overall expansion of deserts and no drop in the rainfall use efficiency of native vegetation. In addition, in a satellite study of the entire Sahel from 1982 to 1990, Prince *et al.* (1998) detected a steady rise in rainfall use efficiency, suggesting that plant productivity and coverage of the desert had increased during this period.

That the greening phenomenon has continued apace is borne out by the study of Eklundh and Olsson (2003), who analyzed Normalized Difference Vegetation Index (NDVI) data obtained from the U.S. National Oceanic and Atmospheric Administration’s satellite-borne Advanced Very High Resolution Radiometer whenever it passed over the African Sahel for the period 1982-2000. As they describe their findings, “strong positive change in NDVI occurred in about 22% of the area, and weak positive change in 60% of the area,” while “weak negative change occurred in 17% of the area, and strong negative change in 0.6% of the area.” In addition, they report that “integrated NDVI has increased by about 80% in the areas with strong positive change,” while in areas with weak negative change, “integrated NDVI has decreased on average by 13%.” The primary story told by these data, therefore, is one of strong positive trends in NDVI for large areas of the African Sahel over the last two decades of the twentieth century. Eklundh and Olsson conclude that the “increased vegetation, as suggested by the observed NDVI trend, could be part of the proposed tropical sink of carbon.”

Due to the increase in vegetation over the past quarter-century in the Sahel, the African region was recently featured in a special issue of the *Journal of Arid Environments* titled “The ‘Greening’ of the Sahel.” Therein, Anyamba and Tucker (2005) describe their development of an NDVI history of the region for the period 1981-2003. Comparing this history with the precipitation history of the Sahel developed by Nicholson (2005), they found that “the persistence and spatial coherence of drought conditions during the 1980s is well represented by the NDVI anomaly patterns and corresponds with the documented rainfall anomalies across the region during this time period.” In addition, they report that

“the prevalence of greener than normal conditions during the 1990s to 2003 follows a similar increase in rainfall over the region during the last decade.”

In another analysis of NDVI and rainfall data in the same issue of the *Journal of Arid Environments*, Olsson *et al.* (2005) report finding “a consistent trend of increasing vegetation greenness in much of the region,” which they describe as “remarkable.” They say increasing rainfall over the last few years “is certainly one reason” for the greening phenomenon. However, they find the increase in rainfall “does not fully explain” the increase in greenness.

For one thing, the three Swedish scientists note that “only eight out of 40 rainfall observations showed a statistically significant increase between 1982-1990 and 1991-1999.” In addition, they report that “further analysis of this relationship does not indicate an overall relationship between rainfall increase and vegetation trend.” So what else could be driving the increase in greenness?

Olsson *et al.* suggest that “another potential explanation could be improved land management, which has been shown to cause similar changes in vegetation response elsewhere (Runnstrom, 2003).” However, in more detailed analyses of Burkina Faso and Mali, where production of millet rose by 55 percent and 35 percent, respectively, since 1980, they could find “no clear relationship” between agricultural productivity and NDVI, which argues against the land management explanation.

A third speculation of Olsson *et al.* is that the greening of the Sahel could be caused by increasing rural-to-urban migration. In this scenario, widespread increases in vegetation occur as a result of “reduced area under cultivation,” due to a shortage of rural laborers, and/or “increasing inputs on cropland,” such as seeds, machinery and fertilizers made possible by an increase in money sent home to rural households by family members working in cities. However, Olsson *et al.* note that “more empirical research is needed to verify this [hypothesis].”

About the only thing left is what Idso (1982, 1986, 1995) has suggested, i.e., that the aerial fertilization effect of the ongoing rise in the air’s CO<sub>2</sub> concentration (which greatly enhances vegetative productivity) and its anti-transpiration effect (which enhances plant water-use efficiency and enables plants to grow in areas that were once too dry for them) are the major players in the greening phenomenon. Whatever was the reason for the greening of the Sahel over the past quarter-century, it is clear that in spite of what the IPCC claims were

unprecedented increases in anthropogenic CO<sub>2</sub> emissions and global temperatures, the Sahel experienced an increase in vegetative cover that was truly, as Olsson *et al.* write, “remarkable.”

### 7.9.2. Asia

We begin a review of Asia with the modeling work of Liu *et al.* (2004), who derived detailed estimates of the economic impact of predicted climate change on agriculture in China, utilizing county-level agricultural, climate, social, economic and edaphic data for 1275 agriculture-dominated counties for the period 1985-1991, together with the outputs of three general circulation models of the atmosphere that were based on five different scenarios of anthropogenic CO<sub>2</sub>-induced climate change that yielded a mean countrywide temperature increase of 3.0°C and a mean precipitation increase of 3.9 percent for the 50-year period ending in AD 2050. In doing so, they determined that “all of China would benefit from climate change in most scenarios.” In addition, they state that “the effects of CO<sub>2</sub> fertilization should [also] be included, for some studies indicate that this may produce a significant increase in yield.” The significance of these findings is readily grasped when it is realized, in Liu *et al.*'s words, that “China's agriculture has to feed more than one-fifth of the world's population, and, historically, China has been famine prone.” They report that “as recently as the late 1950s and early 1960s a great famine claimed about thirty million lives (Ashton *et al.*, 1984; Cambridge History of China, 1987).”

Moving from agro-ecosystems to natural ones, Su *et al.* (2004) used an ecosystem process model to explore the sensitivity of the net primary productivity (NPP) of an oak forest near Beijing (China) to the global climate changes projected to result from a doubling of the atmosphere's CO<sub>2</sub> concentration from 355 to 710 ppm. The results of this work suggested that the aerial fertilization effect of the specified increase in the air's CO<sub>2</sub> content would raise the forest's NPP by 14.0 percent, that a concomitant temperature increase of 2°C would boost the NPP increase to 15.7 percent, and that adding a 20 percent increase in precipitation would push the NPP increase to 25.7 percent. They calculated that a 20 percent increase in precipitation and a 4°C increase in temperature would also boost the forest's NPP by 25.7 percent.

Grunzweig *et al.* (2003) tell the tale of the Yatir forest, a 2,800-hectare stand of Aleppo and other pine trees, that had been planted some 35 years earlier at the edge of the Negev Desert in Israel. An intriguing aspect of this particular forest, which they characterize as growing in poor soil of only 0.2 to 1.0 meter's depth above chalk and limestone, is that

although it is located in an arid part of Asia that receives less annual precipitation than all of the other scores of FluxNet stations in the global network of micrometeorological tower sites that use eddy covariance methods to measure exchanges of CO<sub>2</sub>, water vapor and energy between terrestrial ecosystems and the atmosphere (Baldocchi *et al.*, 2001), the forest's annual net ecosystem CO<sub>2</sub> exchange was just as high as that of many high-latitude boreal forests and actually higher than that of most temperate forests. Grunzweig *et al.* note that the increase in atmospheric CO<sub>2</sub> concentration that has occurred since pre-industrial times should have improved water use efficiency (WUE) in most plants by increasing the ratio of CO<sub>2</sub> fixed to water lost via evapotranspiration. They report that “reducing water loss in arid regions improves soil moisture conditions, decreases water stress and extends water availability,” which “can indirectly increase carbon sequestration by influencing plant distribution, survival and expansion into water-limited environments.”

That this hypothesis is correct has been demonstrated by Leavitt *et al.* (2003) within the context of the long-term atmospheric CO<sub>2</sub> enrichment experiment of Idso and Kimball (2001) on sour orange trees. It has also been confirmed in nature by Fang (2003), who obtained identical (to the study of Leavitt *et al.*) CO<sub>2</sub>-induced WUE responses for 23 groups of naturally occurring trees scattered across western North America over the period 1800-1985, which response, Fang concludes, “would have caused natural trees in arid environments to grow more rapidly, acting as a carbon sink for anthropogenic CO<sub>2</sub>,” which is exactly what Grunzweig *et al.* found to be happening in the Yatir forest on the edge of the Negev Desert.

Based primarily on satellite-derived Normalized Difference Vegetation Index (NDVI) data, Zhou *et al.* (2001) found that from July 1981 to December 1999, between 40 and 70° N latitude, there was a persistent increase in growing season vegetative productivity in excess of 12 percent over a broad contiguous swath of Asia stretching from Europe through Siberia to the Aldan plateau, where almost 58 percent of the land is forested. And in a companion study, Bogaert *et al.* (2002) determined that this productivity increase occurred at a time when this vast Asian region showed an overall warming trend “with negligible occurrence of cooling.”

In another study that included a portion of Europe, Lapenis *et al.* (2005) analyzed trends in forest biomass in all 28 ecoregions of the Russian

territory, based on data collected from 1953 to 2002 within 3196 sample plots comprised of about 50,000 entries, which database, in their words, “contains all available archived and published data.” This work revealed that over the period 1961-1998, as they describe it, “aboveground wood, roots, and green parts increased by 4%, 21%, and 33%, respectively,” such that “the total carbon density of the living biomass stock of the Russian forests increased by ~9%.” They also report there was a concomitant increase of ~11 percent in the area of Russian forests. In addition, the team of U.S., Austrian and Russian scientists reported that “within the range of 50-65° of latitude [the range of 90 percent of Russian forests], the relationship between biomass density and the area-averaged NDVI is very close to a linear function, with a slope of ~1,” citing the work of Myneni *et al.* (2001). Therefore, as they continue, “changes in the carbon density of live biomass in Russian forests occur at about the same rate as the increase in the satellite-based estimate in the seasonally accumulated NDVI,” which observation strengthens the findings of *all* satellite-based NDVI studies.

Returning to China for several concluding reports, we begin with the work of Brogaard *et al.* (2005), who studied the dry northern and northwestern regions of the country—including the Inner Mongolia Autonomous Region (IMAR)—which had been thought to have experienced declining vegetative productivity over the past few decades due to “increasing livestock numbers, expansion of cultivated land on erosive soils and the gathering of fuel wood and herb digging,” which practices were believed to have been driven by rising living standards, which in combination with a growing population were assumed to have increased the pressure on these marginal lands. In the case of increasing grazing, for example, Brogaard *et al.* note that the total number of livestock in the IMAR increased from approximately 46 million head in 1980 to about 71 million in 1997.

To better assess the seriousness of this supposedly “ongoing land degradation process,” as they describe it, the researchers adapted a satellite-driven parametric model, originally developed for Sahelian conditions, to the central Asian steppe region of the IMAR by including “additional stress factors and growth efficiency computations.” The applied model, in their words, “uses satellite sensor-acquired reflectance in combination with climate data to generate monthly estimates of gross primary production.” To their great surprise, this work

revealed that “despite a rapid increase in grazing animals on the steppes of the IMAR for the 1982-1999 period,” their model estimates did “not indicate declining biological production.”

Clearly, some strong positive influence compensated for the increased human and animal pressures on the lands of the IMAR over the period of Brogaard *et al.*'s study. In this regard, they mention the possibility of increasing productivity on the agricultural lands of the IMAR, but they note that crops are grown on “only a small proportion of the total land area.” Other potential contributing factors they mention are “an increase in precipitation, as well as afforestation projects.” Two things they do *not* mention are the aerial fertilization effect and the transpiration-reducing effect of the increase in the air's CO<sub>2</sub> concentration that was experienced over the study period. Applied together, the sum of these positive influences (and possibly others that remain unknown) was demonstrably sufficient to keep plant productivity from declining in the face of greatly increasing animal and human pressures on the lands of the IMAR from 1982 to 1999.

Piao *et al.* (2005a) used a time series of NDVI data from 1982 to 1999, together with precipitation and temperature data, to investigate variations of desert area in China by “identifying the climatic boundaries of arid area and semiarid area, and changes in NDVI in these areas.” In doing so, they discovered that “average rainy season NDVI in arid and semiarid regions both increased significantly during the period 1982-1999.” Specifically, they found that the NDVI increased for 72.3 percent of total arid regions and for 88.2 percent of total semiarid regions, such that the area of arid regions decreased by 6.9 percent and the area of semiarid regions decreased by 7.9 percent. They also report that by analyzing Thematic Mapper satellite images, “Zhang *et al.* (2003) documented that the process of desertification in the Yulin area, Shannxi Province showed a decreased trend between 1987 and 1999,” and that “according to the national monitoring data on desertification in western China (Shi, 2003), the annual desertification rate decreased from 1.2% in the 1950s to -0.2% at present.”

Further noting that “variations in the vegetation coverage of these regions partly affect the frequency of sand-dust storm occurrence (Zou and Zhai, 2004),” Piao *et al.* concluded that “increased vegetation coverage in these areas will likely fix soil, enhance its anti-wind-erosion ability, reduce the possibility of released dust, and consequently cause a mitigation of

sand-dust storms.” They also reported that “recent studies have suggested that the frequencies of strong and extremely strong sand-dust storms in northern China have significantly declined from the early 1980s to the end of the 1990s (Qian *et al.*, 2002; Zhao *et al.*, 2004).”

Piao *et al.* (2006) investigated vegetation net primary production (NPP) derived from a carbon model (Carnegie-Ames-Stanford approach, CASA) and its interannual change in the Qinghai-Xizang (Tibetan) Plateau using 1982-1999 NDVI data and paired ground-based information on vegetation, climate, soil, and solar radiation. This work revealed that over the entire study period, NPP rose at a mean annual rate of 0.7 percent. However, Piao *et al.* report that “the NPP trends in the plateau over the two decades were divided into two distinguished periods: without any clear trend from 1982 to 1990 and significant increase from 1991 to 1999.”

The three researchers say their findings suggest that “vegetation growth on the plateau in the 1990s has been much enhanced compared to that in [the] 1980s, consistent with the trend in the northern latitudes indicated by Schimel *et al.* (2001).” In addition, they say that “previous observational and NPP modeling studies have documented substantial evidence that terrestrial photosynthetic activity has increased over the past two to three decades in the middle and high latitudes in the Northern Hemisphere,” and that “satellite-based NDVI data sets for the period of 1982-1999 also indicate consistent trends of NDVI increase,” citing multiple references in support of each of these statements. Piao *et al.*'s findings, therefore, add to the growing body of evidence that reveals a significant “greening of the earth” is occurring.

Applying the same techniques, Fang *et al.* (2003) looked at the whole of China, finding that its terrestrial NPP increased by 18.7 percent between 1982 and 1999. Referring to this result as “an unexpected aspect of biosphere dynamics,” they say that this increase “is much greater than would be expected to result from the fertilization effect of elevated CO<sub>2</sub>, and also greater than expected from climate, based on broad geographic patterns.” From 1982 to 1999, the atmosphere's CO<sub>2</sub> concentration rose by approximately 27.4 ppm. The aerial fertilization effect of this CO<sub>2</sub> increase could be expected to have increased the NPP of the conglomerate of forest types found in China by about 7.3 percent. (See the procedures and reasoning described in a CO<sub>2</sub> Science editorial, September 18,

2002, <http://www.co2science.org/articles/V5/N38/EDIT.php>). But this increase is only a part of the total NPP increase we could expect, for Fang *et al.* note that “much of the trend in NPP appeared to reflect a change towards an earlier growing season,” which was driven by the 1.1°C increase in temperature they found to have occurred in their region of study between 1982 and 1999.

Following this lead, we learn from the study of White *et al.* (1999)—which utilized 88 years of data (1900-1987) that were obtained from 12 different locations within the eastern U.S. deciduous forest that stretches from Charleston, SC (32.8°N latitude) to Burlington, VT (44.5°N latitude)—that a 1°C increase in mean annual air temperature increases the length of the forest's growing season by approximately five days. In addition, White *et al.* determined that a one-day extension in growing season length increased the mean forest NPP of the 12 sites they studied by an average of 1.6 percent. Hence, we could expect an additional NPP increase due to the warming-induced growing season expansion experienced in China from 1982 to 1999 of 1.6 percent/day x 5 days = 8.0 percent, which brings the total CO<sub>2</sub>-induced plus warming-induced increase in NPP to 15.3 percent.

Last, we note there is a well-documented positive synergism between increasing air temperature and CO<sub>2</sub> concentration (Idso and Idso, 1994), such that the 1°C increase in temperature experienced in China between 1982 and 1999 could easily boost the initial CO<sub>2</sub>-induced 7.3 percent NPP enhancement to the 10.7 percent enhancement that when combined with the 8.0 percent enhancement caused by the warming-induced increase in growing season length would produce the 18.7 percent increase in NPP detected in the satellite data.

In view of these observations, the findings of Fang *et al.* are seen to be right in line with what would be expected to result from the increases in air temperature and atmospheric CO<sub>2</sub> concentration that occurred between 1982 and 1999 in China: a stimulated terrestrial biosphere that is growing ever more productive with each passing year. This is the true observed consequence of rising CO<sub>2</sub> and temperature, and it is about as far removed as one can get from the negative scenarios offered by the IPCC.

Analyzing the same set of data still further, Piao *et al.* (2005b) say their results suggest that “terrestrial NPP in China increased at a rate of 0.015 Pg C yr<sup>-1</sup> over the period 1982-1999, corresponding to a total increase of 18.5%, or 1.03% annually.” They also found that “during the past 2 decades the amplitude of

the seasonal curve of NPP has increased and the annual peak NPP has advanced,” which they say “may indirectly explain the enhanced amplitude and advanced timing of the seasonal cycle of atmospheric CO<sub>2</sub> concentration (Keeling *et al.*, 1996),” the former of which phenomena they further suggest “was probably due to the rise in atmospheric CO<sub>2</sub> concentration, elevated temperature, and increased atmospheric N and P deposition,” while the latter phenomenon they attribute to “advanced spring onset and extended autumn growth owing to climate warming.” We are in basic agreement on most of these points, but note that the advanced onset of what may be called biological spring is also fostered by the enhancement of early spring growth that is provided by the ongoing rise in the air’s CO<sub>2</sub> concentration.

Citing a total of 20 scientific papers at various places in the following sentence from their research report, Piao *et al.* conclude that “results from observed atmospheric CO<sub>2</sub> and O<sub>2</sub> concentrations, inventory data, remote sensing data, and carbon process models have all suggested that terrestrial vegetation NPP of the Northern Hemisphere has increased over the past 2 decades and, as a result, the northern terrestrial ecosystems have become important sinks for atmospheric CO<sub>2</sub>.”

In conclusion, the historical increases in the atmosphere’s CO<sub>2</sub> concentration and temperature have fostered a significant greening of the earth, including that observed throughout the length and breadth of Asia. It would appear that the climatic change claimed by the IPCC to have been experienced by the globe over the latter part of the twentieth century either did not occur or was dwarfed by opposing phenomena that significantly benefited China, as its lands grew ever greener during this period and its increased vegetative cover helped to stabilize its soils and throw feared desertification into reverse.

Additional information on this topic, including reviews of newer publications as they become available, can be found at <http://www.co2science.org/subject/g/asiagreen.php>.

### 7.9.3. Europe

Allen *et al.* (1999) analyzed sediment cores from a lake in southern Italy and from the Mediterranean Sea, developing high-resolution climate and vegetation data sets for this region over the last 102,000 years. These materials indicated that rapid changes in vegetation were well correlated with rapid changes in climate, such that complete shifts in natural ecosystems would sometimes occur over periods of less than 200 years. Over the warmest portion of the record (the Holocene), the total organic carbon content of the vegetation reached its highest level, more than doubling values experienced over the rest of the record, while other proxy indicators revealed that during the more productive woody-plant period of the Holocene, the increased vegetative cover also led to less soil erosion. The results of this study demonstrate that the biosphere can successfully respond to rapid changes in climate. As the 15 researchers involved in the work put it, “the biosphere was a full participant in these rapid fluctuations, contrary to widely held views that vegetation is unable to change with such rapidity.” Furthermore, their work revealed that warmer was always better in terms of vegetative productivity.

Osborne *et al.* (2000) used an empirically based mechanistic model of Mediterranean shrub vegetation to address two important questions: (1) Has recent climate change, especially increased drought, negatively impacted Mediterranean shrublands? and (2) Has the historical increase in the air’s CO<sub>2</sub> concentration modified this impact? The data-based model they employed suggests that the warming and reduced precipitation experienced in the Mediterranean area over the past century should have had negative impacts on net primary production and leaf area index. When the measured increase in

atmospheric CO<sub>2</sub> concentration experienced over the period was factored into the calculation, however, these negative influences were overpowered, with the net effect that both measures of vegetative prowess increased: net primary productivity by 25 percent and leaf area index by 7 percent. These results, in their words, “indicate that the recent rise in atmospheric CO<sub>2</sub> may already have had significant impacts on productivity, structure and water relations of sclerophyllous shrub vegetation, which tended to offset the detrimental effects of climate change in the region.”

How can we relate this observation to climate change predictions for the earth as a whole? For a nominal doubling of the air’s CO<sub>2</sub> concentration from 300 to 600 ppm, earth’s mean surface air temperature is predicted by current climate models to rise by approximately 3°C, which equates to a temperature rise of 0.01°C per ppm CO<sub>2</sub>. In the case of the Mediterranean region here described, the temperature rise over the past century was quoted by Osborne *et al.* as being 0.75°C, over which period of time the air’s CO<sub>2</sub> concentration rose by approximately 75 ppm, for an analogous climate response of exactly the same value: 0.01°C per ppm CO<sub>2</sub>.

With respect to model-predicted changes in earth’s precipitation regime, a doubling of the air’s CO<sub>2</sub> content is projected to lead to a modest intensification of the planet’s hydrologic cycle. In the case of the Mediterranean region over the last century, however, there has been a recent tendency toward drier conditions. Hence, the specific case investigated by Osborne *et al.* represents a much-worse-case scenario than what is predicted by current climate models for the earth as a whole. Nevertheless, the area’s vegetation has done even better than it did before the climatic change, thanks to the over-powering beneficial biological effects of the concurrent rise in the air’s CO<sub>2</sub> content.

Cheddadi *et al.* (2001) employed a standard biogeochemical model (BIOME3)—which uses monthly temperature and precipitation data, certain soil characteristics, cloudiness, and atmospheric CO<sub>2</sub> concentration as inputs—to simulate the responses of various biomes in the region surrounding the Mediterranean Sea to changes in both climate (temperature and precipitation) and the air’s CO<sub>2</sub> content. Their first step was to validate the model for two test periods: the present and 6000 years before present (BP). Recent instrumental records provided actual atmospheric CO<sub>2</sub>, temperature and precipitation data for the present period; while pollen data were

used to reconstruct monthly temperature and precipitation values for 6000 years BP, and ice core records were used to determine the atmospheric CO<sub>2</sub> concentration of that earlier epoch. These efforts suggested that winter temperatures 6000 years ago were about 2°C cooler than they are now, that annual rainfall was approximately 200 mm less than today, and that the air’s CO<sub>2</sub> concentration averaged 280 ppm, which is considerably less than the value of 345 ppm the researchers used to represent the present, i.e., the mid-point of the period used for calculating 30-year climate normals at the time they wrote their paper. Applying the model to these two sets of conditions, they demonstrated that “BIOME3 can be used to simulate ... the vegetation distribution under ... different climate and [CO<sub>2</sub>] conditions than today,” where [CO<sub>2</sub>] is the abbreviation they use to represent “atmospheric CO<sub>2</sub> concentration.”

Cheddadi *et al.*’s next step was to use their validated model to explore the vegetative consequences of an increase in anthropogenic CO<sub>2</sub> emissions that pushes the air’s CO<sub>2</sub> concentration to a value of 500 ppm and its mean annual temperature to a value 2°C higher than today’s mean value. The basic response of the vegetation to this change in environmental conditions was “a substantial southward shift of Mediterranean vegetation and a spread of evergreen and conifer forests in the northern Mediterranean.”

More specifically, in the words of the researchers, “when precipitation is maintained at its present-day level, an evergreen forest spreads in the eastern Mediterranean and a conifer forest in Turkey.” Current xerophytic woodlands in this scenario become “restricted to southern Spain and southern Italy and they no longer occur in southern France.” In northwest Africa, on the other hand, “Mediterranean xerophytic vegetation occupies a more extensive territory than today and the arid steppe/desert boundary shifts southward,” as each vegetation zone becomes significantly more verdant than it is currently.

What is the basis for these positive developments? Cheddadi *et al.* say “the replacement of xerophytic woodlands by evergreen and conifer forests could be explained by the enhancement of photosynthesis due to the increase of [CO<sub>2</sub>].” Likewise, they note that “under a high [CO<sub>2</sub>] stomata will be much less open which will lead to a reduced evapotranspiration and lower water loss, both for C<sub>3</sub> and C<sub>4</sub> plants,” adding that “such mechanisms may

help plants to resist long-lasting drought periods that characterize the Mediterranean climate.”

Contrary to what is often predicted for much of the world’s moisture-challenged lands, therefore, the authors were able to report that “an increase of [CO<sub>2</sub>], jointly with an increase of *ca.* 2°C in annual temperature would not lead to desertification on any part of the Mediterranean unless annual precipitation decreased drastically,” where they define a drastic decrease as a decline of 30 percent or more. Equally important in this context is the fact that Hennessy *et al.* (1997) have indicated that a doubling of the air’s CO<sub>2</sub> content would in all likelihood lead to a 5 to 10 percent increase in annual precipitation at Mediterranean latitudes, which is also what is predicted for most of the rest of the world. Hence, the results of the present study—where precipitation was held constant—may validly be considered to be a worst-case scenario, with the true vegetative response being even better than the good-news results reported by Cheddadi *et al.*, even when utilizing what we believe to be erroneously inflated global warming predictions.

Julien *et al.* (2006) “used land surface temperature (LST) algorithms and NDVI [Normalized Difference Vegetation Index] values to estimate changes in vegetation in the European continent between 1982 and 1999 from the Pathfinder AVHRR [Advanced Very High Resolution Radiometer] Land (PAL) dataset.” This program revealed that arid and semi-arid areas (Northern Africa, Southern Spain and the Middle East) have seen their mean LST increase and NDVI decrease, while temperate areas (Western and Central Europe) have suffered a slight decrease in LST but a more substantial increase in NDVI, especially in Germany, the Czech Republic, Poland and Belarus. In addition, parts of continental and Northern Europe have experienced either slight increases or decreases in NDVI while LST values have decreased. Considering the results in their totality, the Dutch and Spanish researchers concluded that, over the last two decades of the twentieth century, “Europe as a whole has a tendency to greening,” and much of it is “seeing an increase in its wood land proportion.”

Working in the Komi Republic in the northeast European sector of Russia, Lopatin *et al.* (2006) (1) collected discs and cores from 151 Siberian spruce trees and 110 Scots pines from which they developed ring-width chronologies that revealed yearly changes in forest productivity, (2) developed satellite-based time series of NDVI for the months of June, July,

August over the period 1982-2001, (3) correlated their site-specific ring-width-derived productivity histories with same-site NDVI time series, (4) used the resulting relationship to establish six regional forest productivity histories for the period 1982-2001, and (5) compared the six regional productivity trends over this period with corresponding-region temperature and precipitation trends. For all six vegetation zones of the Komi Republic, this work indicated that the 1982-2001 trends of integrated NDVI values from June to August were positive, and that the “increase in productivity reflected in [the] NDVI data [was] maximal on the sites with increased temperature and decreased precipitation.”

In discussing their findings, the three scientists state that “several studies (Riebsame *et al.*, 1994; Myneni *et al.*, 1998; Vicente-Serrano *et al.*, 2004) have shown a recent increase in vegetation cover in different world ecosystems.” What is special about their study, as they describe it, is that “in Europe, most forests are managed, except for those in northwestern Russia [the location of their work], where old-growth natural forests are dominant (Aksenov *et al.*, 2002).” Consequently, and because of their positive findings, they say we can now conclude that “productivity during recent decades also increased in relatively untouched forests,” where non-management-related “climate change with lengthening growing season, increasing CO<sub>2</sub> and nitrogen deposition” are the primary determinants of changes in forest productivity.

In conclusion, this brief review of pertinent studies conducted in Europe strongly contradicts today’s obsession with the ongoing rise in the atmosphere’s CO<sub>2</sub> content, as well as the many environmental catastrophes it has been predicted to produce. The results of rising CO<sub>2</sub> concentrations and temperatures in the twentieth century were overwhelmingly positive.

#### 7.9.4. North America

In a paper titled “Variations in northern vegetation activity inferred from satellite data of vegetation index during 1981-1999,” Zhou *et al.* (2001) determined that the magnitude of the satellite-derived normalized difference vegetation index (NDVI) rose by 8.44 percent in North America over this period. Noting that the NDVI “can be used to proxy the vegetation’s responses to climate changes because it is well correlated with the fraction of photosynthetically active radiation absorbed by plant

canopies and thus leaf area, leaf biomass, and potential photosynthesis,” they went on to suggest that the increases in plant growth and vitality implied by their NDVI data were primarily driven by concurrent increases in near-surface air temperature, although temperatures may have actually declined throughout the eastern part of the United States over the period of their study.

Zhou *et al.*’s attribution of this “greening” of the continent to increases in near-surface air temperature was challenged by Ahlbeck (2002), who suggested that the observed upward trend in NDVI was primarily driven by the increase in the air’s CO<sub>2</sub> concentration, and that fluctuations in temperature were primarily responsible for variations about the more steady upward trend defined by the increase in CO<sub>2</sub>. In replying to this challenge, Kaufmann *et al.* (2002) claimed Ahlbeck was wrong and reaffirmed their initial take on the issue. We believe it was Ahlbeck who was “clearly the ‘more correct’ of the two camps.” (See the discussion in *CO<sub>2</sub> Science* at [www.co2science.org/articles/V5/N38/EDIT.php](http://www.co2science.org/articles/V5/N38/EDIT.php).)

About the same time, Hicke *et al.* (2002) computed net primary productivity (NPP) over North America for the years 1982-1998 using the Carnegie-Ames-Stanford Approach (CASA) carbon cycle model, which was driven by a satellite NDVI record at 8-km spatial resolution. This effort revealed that NPP increases of 30 percent or more occurred across the continent from 1982 to 1998. During this period, the air’s CO<sub>2</sub> concentration rose by 25.74 ppm, as calculated from the Mauna Loa data of Keeling and Whorf (1998), which amount is 8.58 percent of the 300 ppm increase often used in experiments on plant growth responses to atmospheric CO<sub>2</sub> enrichment. Consequently, for herbaceous plants that display NPP increases of 30-40 percent in response to a 300-ppm increase in atmospheric CO<sub>2</sub> concentration, the CO<sub>2</sub>-induced NPP increase experienced between 1982 and 1998 would be expected to have been 2.6-3.4 percent. Similarly, for woody plants that display NPP increases of 60-80 percent in response to a 300-ppm increase in atmospheric CO<sub>2</sub> (Saxe *et al.*, 1998; Idso and Kimball, 2001), the expected increase in productivity between 1982 and 1998 would have been 5.1-6.9 percent. Since both of these NPP increases are considerably less than the 30 percent or more observed by Hicke *et al.*, additional factors must have helped to stimulate NPP over this period, some of which may have been concomitant increases in precipitation and air temperature, the tendency for warming to lengthen growing seasons and enhance

the aerial fertilization effect of rising CO<sub>2</sub> concentrations, increasingly intensive crop and forest management, increasing use of genetically improved plants, the regrowth of forests on abandoned cropland, and improvements in agricultural practices such as irrigation and fertilization. Whatever the mix might have been, one thing is clear: Its effect was overwhelmingly positive.

In a study based on a 48-year record derived from an average of 17 measurements per year, Raymond and Cole (2003) demonstrated that the export of alkalinity, in the form of bicarbonate ions, from the Mississippi River to the Gulf of Mexico had increased by approximately 60 percent since 1953. "This increased export," as they described it, was "in part the result of increased flow resulting from higher rainfall in the Mississippi basin," which had led to a 40 percent increase in annual Mississippi River discharge to the Gulf of Mexico over the same time period. The remainder, however, had to have been due to increased rates of chemical weathering of soil minerals. What factors might have been responsible for this phenomenon? The two researchers noted that potential mechanisms included "an increase in atmospheric CO<sub>2</sub>, an increase [in] rainwater throughput, or an increase in plant and microbial production of CO<sub>2</sub> and organic acids in soils due to biological responses to increased rainfall and temperature." Unfortunately, they forgot to mention the increase in terrestrial plant productivity that is produced by the increase in the aerial fertilization effect provided by the historical rise in the air's CO<sub>2</sub> content, which also leads to "an increase in plant and microbial production of CO<sub>2</sub> and organic acids in soils." This phenomenon should have led to an increase in Mississippi River alkalinity equivalent to that which they had observed since 1953.

In a study using data obtained from dominant stands of loblolly pine plantations growing at 94 locations spread across the southeastern United States, Westfall and Amateis (2003) employed mean height measurements made at three-year intervals over a period of 15 years to calculate a site index related to the mean growth rate for each of five three-year periods, which index would be expected to increase monotonically if growth rates were being enhanced above normal by some monotonically increasing factor that promotes growth. This work revealed, in their words, that "mean site index over the 94 plots consistently increased at each remeasurement period," which would suggest, as they further state, that "loblolly pine plantations are

realizing greater than expected growth rates," and, we would add, that the growth rate increases are growing larger and larger with each succeeding three-year period. As to what could be causing the monotonically increasing growth rates of loblolly pine trees over the entire southeastern United States, Westfall and Amateis named increases in temperature and precipitation in addition to rising atmospheric CO<sub>2</sub> concentrations. However, they report that a review of annual precipitation amounts and mean ground surface temperatures showed no trends in these factors over the period of their study. They also suggested that if increased nitrogen deposition were the cause, "such a factor would have to be acting on a regional scale to produce growth increases over the range of study plots." Hence, they tended to favor the ever-increasing aerial fertilization effect of atmospheric CO<sub>2</sub> enrichment as being responsible for the accelerating pine tree growth rates.

Returning to satellite studies, Lim *et al.* (2004) correlated the monthly rate of relative change in NDVI, which they derived from advanced very high resolution radiometer data, with the rate of change in atmospheric CO<sub>2</sub> concentration during the natural vegetation growing season within three different ecoregion zones of North America (Arctic and Sub-Arctic Zone, Humid Temperate Zone, and Dry and Desert Zone, which they further subdivided into 17 regions) over the period 1982-1992, after which they explored the temporal progression of annual minimum NDVI over the period 1982-2001 throughout the eastern humid temperate zone of North America. The result of these operations was that in all of the regions but one, according to the researchers, "δCO<sub>2</sub> was positively correlated with the rate of change in vegetation greenness in the following month, and most correlations were high," which they say is "consistent with a CO<sub>2</sub> fertilization effect" of the type observed in "experimental manipulations of atmospheric CO<sub>2</sub> that report a stimulation of photosynthesis and above-ground productivity at high CO<sub>2</sub>." In addition, they determined that the yearly "minimum vegetation greenness increased over the period 1982-2001 for all the regions of the eastern humid temperate zone in North America." As for the cause of this phenomenon, Lim *et al.* say that rising CO<sub>2</sub> could "increase minimum greenness by stimulating photosynthesis at the beginning of the growing season," citing the work of Idso *et al.* (2000).

In a somewhat similar study, but one that focused more intensely on climate change, Xiao and Moody (2004) examined the responses of the normalized

difference vegetation index integrated over the growing season (gNDVI) to annual and seasonal precipitation, maximum temperature (Tmax) and minimum temperature (Tmin) over an 11-year period (1990-2000) for six biomes in the conterminous United States (Evergreen Needleleaf Forest, Deciduous Broadleaf Forest, Mixed Forest, Open Shrubland, Woody Savanna and Grassland), focusing on within- and across-biome variance in long-term average gNDVI and emphasizing the degree to which this variance is explained by spatial gradients in long-term average seasonal climate. The results of these protocols indicated that the greatest positive climate-change impacts on biome productivity were caused by increases in spring, winter and fall precipitation, as well as increases in fall and spring temperature, especially Tmin, which has historically increased at roughly twice the rate of Tmax in the United States. Hence, “if historical climatic trends and the biotic responses suggested in this analysis continue to hold true, we can anticipate further increases in productivity for both forested and nonforested ecoregions in the conterminous US, with associated implications for carbon budgets and woody proliferation.”

Goetz *et al.* (2005) transformed satellite-derived NDVI data obtained across boreal North America (Canada and Alaska) for the period 1982-2003 into photosynthetically active radiation absorbed by green vegetation and treated the result as a proxy for relative June-August gross photosynthesis (Pg), stratifying the results by vegetation type and comparing them with spatially matched concomitant trends in surface air temperature data. Over the course of the study, this work revealed that area-wide tundra experienced a significant increase in Pg in response to a similar increase in air temperature; and Goetz *et al.* say “this observation is supported by a wide and increasing range of local field measurements characterizing elevated net CO<sub>2</sub> uptake (Oechel *et al.*, 2000), greater depths of seasonal thaw (Goulden *et al.*, 1998), changes in the composition and density of herbaceous vegetation (Chapin *et al.*, 2000; Epstein *et al.*, 2004), and increased woody encroachment in the tundra areas of North America (Sturm *et al.*, 2001).” In the case of interior forest, on the other hand, there was no significant increase in air temperature and essentially no change in Pg, with the last data point of the series being essentially indistinguishable from the first. This latter seemingly aberrant observation is in harmony with the fact that at low temperatures the growth-promoting effects of increasing atmospheric

CO<sub>2</sub> levels are often very small or even non-existent (Idso and Idso, 1994), which is what appears to have been the case with North American boreal forests over the same time period. As a result, Canada’s and Alaska’s tundra ecosystems exhibited increasing productivity over the past couple of decades, while their boreal forests did not.

Also working in Alaska, Tape *et al.* (2006) analyzed repeat photography data from a photo study of the Colville River conducted between 1945 and 1953, as well as 202 new photos of the same sites that were obtained between 1999 and 2002, to determine the nature of shrub expansion in that region over the past half-century. This approach revealed, in their words, that “large shrubs have increased in size and abundance over the past 50 years, colonizing areas where previously there were no large shrubs.” In addition, they say their review of plot and remote sensing studies confirms that “shrubs in Alaska have expanded their range and grown in size” and that “a population of smaller, intertussock shrubs not generally sampled by the repeat photography, is also expanding and growing.” Taken together, they conclude that “these three lines of evidence allow us to infer a general increase in tundra shrubs across northern Alaska.” Tape *et al.* attribute this to large-scale pan-Arctic warming. From analyses of logistic growth curves, they estimate that the expansion began about 1900, “well before the current warming in Alaska (which started about 1970).” Hence, they conclude that “the expansion predates the most recent warming trend and is perhaps associated with the general warming since the Little Ice Age.” These inferences appear reasonable, although we would add that the 80-ppm increase in the atmosphere’s CO<sub>2</sub> concentration since 1900 likely played a role in the shrub expansion as well. If continued, the researchers say the transition “will alter the fundamental architecture and function of this ecosystem with important ramifications,” the great bulk of which, in our opinion, will be positive.

Working at eight different sites within the Pacific Northwest of the United States, Soule and Knapp (2006) studied ponderosa pine trees to see how they may have responded to the increase in the atmosphere’s CO<sub>2</sub> concentration that occurred after 1950. The two geographers say the sites they chose “fit several criteria designed to limit potential confounding influences associated with anthropogenic disturbance.” In addition, they selected locations with “a variety of climatic and topo-edaphic conditions, ranging from extremely water-limiting

environments ... to areas where soil moisture should be a limiting factor for growth only during extreme drought years.” They also say that all sites were located in areas “where ozone concentrations and nitrogen deposition are typically low.”

At all eight of the sites that met all of these criteria, Soule and Knapp obtained core samples from about 40 mature trees that included “the potentially oldest trees on each site,” so that their results would indicate, as they put it, “the response of mature, naturally occurring ponderosa pine trees that germinated before anthropogenically elevated CO<sub>2</sub> levels, but where growth, particularly post-1950, has occurred under increasing and substantially higher atmospheric CO<sub>2</sub> concentrations.” Utilizing meteorological evaluations of the Palmer Drought Severity Index, they thus compared ponderosa pine radial growth rates during matched wet and dry years pre- and post-1950. Overall, the two researchers found a post-1950 radial growth enhancement that was “more pronounced during drought years compared with wet years, and the greatest response occurred at the most stressed site.” As for the magnitude of the response, they determined that “the relative change in growth [was] upward at seven of our [eight] sites, ranging from 11 to 133%.” With respect to the significance of their observations, Soule and Knapp say their results show that “radial growth has increased in the post-1950s period ... while climatic conditions have generally been unchanged,” which further suggests that “nonclimatic driving forces are operative.” In addition, they say the “radial growth responses are generally consistent with what has been shown in long-term open-top chamber (Idso and Kimball, 2001) and free-air CO<sub>2</sub> enrichment (FACE) studies (Ainsworth and Long, 2005).” They conclude their findings “suggest that elevated levels of atmospheric CO<sub>2</sub> are acting as a driving force for increased radial growth of ponderosa pine, but that the overall influence of this effect may be enhanced, reduced or obviated by site-specific conditions.”

Wang *et al.* (2006) examined ring-width development in cohorts of young and old white spruce trees in a mixed grass-prairie ecosystem in southwestern Manitoba, Canada, where a 1997 wildfire killed most of the older trees growing in high-density spruce islands, but where younger trees slightly removed from the islands escaped the ravages of the flames. There, “within each of a total of 24 burned islands,” in the words of the three researchers, “the largest dominant tree (dead) was cut down and a disc was then sampled from the stump height,” while

“adjacent to each sampled island, a smaller, younger tree (live) was also cut down, and a disc was sampled from the stump height.”

After removing size-, age- and climate-related trends in radial growth from the ring-width histories of the trees, Wang *et al.* plotted the residuals as functions of time for the 30-year periods for which both the old and young trees would have been approximately the same age: 1900-1929 for the old trees and 1970-1999 for the young trees. During the first of these periods, the atmosphere’s CO<sub>2</sub> concentration averaged 299 ppm; during the second it averaged 346 ppm. Also, the mean rate-of-rise of the atmosphere’s CO<sub>2</sub> concentration was 0.37 ppm/year for first period and 1.43 ppm/year for the second.

The results of this exercise revealed that the slope of the linear regression describing the rate-of-growth of the ring-width residuals for the later period (when the air’s CO<sub>2</sub> concentration was 15 percent greater and its rate-of-rise 285 percent greater) was more than twice that of the linear regression describing the rate-of-growth of the ring-width residuals during the earlier period. As the researchers describe it, these results show that “at the same developmental stage, a greater growth response occurred in the late period when atmospheric CO<sub>2</sub> concentration and the rate of atmospheric CO<sub>2</sub> increase were both relatively high,” and they say that “these results are consistent with expectations for CO<sub>2</sub>-fertilization effects.” In fact, they say “the response of the studied young trees can be taken as strong circumstantial evidence for the atmospheric CO<sub>2</sub>-fertilization effect.”

Another thing Wang *et al.* learned was that “postdrought growth response was much stronger for young trees (1970-1999) compared with old trees at the same development stage (1900-1929),” and they add that “higher atmospheric CO<sub>2</sub> concentration in the period from 1970-1999 may have helped white spruce recover from severe drought.” In a similar vein, they also determined that young trees showed a weaker relationship to precipitation than did old trees, noting that “more CO<sub>2</sub> would lead to greater water-use efficiency, which may be dampening the precipitation signal in young trees.”

In summary, Wang *et al.*’s unique study provides an exciting real-world example of the benefits the historical increase in the air’s CO<sub>2</sub> content has likely conferred on nearly all of earth’s plants, and especially its long-lived woody species. Together with the results of the other North American studies we have reviewed, this body of research paints a

picture of a significant greening of North America in the twentieth century.

### 7.9.5. Oceans

Rising air temperatures and atmospheric CO<sub>2</sub> concentrations in the twentieth century also have affected the productivity of earth's seas. We begin with a study that takes a much longer view of the subject.

Elderfield and Rickaby (2000) note that the typically low atmospheric CO<sub>2</sub> concentrations of glacial periods have generally been attributed to an increased oceanic uptake of CO<sub>2</sub>, "particularly in the southern oceans." However, the assumption that intensified phytoplanktonic photosynthesis may have stimulated CO<sub>2</sub> uptake rates during glacial periods has always seemed at odds with the observational fact that rates of photosynthesis are generally much reduced in environments of significantly lower-than-current atmospheric CO<sub>2</sub> concentrations, such as typically prevail during glacial periods.

The two scientists provide a new interpretation of Cd/Ca systematics in sea water that helps to resolve this puzzle, as it allows them to more accurately estimate surface water phosphate conditions during glacial times and thereby determine the implications for concomitant atmospheric CO<sub>2</sub> concentrations. What they found, in their words, is that "results from the Last Glacial Maximum [LGM] show similar phosphate utilization in the subantarctic to that of today, but much smaller utilization in the polar Southern Ocean," which implies, according to Delaney (2000), that Antarctic productivity was lower at that time than it is now, but that *subantarctic* productivity was about the same as it has been in modern times, due perhaps to greater concentrations of bio-available iron compensating for the lower atmospheric CO<sub>2</sub> concentrations of the LGM.

So what caused the much smaller utilization of phosphate in the polar Southern Ocean during the LGM? Noting that the area of sea-ice cover in the

Southern Ocean during glacial periods may have been as much as double that of modern times, Elderfield and Rickaby suggest that "by restricting communication between the ocean and atmosphere, sea ice expansion also provides a mechanism for reduced CO<sub>2</sub> release by the Southern Ocean and lower glacial atmospheric CO<sub>2</sub>." Hence, it is possible that phytoplanktonic productivity in the glacial Southern Ocean may have been no higher than it is at the present time, notwithstanding the greater supply of bio-available iron typical of glacial epochs.

In the case of the interglacial period in which we currently live, Dupouy *et al.* (2000) say it has long been believed that N<sub>2</sub> fixation in the world's oceans is unduly low, in consequence of the present low supply of wind-blown iron compared to that of glacial periods, and that this state of affairs leads to low phytoplanktonic productivity, even in the presence of higher atmospheric CO<sub>2</sub> concentrations. The evidence they acquired, however, suggests that marine N<sub>2</sub> fixation may be much greater than what has generally been thought to be the case. In particular, they note that several *Trichodesmium* species of N<sub>2</sub>-fixing cyanobacteria have "a nearly ubiquitous distribution in the euphotic zone of tropical and subtropical seas and could play a major role in bringing new N to these oligotrophic systems." And this feat, in their words, "could play a significant role in enhancing new production."

The importance of these findings is perhaps best appreciated in light of the findings of Pahlow and Riebesell (2000), who in studying data obtained from 1173 stations in the Atlantic and Pacific Oceans, covering the years 1947 to 1994, detected changes in Northern Hemispheric deep-ocean Redfield ratios that are indicative of increasing nitrogen availability there, which increase was concomitant with an increase in export production that has resulted in ever-increasing oceanic carbon sequestration. These investigators further suggest that the growing supply of nitrogen has its origin in anthropogenic activities that release nitrous oxides to the air. In addition, the increased carbon export may be partly a consequence of the historical increase in the air's CO<sub>2</sub> concentration, which has been demonstrated to have the ability to enhance phytoplanktonic productivity (see Section 6.1.3.4. in this document), analogous to the way in which elevated concentrations of atmospheric CO<sub>2</sub> enhance the productivity of terrestrial plants, including their ability to fix nitrogen.

Further elucidating the productivity-enhancing power of the ongoing rise in the air's CO<sub>2</sub> content is

the study of Pasquer *et al.* (2005), who employed a complex model of growth regulation of diatoms, pico/nano phytoplankton, coccolithophorids and *Phaeocystis* spp. by light, temperature and nutrients (based on a comprehensive analysis of literature reviews focusing on these taxonomic groups) to calculate changes in the ocean uptake of carbon in response to a sustained increase in atmospheric CO<sub>2</sub> concentration of 1.2 ppm per year for three marine ecosystems where biogeochemical time-series of the data required for model initialization and comparison of results were readily available. These systems were (1) the ice-free Southern Ocean Time Series station KERFIX (50°40'S, 68°E) for the period 1993-1994 (diatom-dominated), (2) the sea-ice associated Ross Sea domain (76°S, 180°W) of the Antarctic Environment and Southern Ocean Process Study AESOPS in 1996-1997 (*Phaeocystis*-dominated), and (3) the North Atlantic Bloom Experiment NABE (60°N, 20°W) in 1991 (coccolithophorids). Their results, in their words, “show that at all tested latitudes the prescribed increase of atmospheric CO<sub>2</sub> enhances the carbon uptake by the ocean.” Indeed, we calculate from their graphical presentations that (1) at the NABE site a sustained atmospheric CO<sub>2</sub> increase of 1.2 ppm per year over a period of eleven years increases the air-sea CO<sub>2</sub> flux in the last year of that period by approximately 17 percent, (2) at the AESOPS site the same protocol applied over a period of six years increases the air-sea CO<sub>2</sub> flux by about 45 percent, and (3) at the KERFIX site it increases the air-sea CO<sub>2</sub> flux after nine years by about 78 percent. Although the results of this interesting study based on the complex SWAMCO model of Lancelot *et al.* (2000), as modified by Hannon *et al.* (2001), seem overly large, they highlight the likelihood that the ongoing rise in the air's CO<sub>2</sub> content may be having a significant positive impact on ocean productivity and the magnitude of the ocean carbon sink.

But what about increasing temperatures? Sarmiento *et al.* (2004) conducted a massive computational study that employed six coupled climate model simulations to determine the biological response of the global ocean to the climate warming they simulated from the beginning of the Industrial Revolution to the year 2050. Based on vertical velocity, maximum winter mixed-layer depth and sea-ice cover, they defined six biomes and calculated how their surface geographies would change in response to their calculated changes in global climate. Next, they used satellite ocean color and climatological observations to develop an empirical model for

predicting surface chlorophyll concentrations from the final physical properties of the world's oceans as derived from their global warming simulations, after which they used three primary production algorithms to estimate the response of oceanic primary production to climate warming based on their calculated chlorophyll concentrations. When all was said and done, the thirteen scientists from Australia, France, Germany, Russia, the United Kingdom and the United States arrived at a global warming-induced *increase* in global ocean primary production that ranged from 0.7 to 8.1 percent.

So what do real-world measurements of oceanic productivity reveal? Goes *et al.* (2005) analyzed seven years (1997-2004) of satellite-derived ocean color data pertaining to the Arabian Sea, as well as associated sea surface temperatures (SSTs) and winds. They report that for the region located between 52 to 57°E and 5 to 10°N, “the most conspicuous observation was the consistent year-by-year increase in phytoplankton biomass over the 7-year period.” This phenomenon was so dramatic that by the summer of 2003, in their words, “chlorophyll *a* concentrations were >350% higher than those observed in the summer of 1997.” They also report that the increase in chlorophyll *a* was “accompanied by an intensification of sea surface winds, in particular of the zonal (east-to-west) component,” noting that these “summer monsoon winds are a coupled atmosphere-land-ocean phenomenon, whose strength is significantly correlated with tropical SSTs and Eurasian snow cover anomalies on a year-to-year basis.” More specifically, they say that “reduced snow cover over Eurasia strengthens the spring and summer land-sea thermal contrast and is considered to be responsible for the stronger southwest monsoon winds.” In addition, they state that “the influence of southwest monsoon winds on phytoplankton in the Arabian Sea is not through their impact on coastal upwelling alone but also via the ability of zonal winds to laterally advect newly upwelled nutrient-rich waters to regions away from the upwelling zone.” They conclude that “escalation in the intensity of summer monsoon winds, accompanied by enhanced upwelling and an increase of more than 350 percent in average summertime phytoplankton biomass along the coast and over 300 percent offshore, raises the possibility that the current warming trend of the Eurasian landmass is making the Arabian Sea more productive.”

To the north and west on the other side of Eurasia, Marasovic *et al.* (2005) analyzed monthly

observations of basic hydrographic, chemical and biological parameters, including primary production, that had been made since the 1960s at two oceanographic stations, one near the coast (Kastela Bay) and one in the open sea. They found that mean annual primary production in Kastela Bay averaged about  $430 \text{ mg C m}^{-2} \text{ d}^{-1}$  over the period 1962-72, exceeded  $600 \text{ mg C m}^{-2} \text{ d}^{-1}$  over the period 1972-82, and rose to over  $700 \text{ mg C m}^{-2} \text{ d}^{-1}$  over the period 1982-96, accompanied by a similar upward trend in percent oxygen saturation of the surface water. The initial value of primary production in the open sea was much less (approximately  $150 \text{ mg C m}^{-2} \text{ d}^{-1}$ ), but it began to follow the upward trend of the Kastela Bay data after about one decade. Marasovic *et al.* thus concluded that “even though all the relevant data indicate that the changes in Kastela Bay are closely related to an increase of anthropogenic nutrient loading, similar changes in the open sea suggest that primary production in the Bay might, at least partly, be due to global climatic changes,” which, in their words, are “occurring in the Mediterranean and Adriatic Sea open waters” and may be directly related to “global warming of air and ocean,” since “higher temperature positively affects photosynthetic processes.”

Raitsos *et al.* (2005) investigated the relationship between Sea-viewing Wide Field-of-view Sensor (SeaWiFS) chlorophyll-*a* measurements in the Central Northeast Atlantic and North Sea (1997-2002) and simultaneous measurements of the Phytoplankton Color Index (PCI) collected by the Continuous Plankton Recorder survey, which is an upper-layer plankton monitoring program that has operated in the North Sea and North Atlantic Ocean since 1931. By developing a relationship between the two data bases over their five years of overlap, they were able to produce a Chl-*a* history for the Central Northeast Atlantic and North Sea for the period 1948-2002. Of this record they say that “an increasing trend is apparent in mean Chl-*a* for the area of study over the period 1948-2002.” They also say “there is clear evidence for a stepwise increase after the mid-1980s, with a minimum of  $1.3 \text{ mg m}^{-3}$  in 1950 and a peak annual mean of  $2.1 \text{ mg m}^{-3}$  in 1989 (62% increase).” Alternatively, it is possible that the data represent a more steady long-term upward trend upon which is superimposed a decadal-scale oscillation. In a final comment on their findings, they note that “changes through time in the PCI are significantly correlated with both sea surface temperature and Northern

Hemisphere temperature,” citing Beaugrand and Reid (2003).

In a contemporaneous study, Antoine *et al.* (2005) applied revised data-processing algorithms to two ocean-sensing satellites, the Coastal Zone Color Scanner (CZCS) and SeaWiFS, over the periods 1979-1986 and 1998-2002, respectively, to provide an analysis of the decadal changes in global oceanic phytoplankton biomass. Results of the analysis showed “an overall increase of the world ocean average chlorophyll concentration by about 22%” over the two decades under study.

Dropping down to the Southern Ocean, Hirawake *et al.* (2005) analyzed chlorophyll *a* data obtained from Japanese Antarctic Research Expedition cruises made by the Fuji and Shirase ice-breakers between Tokyo and Antarctica from 15 November to 28 December of nearly every year between 1965 and 2002 in a study of interannual variations of phytoplankton biomass, calculating results for the equatorial region between  $10^{\circ}\text{N}$  and  $10^{\circ}\text{S}$ , the Subtropical Front (STF) region between  $35^{\circ}\text{S}$  and  $45^{\circ}\text{S}$ , and the Polar Front (PF) region between  $45^{\circ}\text{S}$  and  $55^{\circ}\text{S}$ . They report that an increase in chl *a* was “recognized in the waters around the STF and the PF, especially after 1980 around the PF in particular,” and that “in the period between 1994 and 1998, the chl *a* in the three regions exhibited rapid gain simultaneously.” They also say “there were significant correlations between chl *a* and year through all of the period of observation around the STF and PF, and the rates of increase are  $0.005$  and  $0.012 \text{ mg chl } a \text{ m}^{-3} \text{ y}^{-1}$ , respectively.” In addition, they report that the satellite data of Gregg and Conkright (2002) “almost coincide with our results.” In commenting on these findings, the Japanese scientists say that “simply considering the significant increase in the chl *a* in the Southern Ocean, a rise in the primary production as a result of the phytoplankton increase in this area is also expected.”

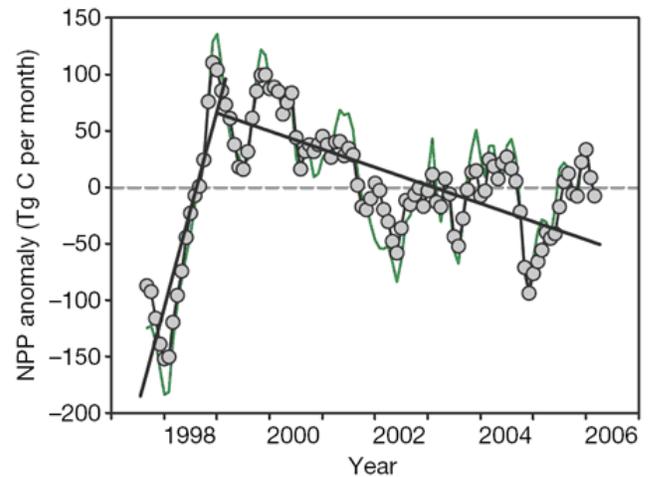

Also working in the Southern Hemisphere, Sepulveda *et al.* (2005) presented “the first reconstruction of changes in surface primary production during the last century from the Puyuhuapi fjord in southern Chile, using a variety of parameters (diatoms, biogenic silica, total organic carbon, chlorins, and proteins) as productivity proxies.” Noting that the fjord is located in “a still-pristine area,” they say it is “suitable to study changes in past export production originating from changes in both the paleo-Patagonian ice caps and the globally important Southern Ocean.”

The analysis revealed that the productivity of the Puyuhuapi fjord “was characterized by a constant increase from the late 19th century to the early 1980s, then decreased until the late 1990s, and then rose again to present-day values.” For the first of these periods (1890-1980), they additionally report that “all proxies were highly correlated ( $r > 0.8$ ,  $p < 0.05$ ),” and that “all proxies reveal an increase in accumulation rates.” From 1980 to the present, however, the pattern differed among the various proxies; and the researchers say that “considering that the top 5 cm of the sediment column (~10 years) are diagenetically active, and that bioturbation by benthic organisms may have modified and mixed the sedimentary signal, paleo-interpretation of the period 1980-2001 must be taken with caution.” Consequently, there is substantial solid evidence that, for the first 90 years of the 111-year record, surface primary production in the Puyuhuapi fjord rose dramatically, while with lesser confidence it appears to have leveled out over the past two decades. In spite of claims that the “unprecedented” increases in mean global air temperature and  $\text{CO}_2$  concentration experienced since the inception of the Industrial Revolution have been bad for the biosphere, Sepulveda *et al.* presented yet another case of an ecosystem apparently thriving in such conditions.

Still, claims of impending ocean productivity declines have not ceased, and some commentators single out the study of Behrenfeld *et al.* (2006) in support of their claims. Working with NASA’s Sea-viewing Wide Field-of-view Sensor (SeaWiFS), the team of 10 U.S. scientists calculated monthly changes in net primary production (NPP) from similar changes in upper-ocean chlorophyll concentrations detected from space over the past decade. (See Figure 7.9.5.) They report that this period was dominated by an initial NPP increase of 1,930 teragrams of carbon per year ( $\text{Tg C yr}^{-1}$ ), which they attributed to the significant cooling of “the 1997 to 1999 El Niño to La Niña transition,” and they note that this increase was “followed by a prolonged decrease averaging  $190 \text{ Tg C yr}^{-1}$ ,” which they attributed to subsequent warming.

The means by which changing temperatures were claimed by the researchers to have driven the two sequential linear-fit trends in NPP is based on their presumption that a warming climate increases the density contrast between warmer surface waters and cooler underlying nutrient-rich waters, so that the enhanced stratification that occurs with warming “suppresses nutrient exchange through vertical mixing,” which decreases NPP by reducing the

supply of nutrients to the surface waters where photosynthesizing phytoplankton predominantly live. By contrast, the ten scientists suggest that “surface cooling favors elevated vertical exchange,” which increases NPP by enhancing the supply of nutrients to the ocean’s surface waters, which are more frequented by phytoplankton than are under-lying waters, due to light requirements for photosynthesis.

**Figure 7.9.5.** Monthly anomalies of global NPP (green line) plus similar results for the permanently stratified ocean regions of the world (grey circles and black line), adapted from Behrenfeld *et al.* (2006).

It is informative to note, however, that from approximately the middle of 2001 to the end of the data series in early 2006 (which interval accounts for more than half of the data record), there has been, if anything, a slight increase in global NPP. (See again Figure 7.9.5.) Does this observation mean there has been little to no net global warming since mid-2001? Or does it mean the global ocean’s mean surface temperature actually cooled a bit over the last five years? Neither alternative is what one would expect if global warming were a real problem. On the other hand, the relationship between global warming and oceanic productivity may not be nearly as strong as what Behrenfeld *et al.* have suggested; and they themselves say “modeling studies suggest that shifts in ecosystem structure from climate variations may be as [important as] or more important than the alterations in bulk integrated properties reported here,” noting that some “susceptible ecosystem characteristics” that might be so shifted include “taxonomic composition, physiological status, and light absorption by colored dissolved organic

material.” It is possible that given enough time, the types of phenomena Behrenfeld *et al.* describe as possibly resulting in important “shifts in ecosystem structure” could compensate for or even overwhelm what might initially appear to be negative warming-induced consequences.

Another reason for not concluding too much from the oceanic NPP data set of Behrenfeld *et al.* is that it may be of too short a duration to reveal what might be occurring on a much longer timescale throughout the world’s oceans, or that its position in time may be such that it does not allow the detection of greater short-term changes of the opposite sign that may have occurred a few years earlier or that might occur in the near future.

Consider, for example, the fact that the central regions of the world’s major oceans were long thought to be essentially vast biological deserts (Ryther, 1969), but that several studies of primary photosynthetic production conducted in those regions over the 1980s (Shulenberger and Reid, 1981; Jenkins, 1982; Jenkins and Goldman, 1985; Reid and Shulenberger, 1986; Marra and Heinemann, 1987; Laws *et al.*, 1987; Venrick *et al.*, 1987; Packard *et al.*, 1988) yielded results that suggested marine productivity at that time was twice or more as great as it likely was for a long time prior to 1969, causing many of that day to speculate that “the ocean’s deserts are blooming” (Kerr, 1986).

Of even greater interest, perhaps, is the fact that over this particular period of time (1970-1988), the data repository of Jones *et al.* (1999) indicates the earth experienced a (linear-regression-derived) global warming of 0.333°C, while the data base of the Global Historical Climatology Network indicates the planet experienced a similarly calculated global warming of 0.397°C. The mean of these two values (0.365°C) is nearly twice as great as the warming that occurred over the post-1999 period studied by Behrenfeld *et al.*; yet this earlier much larger warming (which according to the ten researchers’ way of thinking should have produced a major decline in ocean productivity) was concomitant with a huge increase in ocean productivity. Consequently, it would appear that just the opposite of what Behrenfeld *et al.* suggest about global warming and ocean productivity is likely to be the more correct of the two opposing cause-and-effect relationships.

Moving closer to the present, Levitan *et al.* (2007) published a study of major significance that addresses the future of oceanic productivity under rising atmospheric CO<sub>2</sub> concentrations. In their paper

the authors note that “among the principal players contributing to global aquatic primary production, the nitrogen (N)-fixing organisms (diazotrophs) are important providers of new N to the oligotrophic areas of the oceans,” and they cite several studies which demonstrate that “cyanobacterial (photo-trophic) diazotrophs in particular fuel primary production and phytoplankton blooms which sustain oceanic food-webs and major economies and impact global carbon (C) and N cycling.” These facts compelled them to examine how the ongoing rise in the air’s CO<sub>2</sub> content might impact these relationships. They began by exploring the response of the cyanobacterial diazotroph *Trichodesmium* to changes in the atmosphere’s CO<sub>2</sub> concentration, choosing this particular diazotroph because it dominates the world’s tropical and sub-tropical oceans in this regard, contributing over 50 percent of total marine N fixation.

The eight Israeli and Czech researchers grew *Trichodesmium* IMS101 stock cultures in YBCII medium (Chen *et al.*, 1996) at 25°C and a 12-hour:12-hour light/dark cycle (with the light portion of the cycle in the range of 80-100 μmol photons m<sup>-2</sup> s<sup>-1</sup>) in equilibrium with air of three different CO<sub>2</sub> concentrations (250, 400 and 900 ppm, representing low, ambient and high concentrations, respectively), which was accomplished by continuously bubbling air of the three CO<sub>2</sub> concentrations through the appropriate culture vessels throughout various experimental runs, each of which lasted a little over three weeks, during which time they periodically monitored a number of diazotrophic physiological processes and properties.

So what did the scientists learn? Levitan *et al.* report that *Trichodesmium* in the high CO<sub>2</sub> treatment “displayed enhanced N fixation, longer trichomes, higher growth rates and biomass yields.” In fact, they write that in the high CO<sub>2</sub> treatment there was “a three- to four-fold increase in N fixation and a doubling of growth rates and biomass,” and that the cultures in the low CO<sub>2</sub> treatment reached a stationary growth phase after only five days, “while both ambient and high CO<sub>2</sub> cultures exhibited exponential growth until day 15 before declining.”

In discussing possible explanations for what they observed, the researchers suggest that “enhanced N fixation and growth in the high CO<sub>2</sub> cultures occurs due to reallocation of energy and resources from carbon concentrating mechanisms required under low and ambient CO<sub>2</sub>.” Consequently, they conclude, in their words, that “in oceanic regions, where light and

nutrients such as P and Fe are not limiting, we expect the projected concentrations of CO<sub>2</sub> to increase N fixation and growth of *Trichodesmium*,” and that “other diazotrophs may be similarly affected, thereby enhancing inputs of new N and increasing primary productivity in the oceans.” And to emphasize these points, they write in the concluding sentence of their paper that “*Trichodesmium*’s dramatic response to elevated CO<sub>2</sub> may consolidate its dominance in subtropical and tropical regions and its role in C and N cycling, fueling subsequent primary production, phytoplankton blooms, and sustaining oceanic food-webs.”

Arrigo *et al.* (2008) introduce their work by writing that “between the late 1970s and the early part of the 21st century, the extent of Arctic Ocean sea ice cover has declined during all months of the year, with the largest declines reported in the boreal summer months, particularly in September ( $8.6 \pm 2.9\%$  per decade),” citing the work of Serreze *et al.* (2007). In an effort to “quantify the change in marine primary productivity in Arctic waters resulting from recent losses of sea ice cover,” the authors “implemented a primary productivity algorithm that accounts for variability in sea ice extent, sea surface temperature, sea level winds, downwelling spectral irradiance, and surface chlorophyll *a* concentrations,” and that “was parameterized and validated specifically for use in the Arctic (Pabi *et al.*, 2008) and utilizes forcing variables derived either from satellite data or NCEP reanalysis fields.”

Arrigo *et al.* determined that “annual primary production in the Arctic increased yearly by an average of 27.5 Tg C per year since 2003 and by 35 Tg C per year between 2006 and 2007,” 30 percent of which total increase was attributable to decreased minimum summer ice extent and 70 percent of which was due to a longer phytoplankton growing season. Arrigo *et al.* thus conclude that if the trends they discovered continue, “additional loss of ice during Arctic spring could boost productivity >3-fold above 1998-2002 levels.” Hence, they additionally state that if the 26 percent increase in annual net CO<sub>2</sub> fixation in the Arctic Ocean between 2003 and 2007 is maintained, “this would represent a weak negative feedback on climate change.”

On the other side of the globe and working in the Southern Ocean, Smith and Comiso (2008) employed phytoplankton pigment assessments, surface temperature estimates, modeled irradiance, and observed sea ice concentrations—all of which parameters were derived from satellite data—and

incorporated them into a vertically integrated production model to estimate primary productivity trends according to the technique of Behrenfeld *et al.* (2002). Of this effort, the two authors say that “the resultant assessment of Southern Ocean productivity is the most exhaustive ever compiled and provides an improvement in the quantitative role of carbon fixation in Antarctic waters.” So what did they find? During the nine years (1997-2006) analyzed in the study, “productivity in the entire Southern Ocean showed a substantial and significant increase,” which increase can be calculated from the graphical representation of their results as ~17 percent per decade. In commenting on their findings, the two researchers note that “the highly significant increase in the productivity of the entire Southern Ocean over the past decade implies that long-term changes in Antarctic food webs and biogeochemical cycles are presently occurring,” which changes we might add are positive.

In light of these several real-world observations, we find no indications of a widespread decline in oceanic productivity over the twentieth century in response to increases in air temperature and CO<sub>2</sub> concentration. In fact, we see evidence that just the opposite is occurring, that environmental changes are occurring that are proving to be beneficial.

Additional information on this topic, including reviews of newer publications as they become available, can be found at <http://www.co2science.org/subject/oceanproductivity.php>.

### 7.9.6. Global

How have earth's terrestrial plants responded—on average and in their entirety—to the atmospheric temperature and CO<sub>2</sub> increases of the past quarter-century? In this subsection we report the results of studies that have looked at either the world as a whole or groups of more than two continents at the same time.

In one of the earlier studies of the subject, Joos and Bruno (1998) used ice core and direct observations of atmospheric CO<sub>2</sub> and <sup>13</sup>C to reconstruct the histories of terrestrial and oceanic uptake of anthropogenic carbon over the past two centuries. This project revealed, in their words, that “the biosphere acted on average as a source [of CO<sub>2</sub>] during the last century and the first decades of this century ... Then, the biosphere turned into a [CO<sub>2</sub>] sink,” which implies a significant increase in global vegetative productivity over the last half of the twentieth century.

More recently, Cao *et al.* (2004) derived net primary production (NPP) values at 8-km and 10-day resolutions for the period 1981-2000 using variables based almost entirely on satellite observations, as described in the Global Production Efficiency Model (GLO-PEM), which consists, in their words, “of linked components that describe the processes of canopy radiation absorption, utilization, autotrophic

respiration, and the regulation of these processes by environmental factors (Prince and Goward, 1995; Goetz *et al.*, 2000).” They learned that over the last two decades of the twentieth century, when temperatures were rising, “there was an increasing trend toward enhanced terrestrial NPP,” which they say was “caused mainly by increases in atmospheric carbon dioxide and precipitation.”

A year later, Cao *et al.* (2005) used the CEVSA (Carbon Exchanges in the Vegetation-Soil-Atmosphere system) model (Cao and Woodward, 1998; Cao *et al.*, 2002), forced by observed variations in climate and atmospheric CO<sub>2</sub>, to quantify changes in NPP, soil heterotrophic respiration (HR) and net ecosystem production (NEP) from 1981 to 1998. As an independent check on the NPP estimate of CEVSA, they also estimated 10-day NPP from 1981-2000 with the GLO-PEM model that uses data almost entirely from remote sensing, including both the normalized difference vegetation index (NDVI) and meteorological variables (Prince and Goward, 1995; Cao *et al.*, 2004). This protocol revealed, in Cao *et al.*'s words, that “global terrestrial temperature increased by 0.21°C from the 1980s to the 1990s, and this alone increased HR more than NPP and hence reduced global annual NEP.” *However*, they found that “combined changes in temperature and precipitation increased global NEP significantly,” and that “increases in atmospheric CO<sub>2</sub> produced further increases in NPP and NEP.” They also discovered that “the CO<sub>2</sub> fertilization effect [was] particularly strong in the tropics, compensating for the negative effect of warming on NPP.” Enlarging on this point, they write that “the response of photosynthetic biochemical reactions to increases in atmospheric CO<sub>2</sub> is greater in warmer conditions, so the CO<sub>2</sub> fertilization effect will increase with warming in cool regions and be high in warm environments.” The end result of the application of these models and measurements was their finding that global NEP increased “from 0.25 Pg C yr<sup>-1</sup> in the 1980s to 1.36 Pg C yr<sup>-1</sup> in the 1990s.”

Commenting on their findings, Cao *et al.* note that “the NEP that was induced by CO<sub>2</sub> fertilization and climatic variation accounted for 30 percent of the total terrestrial carbon sink implied by the atmospheric carbon budget (Schimel *et al.*, 2001), and the fraction changed from 13 percent in the 1980s to 49 percent in the 1990s,” which indicates the growing importance of the CO<sub>2</sub> fertilization effect. Also, they say “the increase in the terrestrial carbon sink from the 1980s to the 1990s was a continuation of the trend

since the middle of the twentieth century, rather than merely a consequence of short-term climate variability,” which suggests that as long as the air’s CO<sub>2</sub> content continues its upward course, so too will its stimulation of the terrestrial biosphere likely continue its upward course.

Using a newly developed satellite-based vegetation index (Version 3 Pathfinder NDVI) in conjunction with a gridded global climate dataset (global monthly mean temperature and precipitation at 0.5° resolution from New *et al.*, 2000), Xiao and Moody (2005) analyzed trends in global vegetative activity from 1982 to 1998. The greening trends they found exhibited substantial latitudinal and longitudinal variability, with the most intense greening of the globe located in high northern latitudes, portions of the tropics, southeastern North America and eastern China. Temperature was found to correlate strongly with greening trends in Europe, eastern Eurasia and tropical Africa. Precipitation, on the other hand, was *not* found to be a significant driver of increases in greenness, except for isolated and spatially fragmented regions. Some decreases in greenness were also observed, mainly in the Southern Hemisphere in southern Africa, southern South America and central Australia, which trends were associated with concomitant increases in temperature and decreases in precipitation. There were also large regions of the globe that showed no trend in greenness over the 17-year period, as well as large areas that underwent strong greening that showed no association with trends of either temperature or precipitation. These greening trends, as they concluded, must have been the result of other factors, such as “CO<sub>2</sub> fertilization, reforestation, forest regrowth, woody plant proliferation and trends in agricultural practices,” about which others will have more to say as we continue.

Working with satellite observations of vegetative activity over the period 1982 to 1999, Nemani *et al.* (2003) discovered that the productivity of earth’s terrestrial vegetation rose significantly over this period. More specifically, they determined that terrestrial net primary production (NPP) increased by 6.17 percent, or 3.42 PgC, over the 18 years between 1982 and 1999. What is more, they observed net positive responses over all latitude bands studied: 4.2 percent (47.5-22.5°S), 7.4 percent (22.5°S-22.5°N), 3.7 percent (22.5-47.5°N), and 6.6 percent (47.5-90.0°N).

The eight researchers mention a number of likely contributing factors to these significant NPP

increases: nitrogen deposition and forest regrowth in northern mid and high latitudes, wetter rainfall regimes in water-limited regions of Australia, Africa, and the Indian subcontinent, increased solar radiation reception over radiation-limited parts of Western Europe and the equatorial tropics, warming in many parts of the world, and the aerial fertilization effect of rising atmospheric CO<sub>2</sub> concentrations everywhere.

With respect to the latter factor, Nemani *et al.* say “an increase in NPP of only 0.2% per 1-ppm increase in CO<sub>2</sub> could explain all of the estimated global NPP increase of 6.17% over 18 years and is within the range of experimental evidence.” However, they report that terrestrial NPP increased by more than 1 percent per year in Amazonia alone, noting that “this result cannot be explained solely by CO<sub>2</sub> fertilization.”

We tend to agree with Nemani *et al.* on this point, but also note that the aerial fertilization effect of atmospheric CO<sub>2</sub> enrichment is most pronounced at higher temperatures, rising from next to nothing at a mean temperature of 10°C to a 0.33 percent NPP increase per 1-ppm increase in CO<sub>2</sub> at a mean temperature of 36°C for a mixture of plants comprised predominantly of herbaceous species (Idso and Idso, 1994). For woody plants, we could possibly expect this number to be two (Idso, 1999) or even three (Saxe *et al.*, 1998; Idso and Kimball, 2001; Leavitt *et al.*, 2003) times larger, yielding a 0.7 percent to 1 percent NPP increase per 1-ppm increase in atmospheric CO<sub>2</sub>, which would represent the lion’s share of the growth stimulation observed by Nemani *et al.* in tropical Amazonia.

The message of Nemani *et al.*’s study is that satellite-derived observations indicate the planet’s terrestrial vegetation significantly increased its productivity over the last two decades of the twentieth century, in the face of a host of both real and imagined environmental stresses, chief among the latter of which was what the IPCC claims to be unprecedented CO<sub>2</sub>-induced global warming.

Perhaps the most striking evidence for the significant twentieth century growth enhancement of earth’s forests by the historical increase in the air’s CO<sub>2</sub> concentration was provided by the study of Phillips and Gentry (1994). Noting that turnover rates of mature tropical forests correlate well with measures of net productivity (Weaver and Murphy, 1990), the two scientists assessed the turnover rates of 40 tropical forests from around the world in order to test the hypothesis that global forest productivity was increasing *in situ*. In doing so, they found that the

turnover rates of these highly productive forests had indeed been rising ever higher since at least 1960, with an apparent pan-tropical acceleration since 1980. In discussing what might be causing this phenomenon, they stated that “the accelerating increase in turnover coincides with an accelerating buildup of CO<sub>2</sub>,” and as Pimm and Sugden (1994) stated in a companion article, it was “the consistency and simultaneity of the changes on several continents that lead Phillips and Gentry to their conclusion that enhanced productivity induced by increased CO<sub>2</sub> is the most plausible candidate for the cause of the increased turnover.”

Four years later, a group of eleven researchers headed by Phillips (Phillips *et al.*, 1998), working with data on tree basal area (a surrogate for tropical forest biomass) for the period 1958-1996, which they obtained from several hundred plots of mature tropical trees scattered about the world, found that average forest biomass for the tropics as a whole had increased substantially. In fact, they calculated that the increase amounted to approximately 40 percent of the missing terrestrial carbon sink of the entire globe. They suggested that “intact forests may be helping to buffer the rate of increase in atmospheric CO<sub>2</sub>, thereby reducing the impacts of global climate change,” as Idso (1991a,b) had earlier suggested, and they identified the aerial fertilization effect of the ongoing rise in the air’s CO<sub>2</sub> content as one of the factors responsible for this phenomenon. Other contemporary studies also supported their findings (Grace *et al.*, 1995; Malhi *et al.*, 1998), verifying the fact that neotropical forests were indeed accumulating ever more carbon. Phillips *et al.* (2002) continued to state that this phenomenon was occurring “possibly in response to the increasing atmospheric concentrations of carbon dioxide (Prentice *et al.*, 2001; Malhi and Grace, 2000).”

As time progressed, however, it became less popular (i.e., more “politically incorrect”) to report positive biological consequences of the ongoing rise in the air’s CO<sub>2</sub> concentration. The conclusions of Phillips and others began to be repeatedly challenged (Sheil, 1995; Sheil and May, 1996; Condit, 1997; Clark, 2002; Clark *et al.*, 2003). In response to those challenges, *CO<sub>2</sub> Science* published an editorial rebuttal (see <http://www.co2science.org/articles/V6/N25/EDIT.php>), after which Phillips, joined by 17 other researchers (Lewis *et al.*, 2005b), including one who had earlier criticized his and his colleagues’ conclusions, published a new analysis that vindicated Phillips *et al.*’s earlier thoughts on the subject.

One of the primary concerns of the critics of Phillips *et al.*’s work was that their meta-analyses included sites with a wide range of tree census intervals (2-38 years), which they claimed could be confounding or “perhaps even driving conclusions from comparative studies,” as Lewis *et al.* (2005b) describe it. However, in Lewis *et al.*’s detailed study of this potential problem, which they concluded was indeed real, they found that re-analysis of Phillips *et al.*’s published results “shows that the pan-tropical increase in stem turnover rates over the late twentieth century cannot be attributed to combining data with differing census intervals.” Or as they state more obtusely in another place, “the conclusion that turnover rates have increased in tropical forests over the late twentieth century is robust to the charge that this is an artifact due to the combination of data that vary in census interval (cf. Sheil, 1995).”

Lewis *et al.* (2005b) additionally noted that “Sheil’s (1995) original critique of the evidence for increasing turnover over the late twentieth century also suggests that the apparent increase could be explained by a single event, the 1982-83 El Niño Southern Oscillation (ENSO), as many of the recent data spanned this event.” However, as they continued, “recent analyses from Amazonia have shown that growth, recruitment and mortality rates have simultaneously increased within the same plots over the 1980s and 1990s, as has net above-ground biomass, both in areas largely unaffected, and in those strongly affected, by ENSO events (Baker *et al.*, 2004; Lewis *et al.*, 2004a; Phillips *et al.*, 2004).”

In a satellite study of the world’s tropical forests, Ichii *et al.* (2005) “simulated and analyzed 1982-1999 Amazonian, African, and Asian carbon fluxes using the Biome-BGC prognostic carbon cycle model driven by National Centers for Environmental Prediction reanalysis daily climate data,” after which they “calculated trends in gross primary productivity (GPP) and net primary productivity (NPP).” This work revealed that solar radiation variability was the primary factor responsible for interannual variations in GPP, followed by temperature and precipitation variability, while in terms of GPP trends, Ichii *et al.* report that “recent changes in atmospheric CO<sub>2</sub> and climate promoted terrestrial GPP increases with a significant linear trend in all three tropical regions.” In the Amazonian region, the rate of GPP increase was 0.67 PgC year<sup>-1</sup> decade<sup>-1</sup>, while in Africa and Asia it was about 0.3 PgC year<sup>-1</sup> decade<sup>-1</sup>. Likewise, they report that “CO<sub>2</sub> fertilization effects strongly increased recent NPP trends in regional totals.”

In a review of these several global forest studies, as well as many others (which led to their citing 186 scientific journal articles), Boisvenue and Running (2006) examined reams of “documented evidence of the impacts of climate change trends on forest productivity since the middle of the twentieth century.” In doing so, they found that “globally, based on both satellite and ground-based data, climatic changes seemed to have a generally positive impact on forest productivity when water was not limiting,” which was most of the time, because they report that “less than 7% of forests are in strongly water-limited systems.”

Last, Young and Harris (2005) analyzed, for the majority of earth’s land surface, a near 20-year time series (1982-1999) of NDVI data, based on measurements obtained from the Advanced Very High Resolution Radiometer (AVHRR) carried aboard U.S. National Oceanic and Atmospheric Administration satellites. In doing so, they employed two different datasets derived from the sensor: the Pathfinder AVHRR Land (PAL) data set and the Global Inventory Modeling and Mapping Studies (GIMMS) dataset. Based on their analysis of the PAL data, the two researchers determined that “globally more than 30% of land pixels increased in annual average NDVI greater than 4% and more than 16% persistently increased greater than 4%,” while “during the same period less than 2% of land pixels declined in NDVI and less than 1% persistently declined.” With respect to the GIMMS dataset, they report that “even more areas were found to be persistently increasing (greater than 20%) and persistently decreasing (more than 3%).” All in all, they report that “between 1982 and 1999 the general trend of vegetation change throughout the world has been one of increasing photosynthesis.”

As for what has been responsible for the worldwide increase in photosynthesis—which is the ultimate food source for nearly all of the biosphere—the researchers mention global warming (perhaps it’s not so bad after all), as well as “associated precipitation change and increases in atmospheric carbon dioxide,” citing Myneni *et al.* (1997) and Ichii *et al.* (2002). In addition, they say that “many of the areas of decreasing NDVI are the result of human activity,” primarily deforestation (Skole and Tucker, 1993; Steininger *et al.*, 2001) and urbanization (Seto *et al.* (2000)).

In conclusion, the results of these many studies demonstrate there has been an increase in plant growth rates throughout the world since the inception

of the Industrial Revolution, and that this phenomenon has been gradually accelerating over the years, in concert with the historical increases in the air’s CO<sub>2</sub> content and its temperature.

Additional information on this topic, including reviews of newer publications as they become available, can be found at <http://www.co2science.org/subject/g/greeningearth.php>.

## Species Extinction

---

### 8. Species Extinction

- 8.1. Explaining Extinction
- 8.2. Terrestrial Plants
- 8.3. Coral Reefs
- 8.4. Polar Bears

### Introduction

The Intergovernmental Panel on Climate Change (IPCC) claims “new evidence suggests that climate-driven extinctions and range retractions are already widespread” and the “projected impacts on biodiversity are significant and of key relevance, since global losses in biodiversity are irreversible (very high confidence)” (IPCC-II, 2007, p. 213). The IPCC even claims to know that “globally about 20% to 30% of species (global uncertainty range from 10% to 40%, but varying among regional biota from as low as 1% to as high as 80%) will be at increasingly high risk of extinction, possibly by 2100, as global mean temperatures exceed 2 to 3°C above pre-industrial levels” (Ibid.).

These claims and predictions are not based on what is known about the phenomenon of extinction or on real-world data about how species have endured the warming of the twentieth century, which the IPCC claims was unprecedented in the past two millennia. Because we addressed the impact of rising CO<sub>2</sub> concentrations and rising temperatures on plants in detail in the previous chapter, we only briefly recap the evidence concerning terrestrial plants here, finding no evidence of a wave of temperature-driven extinctions, and in fact evidence of just the opposite. We then devote the largest part of the chapter to the effects of global warming on two species to which the IPCC devotes special attention, coral reefs and polar bears.

Additional information on this topic, including reviews of newer publications as they become available, can be found at <http://www.co2science.org/subject/e/extinction.php>.

### 8.1. Explaining Extinction

There is a large gap between what scientists understand about the definition and causes of extinctions and what is reported in the popular press and even in some headline-seeking scientific journals. We start our analysis by asking what we know about the causes of past extinctions, the shortcomings of popular predictions of pending extinctions due to climate change, and the phenomenon of rapid evolutionary change.

#### 8.1.1. Defining Extinction

Looking at the research papers selected to support the theory of massive warming extinctions, we are struck by many biologists’ apparent misunderstanding of extinction. Some biologists seem to believe that effective conservation means every local population of butterflies and mountain flowers must be preserved. This is obviously impossible on a planet

with continual, massive climate changes and human impacts. Some biologists try to define more and more local populations as separate species—a subterfuge.

A recent article in *Science* amply illustrates the conflicted feelings and biologists' frantic desire to protect everything. In an article titled "All Downhill from Here," Krajick (2004) laments the supposed danger to pikas (rodents, cousins to rabbits) that live on treeless mountaintops:

As global temperatures rise, the pika's numbers are nose-diving in far-flung mountain ranges ... researchers fear that if the heat keeps rising, many alpine plants and animals will face quick declines or extinctions ... creatures everywhere are responding to warming, but mountain biota, like cold-loving polar species, have fewer options for coping. ... Comprising just 3% of the vegetated terrestrial surface, these islands of tundra are Noah's ark refuges where whole ecosystems, often left over from glacial times, are now stranded amid un-crossable seas of warm lowlands.

Krajick himself seems to forget the words in his own opening paragraph: pikas "are also some of the world's toughest mammals." As for his "un-crossable seas of warm lowlands," pikas may not be able to thrive in the lowlands competition, but it does seem likely they could find enough vegetation there during their travels to tide them over until they find other, cooler mountaintops.

Parmesan and Yohe (2003) also present a distorted version of the term "extinction." They counted Edith's checkerspot butterflies at 115 North American sites with historical records of harboring the species and then classified the sites as "extinct or intact." They found local checkerspot populations in much-warmer Mexico were four times more likely to be "locally extinct" than those in much-cooler Canada. Similarly, Ian Stirling, an expert on polar bears who is widely quoted in the debate over whether global warming may reduce polar bear populations, was quoted by the World Wide Fund for Nature in 2002 as saying "polar bear numbers will be reduced in the southern portions of their range [and] may even become locally extinct" (WWF, 2002). However, "locally extinct" is not a scientific term. Extinct means "no longer in existence; died out." Gone forever. Parmesan and Yohe are using it in reference to butterfly populations that have simply moved—and even left forwarding addresses farther north. Polar bears, too, are known to migrate to different areas in response to changes in climate and

competition for food. This is not extinction, but extirpation—the loss of a population in a given location. The butterflies are responding effectively to climate change—which is certainly what we would hope a butterfly species would do on a planet with a climate history as variable as Earth's. Parmesan and Yohe found populations of Edith's checkerspot butterflies thriving over most of western North America, but fewer of them at the southernmost extremity of their range—in Baja California and near San Diego—than in the past. However, parts of Canada have been warming into their preferred climate range.

Species resist extinction strongly and they often persist even when humans think they've been wiped out. The supposedly extinct ivory-billed woodpecker was recently found in two forests in eastern Arkansas (Arkansas Game and Fish Commission, 2005). The Nature Conservancy recently found three "extinct" snails in Alabama and California. Botanists have found the Mount Diablo buckwheat plant for the first time since 1936. At least 24 other "extinct" species have been found during natural heritage surveys in North America since 1974 (Holloway, 2005).

### 8.1.2. Past Extinctions

Most of the world's major species "body types" were laid down during the Cambrian period 600 million years ago (Levinton, 1992), so we know the major species have dealt successfully through the ages with new pest enemies, new diseases, ice ages, and global warmings greater than today's. Most wild species are at least one million years old, which means they have

all been through at least six hundred 1,500-year climate cycles. Not the least of the warmings was the Holocene Climate Optimum, which was warmer than even the predictions of the IPCC for 2100 (IPCC, 2007). That very warm period ended less than 5,000 years ago.

Environmentalists argue that the speed of today's climate change is greater than previous warmings and will overwhelm the adaptive capacities of plants and animals. Yet history and paleontology agree that many of the past global temperature changes arrived very quickly, sometimes in a few decades. For example, 12,000 years ago, the Younger Dryas event suddenly and violently swung from warm temperatures back to Ice Age levels by the shutdown of the Gulf Stream as melting water from the extra trillion tons of ice built up in the glaciers and ice sheets over the previous 90,000 years of frigid climate was released into the oceans. The shutdown of the oceans' Atlantic Conveyor quickly triggered another thousand years of Ice Age. How did wild species deal with Mother Nature's sudden, sharp reversals then? In another example, starting about 1840 a Wyoming glacier went from Little Ice Age cold to near present-day warmth in about a decade (Schuster *et al.*, 2000). There's no evidence of any local species being destroyed by that rapid temperature change.

In contrast to the missing evidence of past climate changes having caused extinctions, we already know how most of the world's extinct species were lost, and in what order of magnitude (Singer and Avery, 2007). The first cause is huge asteroids striking the planet. The web sites of such universities as the University of California–Berkeley, Smith, and North Carolina State are replete with evidence of these “big bangs.” Earth's collisions with massive missiles from outer space explode billions of tons of ash and debris into the planet's atmosphere, darken the skies, and virtually eradicate growing seasons for years at a time. There apparently have been more than a dozen such collisions in the Earth's past and they have destroyed millions of species, most of which we know about only through the fossil record.

In 2004, researchers announced that geological evidence suggests an object crashed at the shoreline of what is now Australia's northwestern coast 251 million years ago, creating climate changes and other natural catastrophes. Gugliotta (2004) filed the following report on the discovery for the *Washington Post*:

Scientists said yesterday they have found evidence that a huge meteorite or comet plunged into the

coastal waters of the Southern Hemisphere 251 million years ago, possibly triggering the most catastrophic mass extinction in Earth's history. The researchers said that geological evidence suggests that an object about six miles in diameter crashed at the shoreline of what is now Australia's northwestern coast, creating climate changes and other natural catastrophes that wiped out 90 percent of marine species and 70 percent of land species.

The second known cause of extinctions is hunting. For a million years or so, humans along with *Homo erectus* in Southeast Asia and Neanderthals in Europe have hunted whatever they could kill. If it went extinct, we hunted something else. In this sense, the last Ice Age did cause some indirect species extinctions. During that extremely cold period, so much of the world's water was trapped in ice caps and glaciers that sea levels dropped as much as 400 feet below today's levels. Stone Age hunters walked across the Bering Strait from Asia and found hordes of wild birds and mammals that did not fear man. More than 40 edible species were wiped out in a historical eye-blink, including North America's mammoths, mastodons, horses, camels, and ground sloths (Diamond, 1997).

A similar spate of human-hunter extinctions recently has been confirmed in Australia by the discovery of a cave full of fossils beneath the Nullabor Plain. The new fossils disarm the claim that a huge number of Australian species—including its marsupial lion, claw-footed kangaroo, giant wombat, and the Genyornis, the heaviest bird ever known—went extinct 46,400 years ago because of climate change. The discovery team said the species found in the cave died during a dry climate similar to today's, which hadn't changed in 400,000 years. However, the fire-sensitive woodlands, to which the species were adapted, disappeared suddenly about 46,000 years ago—apparently because the newly arrived aboriginal people burned the woods to drive game into the arms of club-wielding hunters. The landscape was reshaped by fire from woods to shrubbery (Western Australian Museum, 2007).

Third: Man learned to farm. Farming for food made us less likely to hunt wild animals and birds to extinction, but eventually we claimed one-third of all the Earth's land area for agriculture. The saving grace was that the best land for farming tended to have few species; instead it had large numbers of a few species, such as bison on the American Great Plains and kangaroo in the Australian grasslands. In contrast,

researchers have found as many species in five square miles of the Amazon as in the whole of North America. Fortunately, man tended to farm the best land for the highest sustainable food yields, leaving much of the poorer land (with its diversity) for nature (Avery, 2000).

Fourth: Alien species. Mankind's ships, cars, and planes transport species across natural barriers, enabling them to reproduce and compete with native species. This has made the survival competition among species much more global. Island species, in particular, have found themselves in more intense competition and many have gone extinct.

These four explanations for the major extinctions of the past are each now well documented and understood. The claim that changes in temperature during the twentieth century—which the IPCC calls unprecedented in the past two millennium—are causing extinctions is much more dubious, as we see in the next section.

### 8.1.3. Theories of Contemporary Extinctions

In striking contrast to the four known causes of past extinctions, which are backed by extensive fossil and archeological evidence, Thomas *et al.* (2004) simply asserted the *theory* that raising or lowering the Earth's temperature would cause major wildlife extinctions on a linear model. Accordingly, small temperature changes lead to relatively small reductions in species numbers while larger temperature increases drive more species to extinction. The team first defined “survival envelopes” for more than 1,100 wildlife species—in Europe, the Brazilian Amazon, the wet tropics of northeastern Australia, the Mexican desert, and the southern tip of South Africa. Then they used a “power equation” to link loss of habitat area with extinction rates. If the equation showed that a species' potential habitat was projected to decline, it was regarded as threatened; the greater the expected habitat loss, the greater the threat. There was no provision for species adaptation or migration.

One of the Thomas team's “moderate” scenarios was an increase in Earth's temperature of 0.8° C in the next 50 years. The researchers said this would cause the extinction of roughly 20 percent of the world's wild species, perhaps one million of them. Fortunately, this prediction can easily be checked. The Earth's temperature has already increased 0.8° C over the past 150 years. How many species died out because of that temperature increase? None that we are aware of.

The Thomas paper tells us in its opening sentence: “Climate change over the past 30 years has produced numerous shifts in the distributions and abundances of species, and has been implicated in one species-level extinction.” The scientists who are predicting that 0.8° C of warming would cause hundreds of thousands of wildlife species extinctions over the next 50 years concede that this level of temperature increase over the past 150 years has resulted in the extinction of *one* species.

Reality takes away even that one extinction claim. Thomas *et al.*'s single cited example of a species driven extinct by the recent warming is the Golden Toad of Costa Rica. That was based on a 1999 paper in *Nature* by J. Alan Pounds and coauthors (Pounds *et al.*, 1999) describing research conducted at the Monteverde Cloud Forest Preserve in Puntarenas, Costa Rica. Pounds *et al.* claimed that, due to rising sea surface temperatures in the equatorial Pacific, 20 of the 50 species of frogs and toads (including the Golden Toad) had disappeared in a cloud forest study

area of 30 square kilometers. (Cloud forests are misty habitats found only in the mountains above 1,500 meters, where the trees are enclosed by cool, wet clouds much of the time. The unusual climate serves as a home to thousands of unique plants and animals.) Pounds and a coauthor explained his thesis to a scientific conference in 1999:

In a cloud forest, moisture is ordinarily plentiful. Even during the dry season ... clouds and mist normally keep the forest wet. Trade winds, blowing in from the Caribbean, carry moisture up the mountain slopes, where it condenses to form a large cloud deck that surrounds the mountains. It is hypothesized that climate warming, particularly since the mid-1970s, has raised the average altitude at which cloud formation begins, thereby reducing the clouds' effectiveness in delivering moisture to the forest. ... Days *without* mist during the dry season ... quadrupled over recent decades (Pounds and Schneider, 1999).

Pounds said at least 22 species of amphibians have disappeared from the cloud forest. Although the other species that disappeared were known to exist in other locations, the Golden Toad lost its only known home. However, two years after Pounds hypothesized that the amphibians lost their cloud forest climate to drying from sea surface warming, another research team demonstrated that it was almost certainly the clearing of lowland forests under the cloud forest of Monteverde that changed the pattern of cloud formation over the Golden Toad's once-mistier home. Lawton *et al.* (2001) noted that trade winds bringing moisture from the Caribbean spend five to 10 hours over the lowlands before they reach the Golden Toad's mountain home in the Cordillera de Tilaran. By 1992, only about 18 percent of the original lowland vegetation remained. The deforestation reduced the infiltration of rainfall, increased water runoff, and thus reduced soil moisture. The shift from trees to crops and pasture also reduced the amount of water-holding canopy.

In March 1999, the Lawton team got satellite imagery showing that late-morning dry season cumulus clouds were much less abundant over the deforested parts of Costa Rica than over the nearby still-forested lowlands of Nicaragua. To check their conclusion, the Lawton team simulated the impact of Costa Rican deforestation using Colorado State University's Regional Atmospheric Modeling System. The computer modeling showed that the cloud base over pastured landscape rose above the altitude of the Cordillera peaks (1,800 meters) by late

morning. Over forests, the cloud base didn't reach 1,800 meters until early afternoon. Lawton says these values "are in reasonable agreement with observed cloud bases in the area." That puts the blame for the cloud forest dryness squarely on the farmers and ranchers who cleared the lowlands. Pounds' own paper noted deforestation as a major threat to mountain cloud forests. The Lawton study leaves the Thomas team's big computerized study of mass species extinction without any evidence that moderate climate changes—even when abrupt—cause species extinctions.

The two other articles in *Nature* also failed to report any evidence of extinctions caused by the recent warming trend. The closest thing to an extinction threat in the Root *et al.* studies was the expansion of red foxes into the southern former range of arctic foxes in North America and Eurasia. However, this is displacement/ replacement, not extinction. Hersteinsson and Macdonald (1992) concluded that the changes in fox ranges were driven by prey availability. The arctic foxes are found primarily in the treeless regions of the Arctic, where they feed on lemmings and voles in the summer and eat heavily from seal carcasses in the winter. The larger red foxes eat a wider range of prey and fruits and are regarded as stronger competitors in forest and brush land. However, they are less well camouflaged for the winters in the treeless tundra than the arctic foxes in their blue-white winter pelts. Warming temperatures have allowed trees, brush, and red foxes to move farther north in the past 150 years—but they also have allowed arctic foxes to retain enough land and prey to succeed north of the red foxes. We do not know what would have happened if there had been no northern habitat and prey to support the arctic foxes during a red fox expansion, but the foxes already have survived more radical warming than they have faced recently. In earlier parts of the interglacial period, the Arctic temperatures were 2° to 6° C higher than they are now (Taira, 1975; Korotsky *et al.*, 1988).

Returning to the study of Thomas *et al.* one more time, it is interesting to note that an earlier study by Thomas contained findings that completely discredit the thesis on which the 2004 claim rests—that species have readily defined "survival envelopes" outside which they cannot survive. The Thomas team began its 2001 paper by restating the long-believed and broadly held concept that many animals are "relatively sedentary and specialized in marginal parts of their geographical distributions." Thus, creatures are "expected to be slow at colonizing new habitats."

Despite this belief, however, the Thomas team cites its own and many other researchers' studies showing that "the cool margins of many species' distributions have expanded rapidly in association with recent climate warming." This mildly undercuts their thesis. Much worse was to come. The two butterfly species the authors studied "increased the variety of habitat types that they can colonize" and the two species of bush cricket they studied showed "increased fractions of longer-winged (dispersive) individuals in recently founded populations." The longer-winged crickets would be able to fly farther in search of new habitat.

As a consequence of the new adaptations, the Thomas authors report, "Increased habitat breadth and dispersal tendencies have resulted in about 3 to 15-fold increases in [range] expansion rates, allowing these insects to cross habitat disjunctions that would have represented major or complete barriers to dispersal before the expansions started." The changes in the butterfly and cricket populations render Thomas's entire thesis of "survival envelopes" inadequate at best and quite likely irrelevant. Yet this paper was not only written before the Root analysis, it was included in the Root analysis as one of the select few research studies supporting the mega-extinction theory.

Buried in the IPCC report are admissions that the computer models based on the dubious notion of "survival envelopes" that it relies on produce "a picture of potential impacts and risks that is far from perfect, in some instances apparently contradictory" (p. 239) and "climate envelope models do not simulate dynamic population or migration processes, and results are typically constrained to the regional level, so that the implications for biodiversity at the global level are difficult to infer," citing Malcolm *et al.*, 2002 (IPCC, 2007-II, p. 240). We agree, which is why, in the following sections, we present more reliable theories and evidence that paint a much different, and more accurate, picture of the fate of wildlife in a warming world.

### 8.1.4. Data on Contemporary Species

What does real-world data say about rates of extinction? In 2002, the United Nations Environmental Program (UNEP) published a new *World Atlas of Biodiversity* (Groombridge and Jenkins, 2002). It reported that the world lost only half as many major wild species in the last three decades of the twentieth century (20 birds, mammals, and fish) as during the last three decades of the nineteenth century (40 extinctions of major species). In fact, UNEP said the rate of extinctions at the end of the twentieth century was the lowest since the sixteenth century—despite 150 years of rising world temperatures, growing populations, and industrialization.

There is a wealth of data to support the fact that

many species have prospered during the twentieth century, starting with research conducted by those who claim rising temperatures have caused a rise in extinctions. Parmesan and Yohe (2003) examined the northern boundaries of 52 butterfly species in northern Europe and the southern boundaries of 40 butterfly species in southern Europe and North Africa over the past century. Given the 0.8° C warming of Europe's temperatures over that period, it is striking to have Parmesan and Yohe tell us that "nearly all northward shifts involved extensions at the northern boundary with the southern boundary remaining stable." Thus, in the researchers own words, "most species effectively expanded the size of their ranges."

Chris Thomas and a coauthor in a study published in 1999 documented changes in the distribution between 1970 and 1990 of many British bird species (Thomas and Lennon, 1999). He found that the northern margins of southerly species shifted northward by an average of 19 km, while the southern margins of northerly species remained unchanged.

On 26 high mountain summits in the middle part of the Alps, a study by Grabherr *et al.* (1994) of the plant species found "species richness has increased during the past few decades, and is more pronounced at lower altitudes." In other words, the mountaintops show little loss of biodiversity at upper elevations, and increased species richness at lower elevations, where plants from still-lower elevations extended their ranges upward.

Pauli *et al.* (1996) examined the summit flora on 30 mountains in the European Alps, with species counts that ranged back in history to 1895. They report that mountaintop temperatures have risen by 2° C since 1920, with an increase of 1.2° C in just the last 30 years. Nine of the 30 mountaintops showed no change in species counts, but 11 gained an average of 59 percent more species, and one mountain gained an astounding 143 percent more species. Did historic species get crowded out by the flood of new warmer-zone plants? The 30 mountains showed a mean species loss of 0.68 out of an average of 15.57 species. There was no documentation that any of the species "lost" on particular mountains represented extinctions rather than local disappearances.

Vesperinas *et al.* (2001) reported that native heat-sensitive plant species have responded to temperature increases in the Iberian Peninsula and the Mediterranean coast over the past 30 years by expanding their ranges "towards colder inland areas where they were previously absent."

Van Herk *et al.* (2002) reported that the number

of lichen species groups present in the Central Netherlands increased from 95 in 1979 to 172 in 2001 as the region warmed. The researchers found the average number of species grouped per site increased from 7.5 to 18.9. Again, more warmth produced increased species richness.

Looking at the distribution of 18 butterfly species widespread and common in the British countryside, "nearly all of the common species have increased in abundance [during the warming], more in the east of Britain than in the west" according to a research team led by Emie Pollard of Britain's Institute of Terrestrial Ecology (Pollard *et al.*, 1995).

Warm-water species of plankton rapidly responded to warming and cooling in the western English Channel, shifting latitudinally by up to 120 miles, and increasing or decreasing their numbers by two to three-fold over 70 years, according to research by A.J. Southward of Britain's Marine Biological Association (Southward, 1995).

In the Antarctic, Adelie penguins need pack ice to thrive, whereas chinstrap penguins prefer ice-free waters. R.C. Smith *et al.* (1994) found that the Adelie penguins in the West Antarctic Peninsula are declining because the warming on the peninsula favors the chinstraps. Meanwhile the chinstraps in the Ross Sea region are suffering because 97 percent of Antarctica—the part that isn't the peninsula—is getting colder. This can hardly be surprising. Two varieties of a highly mobile species have moved to the sites that favor their respective feeding and breeding requirements while their populations decline in the unfavorable sites.

The Antarctic's only two higher-level plant species have responded to the Antarctic Peninsula's warming by increasing their numbers at two widely separated localities (Smith, 1994). Fortunately, it would take thousands of years of increased warming to melt all the Antarctic ice and a very long period of extended cold to close all the open water around the Antarctic Peninsula. The 1,500-year climate cycle makes it almost certain that Antarctica's plants and penguins will continue to adapt rather than disappear.

Invertebrates in a rocky intertidal site at Pacific Grove, California can't move, but their populations change. The invertebrates were surveyed by Saragin *et al.* (1999) in 1931–1933 and again in 1993–1996 after a warming of 0.8° C. Ten of the 11 southern species increased in abundance, whereas five of seven northern species decreased.

New photographs were taken by Sturm *et al.* (2001) to match a set of 1948–1950 photographs of

the Brooks Range and the Arctic coast of Alaska. At more than half of the matched locations, researchers found “distinctive and, in some cases, dramatic increases in the height and diameter of individual shrubs ... and expansion of shrubs into previously shrub-free areas.”

Western American bird species are pioneering and expanding their ranges over vast areas and huge climatic differences as the climate warms. N.K. Johnson of the University of California–Berkeley compiled records for 24 bird species from *Audubon Field Notes*, *American Birds* and other sources (Johnson, 1994). He found “four northern species have extended their ranges southward, three eastern species have expanded westward, fourteen southwestern or Mexican species have moved northward, one Great Basin–Colorado Plateau species has expanded radially, and two Great Basin–Rocky Mountain subspecies have expanded westward.”

Brommer (2004) studied the birds of Finland, which were categorized as either northerly (34 species) or southerly (116 species). Brommer quantified changes in their range margins and distributions from two atlases of breeding birds, one covering the period 1974–79 and one covering the period 1986–89, in an attempt to determine how the two groups of species responded to what he called “the period of the earth’s most rapid climate warming in the last 10,000 years.” Once again, it was determined that the southerly group of bird species experienced a mean poleward advancement of their northern range boundaries of 18.8 km over the 12-year period of supposedly unprecedented warming. The southern range boundaries of the northerly species, on the other hand, were essentially unmoved, leading once again to range expansions that should have rendered the Finnish birds less subject to extinction than they were before the warming.

Similar results were obtained in a study by Hickling *et al.* (2005) of changes in the northern and southern range boundaries of 37 non-migratory British dragonfly and damselfly species between the two 10-year periods 1960–70 and 1985–95. All but two of the 37 species increased the sizes of their ranges between the two 10-year periods, with the researchers reporting that “species are shifting northwards faster at their northern range margin than at their southern range margin,” and concluding that “this could suggest that species at their southern range margins are less constrained by climate than by other factors,” which surely appears to be the case.

Chamaille-Jammes *et al.* (2006) studied four unconnected populations of a small live-bearing lizard that lives in peat bogs and heath lands scattered across Europe and Asia, concentrating on a small region near the top of a mountain in southeast France at the southern limit of the species’ range. There, from 1984 to 2001, they monitored a number of life-history traits of the populations, including body size, reproductive characteristics, and survival rates, during which time local air temperatures rose by approximately 2.2°C. In doing so, they observed that individual body size increased dramatically in all four populations over the 18-year study period in all age classes and, in the words of the researchers, “appeared related to a concomitant increase in temperature experienced during the first month of life.” As a result, since fecundity is strongly dependent on female body size, they found that “clutch size and total reproductive output also increased.” In addition, they learned that “adult survival was positively related to May temperature.”

In discussing their findings, the French researchers say that since all fitness components investigated responded positively to the increase in temperature, “it might be concluded that the common lizard has been advantaged by the shift in temperature.” This finding, as they describe it, stands in stark contrast to what they call the “habitat-based prediction that these populations located close to mountaintops on the southern margin of the species range should be unable to cope with the alteration of their habitat.” They conclude that “to achieve a better prediction of a species persistence, one will probably need to combine both habitat and individual-based approaches,” noting, however, that individual responses, such as those documented in their study (which were all positive), represent “the ultimate driver of a species response to climate change.”

The Audubon Society (2009) released a report in February 2009 calling attention to the correlation between the movement of North American bird populations and an increase in average January temperatures in the lower 48 U.S. states from 1969 to 2005. The report breathlessly recounted the expansion of the northern boundaries of the habitats of 58 percent of observed species of birds over the past four decades and concluded that “we must act decisively to control global warming pollution to curb the worst impacts of climate change, and take immediate steps to help birds and other species weather the changes we cannot avoid.” But the study did not ask whether the warming that occurred during this period

benefitted or hurt most bird populations by moving poleward the northern edge of their habitats. One might suppose the net effect would be beneficial, and in fact this is what Audubon itself found but failed to mention in the body of the report. In a data table presented in an appendix to the report, one finds that 120 of the 305 species reported in the study (39 percent) showed statistically significant population increases, 128 (42 percent) showed no change, and only 57 (19 percent) showed statistically significant declines. These numbers suggest that North American bird species overall benefitted from the modest warming from 1969 to 2005.

Many, and probably most, of the world's species have benefitted from rising temperatures in the twentieth century. There is very little evidence of any extinctions. What should be plain is that, despite predictions of extinctions based on theories and computer models, real-world observations confirm that a warmer world is more, not less, hospitable to wildlife.

### 8.1.5. Rapid Evolutionary Change

Skelly *et al.* (2007) critiqued the climate-envelope approach to predicting extinctions used by Thomas *et al.* (2004), citing as their primary reason for doing so the fact that this approach "implicitly assumes that species cannot evolve in response to changing climate." As they correctly point out, "many examples of contemporary evolution in response to

climate change exist,” such as populations of a frog they had studied that had “undergone localized evolution in thermal tolerance (Skelly and Freidenburg, 2000), temperature-specific development rate (Skelly, 2004), and thermal preference (Freidenburg and Skelly, 2004),” in less than 40 years. Similarly, they report, “laboratory studies of insects show that thermal tolerance can change markedly after as few as 10 generations (Good, 1993).”

Adding that “studies of microevolution in plants show substantial trait evolution in response to climate manipulations (Bone and Farres, 2001),” the researchers further noted that “collectively, these findings show that genetic variation for traits related to thermal performance is common and evolutionary response to changing climate has been the typical finding in experimental and observational studies (Hendry and Kinnison, 1999; Kinnison and Hendry, 2001).”

Although evolution will obviously be slower in the cases of long-lived trees and large mammals, where long generation times are the norm, the scientists say the case for rapid evolutionary responses among many other species “has grown much stronger,” citing, in this regard, the work of six other groups of researchers comprised of two dozen individuals (Stockwell *et al.*, 2003; Berteaux *et al.*, 2004; Hairston *et al.*, 2005; Bradshaw and Holzapfel, 2006; Schwartz *et al.*, 2006; Urban *et al.*, 2007). As a result, they write, “on the basis of the present knowledge of genetic variation in performance traits and species’ capacity for evolutionary response, it can be concluded that evolutionary change will often occur concomitantly with changes in climate as well as other environmental changes (Stockwell *et al.*, 2003; Grant and Grant, 2002; Balanya *et al.*, 2006; Jump *et al.*, 2006; Pelletier *et al.*, 2007).”

Much the same conclusion has been reached by still other groups of scientists. In a study of the field mustard plant, for example, a group of three researchers (Franks *et al.*, 2007) found evidence for what they describe as “a rapid, adaptive evolutionary shift in flowering phenology after a climatic fluctuation,” which finding, in their words, “adds to the growing evidence that evolution is not always a slow, gradual process but can occur on contemporary time scales in natural populations.”

Likewise, another group of researchers who published in 2007 (Rae *et al.*, 2007)—who worked with hybrids of two *Populus* tree species—obtained results which, as they phrased it, “quantify and

identify genetic variation in response to elevated CO<sub>2</sub> and provide an insight into genomic response to the changing environment.” The results, they wrote, “should lead to an understanding of microevolutionary response to elevated CO<sub>2</sub> ... and aid future plant breeding and selection,” noting that various research groups have already identified numerous genes that appear sensitive to elevated CO<sub>2</sub> (Gupta *et al.*, 2005; Taylor *et al.*, 2005; Ainsworth *et al.*, 2006; Rae *et al.*, 2006).

Life in the sea, in this regard, is no different from life on land. In another study published in 2007, for example, a team of four marine biologists (Van Doorslaer *et al.*, 2007) conducted an experiment with a species of zooplankton in which they say they “were able to demonstrate a rapid microevolutionary response (within 1 year) in survival, age at reproduction and offspring number to elevated temperatures,” and they state that “these responses may allow the species to maintain itself under the forecasted global warming scenarios,” noting that what they learned “strongly indicates rapid microevolution of the ability to cope with higher temperatures.” Many other studies, some of them cited in Section 8.3, have produced analogous results with respect to increases in temperature on corals (Kumaraguru *et al.*, 2003; Willis *et al.*, 2006) and increases in CO<sub>2</sub> on freshwater microalgae (Collins *et al.*, 2006).

In conclusion, many species have shown the ability to adapt rapidly to changes in climate. Claims that global warming threatens large numbers of species with extinction typically rest on a false definition of extinction (the loss of a particular population rather than entire species) and speculation rather than real-world evidence. The world’s species have proven to be very resilient, having survived past natural climate cycles that involved much greater warming and higher CO<sub>2</sub> concentrations than exist today or are likely to occur in the coming centuries.

## 8.2. Terrestrial Plants

The IPCC's global warming extinction scenario is that if it gets "too hot" for a species of plant or animal where it currently lives, individuals of the heat-stressed species would have to move to a cooler location in order to survive. In many cases, however, acclimation can adequately substitute for migration, as has been demonstrated by several studies in which the temperatures at which plants grow best rose substantially (by several degrees Centigrade) in response to increases in the air temperature regimes to which they had long been accustomed (Mooney and West, 1964; Strain *et al.*, 1976; Bjorkman *et al.*, 1978; Seemann *et al.*, 1984; Veres and Williams, 1984; El-Sharkawy *et al.*, 1992, Battaglia *et al.*, 1996).

How does acclimation happen? One possible way is described by Kelly *et al.* (2003). In reference to the view of the IPCC, they note that "models of future ecological change assume that *in situ* populations of plants lack the capacity to adapt quickly to warming and as a consequence will be displaced by species better able to exploit the warmer conditions anticipated from 'global warming'." In contrast to this assumption, they report finding individual trees within a naturally occurring stand of *Betula pendula* (birch) that are genetically adapted to a range of different temperatures. As they describe it, they discovered "the existence of 'pre-adapted' individuals in standing tree populations" that "would reduce temperature-based advantages for invading species," which finding, they say, "bring[s] into question assumptions currently used in models of global climate change."

Another perspective on the adaptation vs. migration theme is provided by the work of Loehle (1998), who notes (using forests as an example) that the CO<sub>2</sub>-induced global warming extinction hypothesis rests on the assumption that the growth rates of trees rise from zero at the cold limits of their natural ranges (their northern boundaries in the Northern Hemisphere) to a broad maximum, after which they decline to zero at the warm limits of their natural ranges (their southern boundaries in the Northern Hemisphere). Loehle demonstrates that this

assumption is only half correct. It properly describes tree growth dynamics near a Northern Hemispheric forest's northern boundary, but not its southern boundary.

Loehle notes that in the Northern Hemisphere (to which we will restrict our discussion for purposes of simplicity), trees planted north of their natural ranges' northern boundaries are able to grow to maturity only within 50-100 miles of those boundaries. Trees planted south of their natural ranges' southern boundaries, however, often grow to maturity as much as 1,000 miles further south (Dressler, 1954; Woodward, 1987, 1988). Loehle reports that "many alpine and arctic plants are extremely tolerant of high temperatures, and in general one cannot distinguish between arctic, temperate, and tropical-moist-habitat types on the basis of heat tolerances, with all three types showing damage at 44-52°C (Gauslaa, 1984; Lange and Lange, 1963; Levitt, 1980; Kappen, 1981)."

What Loehle finds from his review of the literature and his experience with various trees in the United States is that as temperatures and growing degree days rise from very low values, the growth rates of boreal trees at some point begin to rise from zero and continue increasing until they either plateau at some maximum value or drop only very slowly thereafter, as temperatures rise still higher and growing degree days continue to accumulate. Trees from the Midwest, by comparison, do not begin to grow until a higher temperature or greater accumulation of growing degree days is reached, after which their growth rates rise considerably higher than those of the colder-adapted boreal species, until they too either level out or begin to decline slowly. Lastly, southern species do not begin to grow until even higher temperatures or growing degree day sums are reached, after which their growth rates rise the highest of all before leveling out and exhibiting essentially no decline thereafter, as temperatures and growing degree days continue to climb.

In light of these observations, it is clear that although the northern range limit of a woody species in the Northern Hemisphere is indeed determined by growth-retarding cool growing seasons and frost damage, the southern boundary of a tree's natural range is not determined by temperature, but by competition between the northern species and more southerly adapted species that have inherently greater growth rates.

Whenever significant long-term warming occurs, therefore, earth's coldest-adapted trees are presented

with an opportunity to rapidly extend the cold-limited boundaries of their ranges northward in the Northern Hemisphere, as many studies have demonstrated they have done in the past and are doing now. Trees at the southern limits of their ranges, however, are little affected by the extra warmth. As time progresses, they may at some point begin to experience pressure from some of the faster-growing southern species encroaching upon their territory; but this potential challenge is by no means assured of quick success. As Loehle describes it:

Seedlings of these southern species will not gain much competitive advantage from faster growth in the face of existing stands of northern species, because the existing adult trees have such an advantage due to light interception. Southern types must wait for gap replacement, disturbances, or stand break up to utilize their faster growth to gain a position in the stand. Thus the replacement of species will be delayed at least until the existing trees die, which can be hundreds of years ... Furthermore, the faster growing southern species will be initially rare and must spread, perhaps across considerable distances or from initially scattered localities. Thus, the replacement of forest (southern types replacing northern types) will be an inherently slow process (several to many hundreds of years).

In summing up the significance of this situation, Loehle says “forests will not suffer catastrophic dieback due to increased temperatures but will rather be replaced gradually by faster growing types.”

Another possibility that must be seriously considered is that northern or high-altitude forests will not be replaced at all by southern or low-altitude forests in a warming world. Rather, the two forest types may merge, creating entirely new forests of greater species diversity, such as those that existed during the warmer Tertiary Period of the Cenozoic Era, when in the western United States many montane taxa regularly grew among mixed conifers and broadleaf sclerophylls (Axelrod 1944a, 1944b, 1956, 1987), creating what could well be called super forest ecosystems, which Axelrod (1988) has described as “much richer than any that exist today.”

Possibly helping warmer temperatures to produce this unique biological phenomenon during the

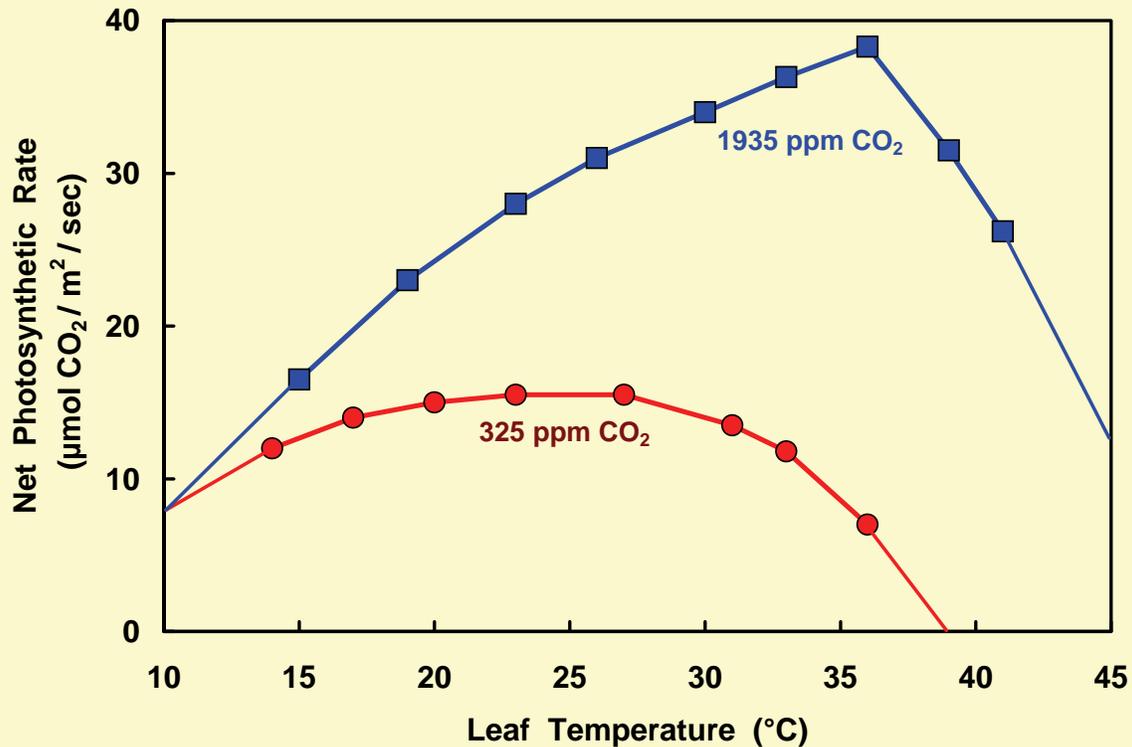

Tertiary were the higher atmospheric CO<sub>2</sub> concentrations of that period (Volk, 1987), as has been suggested by Idso (1989). As documented extensively in Chapter 7, elevated concentrations of atmospheric CO<sub>2</sub> significantly stimulate plant growth rates (Kimball, 1983)—especially those of trees (Saxe *et al.*, 1998; Idso and Kimball, 2001)—and they also greatly enhance water use efficiency (Feng, 1999). Even more important, however, is how atmospheric CO<sub>2</sub> enrichment alters plant photosynthetic and growth responses to rising temperatures.

It has long been known that photo-respiration—which can “cannibalize” as much as 40 percent to 50 percent of the recently produced photosynthetic products of C<sub>3</sub> plants (Wittwer, 1988)—becomes increasingly more pronounced as air temperature rises (Hanson and Peterson, 1986). It also has been established that photorespiration is increasingly more inhibited as the air’s CO<sub>2</sub> content rises (Grodzinski *et al.*, 1987). Hence, there is a greater potential for rising CO<sub>2</sub> concentrations to benefit C<sub>3</sub> plants at higher temperatures, as was demonstrated by the early experimental work of Idso *et al.* (1987) and Mortensen (1987), as well as by the theoretical work of Gifford (1992), Kirschbaum (1994) and Wilks *et al.* (1995). In an analysis of 42 experimental datasets collected by numerous scientists, Idso and Idso (1994) showed that the mean growth enhancement due to a 300-ppm increase in atmospheric CO<sub>2</sub> concentration rises from close to zero at an air temperature of 10°C to 100 percent (doubled growth) at approximately 38°C, while at higher temperatures the growth stimulation rises higher still, as also has been shown by Cannell and Thornley (1998).

Several studies have additionally demonstrated that atmospheric CO<sub>2</sub> enrichment tends to alleviate high-temperature stress in plants (Faria *et al.*, 1996; Nijs and Impens, 1996; Vu *et al.*, 1997); and it has been proven that at temperatures that are high enough to cause plants to die, atmospheric CO<sub>2</sub> enrichment can sometimes preserve their lives (Idso *et al.*, 1989; Idso, 1995; Baker *et al.*, 1992; Rowland-Bamford *et al.*, 1996; Taub *et al.*, 2000), just as it can often stave off their demise in the very dry conditions that typically accompany high air temperatures (Tuba *et al.*, 1998; Hamerlynck, *et al.*, 2000; Polley *et al.*, 2002).

### Box 1: The CO<sub>2</sub>-Temperature-Growth Interaction

The growth-enhancing effects of elevated CO<sub>2</sub> typically increase with rising temperature. This phenomenon is illustrated by the data of Jurik *et al.* (1984), who exposed bigtooth aspen leaves to atmospheric CO<sub>2</sub> concentrations of 325 and 1,935 ppm and measured their photosynthetic rates at a number of different temperatures. In the figure below, we have reproduced their results and slightly extended the two relationships defined by their data to both warmer and cooler conditions.

At 10°C, elevated CO<sub>2</sub> has essentially no effect on net photosynthesis in this particular species, as Idso and Idso (1994) have demonstrated is characteristic of plants in general. At 25°C, however, where the net photosynthetic rate of the leaves exposed to 325 ppm CO<sub>2</sub> is maximal, the extra CO<sub>2</sub> of this study boosts the net photosynthetic rate of the foliage by nearly 100 percent; and at 36°C, where the net photosynthetic rate of the leaves exposed to 1,935 ppm CO<sub>2</sub> is maximal, the extra CO<sub>2</sub> boosts the net photosynthetic rate of the foliage by a whopping 450 percent. The extra CO<sub>2</sub> increases the optimum temperature for net photosynthesis in this species by about 11°C, from 25°C in air of 325 ppm CO<sub>2</sub> to 36°C in air of 1,935 ppm CO<sub>2</sub>.

In viewing the warm-temperature projections of the two relationships, it can also be seen that the transition from positive to negative net photosynthesis—which denotes a change from life-sustaining to life-depleting conditions—likely occurs somewhere in the vicinity of 39°C in air of 325 ppm CO<sub>2</sub> but somewhere in the vicinity of 50°C in air of 1,935 ppm CO<sub>2</sub>. Hence, not only was the optimum temperature for the growth of bigtooth aspen greatly increased by the extra CO<sub>2</sub> of this experiment, so too was the temperature above which life cannot be sustained increased, and by about the same amount, i.e., 11°C.

A major consequence of these facts is that the optimum temperature ( $T_{opt}$ ) for plant growth—the temperature at which plants photosynthesize and grow best—generally rises with atmospheric CO<sub>2</sub> enrichment (Berry and Bjorkman, 1980; Taiz and Zeiger, 1991). An example of this phenomenon is presented in Box 1, where it can be seen that the increase in atmospheric CO<sub>2</sub> concentration utilized in this particular study increases the optimum temperature for photosynthesis in this species from a

broad maximum centered at 25°C in ambient air to a well-defined peak at about 36°C in CO<sub>2</sub>-enriched air.

How much is plant optimum temperature typically increased by an extra 300 ppm of CO<sub>2</sub>? Based largely on theoretical considerations, Long (1991) calculated that such an increase in the air's CO<sub>2</sub> concentration should increase  $T_{opt}$ , in the mean, by about 5°C, while McMurtrie and Wang (1993) calculated the increase at somewhere between 4° and 8°C.

The implication of the finding that plant optimum temperature rises so dramatically in response to increasing atmospheric CO<sub>2</sub> concentration is that if the planet were to warm in response to the ongoing rise in the air's CO<sub>2</sub> content—even to the degree predicted by the worst-case scenario of the IPCC (6.4°C by 2100)—the vast majority of earth's plants would likely not need to migrate towards cooler parts of the globe. Any warming would provide them an opportunity to move into regions that were previously too cold for them, but it would not force them to move, even at the hottest extremes of their ranges; for as the planet warmed, the rising atmospheric CO<sub>2</sub> concentration would significantly increase the temperatures at which most of earth's C<sub>3</sub> plants—which comprise fully 95 percent of the planet's vegetation (Drake, 1992)—function best, creating a situation where earth's plant life would actually prefer warmer conditions.

With respect to the C<sub>4</sub> and CAM plants that make up the remaining 5 percent of earth's vegetative cover, most of them are endemic to the planet's hotter environments (De Jong *et al.*, 1982; Drake, 1989; Johnson *et al.*, 1993), which according to the IPCC are expected to warm much less than the cooler regions of the globe. Hence, the planet's C<sub>4</sub> and CAM plants would not face as great a thermal challenge as earth's C<sub>3</sub> plants in a warming world. Nevertheless, the work of Chen *et al.* (1994) suggests they too may experience a modest increase in their optimum temperatures as the air's CO<sub>2</sub> content rises (a 1.5°C increase in response to a 350-ppm increase in atmospheric CO<sub>2</sub> concentration). Consequently, and in view of the non-CO<sub>2</sub>-related abilities of earth's vegetation to adapt to rising temperatures discussed in the previous section, plants of all photosynthetic persuasions should be able to successfully adapt to any future warming that could be caused by the enhanced greenhouse effect. So obvious is this conclusion, in fact, that Cowling (1999) has bluntly stated, “maybe we should be less concerned about rising CO<sub>2</sub> and rising temperatures and more worried about the possibility that future atmospheric CO<sub>2</sub> will suddenly stop increasing, while global temperatures continue rising.”

James Hansen, in testimony to a U.S. House of Representatives committee, has claimed that life in alpine regions is “in danger of being pushed off the planet” because of rising temperatures. In July and August 2003, a team of three researchers investigated this scenario by resurveying the floristic composition of the uppermost 10 meters of 10 mountain summits

in the Swiss Alps (Walther *et al.*, 2005), applying the same methodology used in earlier surveys that were conducted there in 1905 (Rubel, 1912) and 1985 (Hofer, 1992). This analysis covered the bulk of the Little Ice Age-to-Current Warm Period transition, and it revealed that plants of many species had indeed marched up the sides of the mountains, as the earth in general—and the Swiss Alps in particular—had warmed. Of even greater significance, however, was the fact that not a single mountaintop species was “pushed off the planet.” Between 1905 and 1985 the mean number of species observed on the 10 mountaintops rose by 86 percent, while by 2003 it had risen by 138 percent, providing, in the words of the researchers who conducted the work, “an enrichment of the overall summit plant diversity.”

Another research team studied the same phenomenon on 12 mountaintops in the Swiss Alps (Holzinger *et al.*, 2008), making complete inventories of vascular plant species that were present there in 2004, while following—“as accurately as possible,” in their words—the same ascension paths used by other researchers in 1885, 1898, 1912, 1913, and 1958, after which they compared their findings with those of the earlier studies. By these means, they detected upward plant migration rates on the order of several meters per decade, which phenomena increased vascular plant species richness at the mountains' summits by 11 percent per decade over the 120-year study period. This finding, in their words, “agrees well with other investigations from the Alps, where similar changes have been detected,” and they cited, in this regard, four additional studies (Grabherr *et al.*, 1994; Pauli *et al.*, 2001; Camenisch, 2002; Walther, 2003).

Another pertinent study was conducted by a researcher who analyzed altitudinal shifts in the ranges of alpine and subalpine plants in the mountains of west-central Sweden (Kullman, 2002), where air temperature had risen approximately 1°C over the past hundred years. This work revealed that since the early twentieth century, alpine and subalpine plants had migrated upslope by an average of 200 m. Most importantly, it also indicated, according to the scientist who did the work, that “no species have yet become extinct from the highest elevations,” which finding was said by the researcher to “converge with observations in other high-mountain regions worldwide,” in support of which statement five more new studies were cited (Keller *et al.*, 2000; Kullman, 2002; Klanderud and Birks, 2003; Virtanen *et al.*, 2003; Lacoul and Freedman, 2006).

In light of these many real-world findings, it is clear that warmer temperatures have not led to an increase in plant extinctions, and in fact have led to the opposite effect: greater plant growth and diversity in larger areas of the globe. Nor did the warming of the past century—which the IPCC claims was unprecedented over the past millennium—push any upward-migrating plants “off the planet” at the tops of its mountains. One of the most highly promoted hypothetical scenarios of the IPCC is contradicted by real-world data.

### 8.3. Coral Reefs

According to the IPCC, “many studies incontrovertibly link coral bleaching to warmer sea surface temperature ... and mass bleaching and coral mortality often results beyond key temperature thresholds” (IPCC 2007-II, p. 235). “Modelling,” the IPCC goes on to say, “predicts a phase switch to algal dominance on the Great Barrier Reef and Caribbean reefs in 2030 to 2050.” The IPCC further claims that “coral reefs will also be affected by rising atmospheric CO<sub>2</sub> concentrations ... resulting in declining calcification” (Ibid.).

In the following pages we review the scientific literature on coral reefs in an effort to determine if the ongoing rise in the air’s CO<sub>2</sub> content, rising temperatures, or rising sea levels pose a threat to

these incomparable underwater ecosystems. Because the fate of the earth's corals has become so prominent in the debate over climate change and because our findings are so entirely at odds with those of the IPCC, we present a brief summary of our key findings here:

- There is no simple linkage between high temperatures and coral bleaching.
- As living entities, corals are not only acted upon by the various elements of their environment, they also react or respond to them. And when changes in environmental factors pose a challenge to their continued existence, they sometimes take major defensive or adaptive actions to ensure their survival.
- A particularly ingenious way coral respond to environmental stress is to replace the zooxanthellae expelled by the coral host during a stress-induced bleaching episode by one or more varieties of zooxanthellae that are more tolerant of the stress that caused the bleaching.
- The persistence of coral reefs through geologic time—when temperatures were as much as 10°-15°C warmer than at present, and atmospheric CO<sub>2</sub> concentrations were two to seven times higher than they are currently—provides substantive evidence that these marine entities can successfully adapt to a dramatically changing global environment. Thus, the recent die-off of many corals cannot be due solely, or even mostly, to global warming or the modest rise in atmospheric CO<sub>2</sub> concentration over the course of the Industrial Revolution.
- The 18- to 59-cm warming-induced sea-level rise that is predicted for the coming century by the IPCC—which could be greatly exaggerated if predictions of CO<sub>2</sub>-induced global warming are wrong—falls well within the range (2 to 6 mm per year) of typical coral vertical extension rates, which exhibited a modal value of 7 to 8 mm per year during the Holocene and can be more than double that value in certain branching corals. Rising sea levels should therefore present no difficulties for coral reefs. In fact, rising sea levels may have a positive effect on reefs, permitting increased coral growth in areas that have already reached the upward limit imposed by current sea levels.

- The rising CO<sub>2</sub> content of the atmosphere may induce changes in ocean chemistry (pH) that could slightly reduce coral calcification rates; but potential positive effects of hydrospheric CO<sub>2</sub> enrichment may more than compensate for this modest negative phenomenon.
- Theoretical predictions indicate that coral calcification rates should decline as a result of increasing atmospheric CO<sub>2</sub> concentrations by as much as 40 percent by 2100. However, real-world observations indicate that elevated CO<sub>2</sub> and elevated temperatures are having the opposite effect.

### 8.3.1. Indirect Threats

Coral bleaching ranks as probably the most frequently cited indirect negative consequence believed to result from CO<sub>2</sub>-induced global warming. It is a phenomenon that is characterized by a loss of color in certain reef-building corals that occurs when the algal symbionts, or *zooxanthellae*, living within the host corals are subjected to various stresses and expelled from them, resulting in a loss of photosynthetic pigments from the coral colony. If the stress is mild, or short in duration, the affected corals often recover and regain their normal complement of zooxanthellae. However, if the stress is prolonged, or extreme, the corals eventually die, being deprived of their primary food source.

We begin our review of the subject by discussing the many suspected causes of coral bleaching, almost all of which have been attributed (often implausibly) to CO<sub>2</sub>-induced global warming. Then, we examine the possibility that corals can adapt to the various environmental threats they face, after which we explore whether the widespread bleaching events seen in recent decades are indeed caused by global warming. We conclude our discussion of the major

indirect threats facing modern coral reefs by examining the threat of rising sea levels, which the IPCC predicts will occur over the course of the twenty-first century.

### 8.3.1.1. Coral Bleaching

#### 8.3.1.1.1. Temperature Effects

One of the most frequently cited causes of coral bleaching is anomalously high water temperature (Linden, 1998). The origin of this attribution can be traced to the strong El Niño event of 1982-83, in which widespread bleaching was reported in corals exposed to unusually high surface water temperatures (Glynn, 1988). Since that time, a number of other such observations have been made (Cook *et al.*, 1990; Glynn 1991; Montgomery and Strong, 1994; Brown *et al.*, 1996); and several laboratory studies have demonstrated that elevated seawater temperatures can indeed induce bleaching in corals (Hoegh-Guldberg and Smith, 1989; Jokiel and Coles, 1990; Glynn and D’Croz, 1990).

However, just as anomalously high seawater temperatures have been found to be correlated with coral reef bleaching events, so too have anomalously low seawater temperatures been identified with this phenomenon (Walker *et al.*, 1982; Coles and Fadlallah, 1990; Muscatine *et al.*, 1991; Gates *et al.*, 1992; Saxby *et al.*, 2003; Hoegh-Guldberg and Fine 2004; Yu *et al.*, 2004). These observations suggest that the crucial link between temperature and coral reef bleaching may not reside in the absolute temperature of the water surrounding the corals, but in the rapidity with which the temperature either rises above or falls below the temperature regime to which the corals are normally adapted. Winter *et al.* (1998), for example, studied relationships between coral bleaching and nine different temperature indices, concluding that although “prolonged heat stress may be an important precondition for bleaching to occur,” sharp temperature changes act as the “immediate trigger.”

In a related study, Jones (1997) reported coral bleaching on a portion of Australia’s Great Barrier Reef just after average daily sea water temperature rose by 2.5°C over the brief period of eight days. Likewise, Kobluk and Lysenko (1994) observed severe coral bleaching following an 18-hour *decline* of 3°C in seawater temperature. Because the corals studied by the latter researchers had experienced

massive bleaching two years earlier as a result of an anomalous 4°C *increase* in water temperature, the authors concluded that coral bleaching is more a function the rapidity of a temperature change than it is of the absolute magnitude or sign of the change, i.e., heating or cooling.

Further evidence that high or low seawater temperatures *per se* are not the critical factors in producing coral bleaching is provided by Podesta and Glynn (1997), who examined a number of temperature-related indices of surface waters in the vicinity of Panama over the period 1970-1994. Their analysis revealed that for the two years of highest maximum monthly sea surface temperature, 1972 and 1983, coral bleaching was reported only in 1983, while 1972 produced no bleaching whatsoever, in spite of the fact that water temperatures that year were just as high as they were in 1983.

### 8.3.1.1.2. Solar Radiation Effects

The link between solar radiation and coral reef bleaching goes back more than a century to when MacMunn (1903) postulated that ultraviolet radiation could be potentially damaging to corals. It wasn't until half a century later, however, that scientists began to confirm this suspicion (Catala-Stucki, 1959; Siebeck, 1988; Gleason and Wellington, 1995).

Many investigators of the solar irradiance-coral reef bleaching link have studied the phenomenon by transplanting reef corals from deep to shallow waters. Gleason and Wellington (1993), for example, transplanted samples of the reef-building coral *Montastrea annularis* from a depth of 24 meters to depths of 18 and 12 meters. Using sheets of acrylic plastic to block out ultraviolet radiation on some of the coral samples, they found that the shielded corals experienced less bleaching than the unshielded corals, and that the unshielded corals at the 12-meter depth had significantly lower amounts of zooxanthellae and chlorophyll per square centimeter than all other treatment and control groups. Likewise, Hoegh-Guldberg and Smith (1989) reported bleaching in the corals *Stylophora pistillata* and *Seriatopora hystrix* when they were moved from a depth of 6 meters to 1.2 meters. Vareschi and Fricke (1986) obtained similar results when moving *Plerogyra sinuosa* from a depth of 25 meters to 5 meters. As in the case of temperature stress, however, Glynn (1996) notes that artificially reduced light levels also have been observed to cause coral bleaching.

A number of laboratory studies have provided additional evidence for a link between intense solar irradiance and coral reef bleaching, but identifying a specific wavelength or range of wavelengths as the cause of the phenomenon has been a difficult task. Fitt and Warner (1995), for example, reported that the most significant decline in symbiont photosynthesis in the coral *Montastrea annularis* occurred when it was exposed to ultraviolet and blue light; but other studies have reported coral bleaching to be most severe at shorter ultraviolet wavelengths (Droller *et al.*, 1994; Gleason and Wellington, 1995). Still others have found it to be most strongly expressed at longer

photosynthetically active wavelengths (Lesser and Shick, 1989; Lesser *et al.*, 1990; Brown *et al.*, 1994).

As additional studies provided evidence for a solar-induced mechanism of coral reef bleaching (Brown *et al.*, 1994; Williams *et al.*, 1997; Lyons *et al.*, 1998), some also provided evidence for a solar radiation-temperature stress synergism (Gleason and Wellington, 1993; Rowan *et al.*, 1997; Jones *et al.*, 1998). There have been a number of situations, for example, in which corals underwent bleaching when changes in both of these parameters combined to produce particularly stressful conditions (Lesser *et al.*, 1990; Glynn *et al.*, 1992; Brown *et al.*, 1995), such as during periods of low wind velocity and calm seas, which favor the intense heating of shallow waters and concurrent strong penetration of solar radiation.

This two-parameter interaction has much to recommend it as a primary cause of coral bleaching. It is, in fact, the mechanism favored by Hoegh-Guldberg (1999), who claimed—in one of the strongest attempts made to that point in time to portray global warming as the cause of bleaching in corals—that “coral bleaching occurs when the photosynthetic symbionts of corals (zooxanthellae) become increasingly vulnerable to damage by light at higher than normal temperatures.” As we shall see, however, the story is considerably more complicated.

#### 8.3.1.1.3. Other Causes

In a review of the causes of coral bleaching, Brown (1997) listed (1) elevated seawater temperature, (2) decreased seawater temperature, (3) intense solar radiation, (4) the combination of intense solar radiation and elevated temperature, (5) reduced salinity, and (6) bacterial infections. In a similar review, Meehan and Ostrander (1997) additionally listed (7) increased sedimentation and (8) exposure to toxicants. We have already commented on the four most prominent of these phenomena; we now address the remaining four.

With respect to seawater salinity, Meehan and Ostrander (1997) noted that, as with temperature, both high and low values have been observed to cause coral bleaching. Low values typically occur as a result of seawater dilution caused by high precipitation events or storm runoff; high values are much more rare, typically occurring only in the vicinity of desalination plants.

A number of studies also have clearly delineated the role of bacterial infections in causing coral reef bleaching (Ritchie and Smith, 1998); this phenomenon, too, may have a connection to high seawater temperatures. In a study of the coral *Oculina patagonica* and the bacterial agent *Vibrio* AK-1, for example, Kushmaro *et al.* (1996, 1997) concluded that bleaching of colonies of this coral along the Mediterranean coast has its origin in bacterial

infection, and that warmer temperatures may lower the resistance of the coral to infection and/or increase the virulence of the bacterium. In subsequent studies of the same coral and bacterium, Toren *et al.* (1998) and Kushmaro *et al.* (1998) further demonstrated that this high temperature effect may operate by enhancing the ability of the bacterium to adhere to the coral.

In discussing their findings, Kushmaro *et al.* (1998) commented on the “speculation that increased seawater temperature, resulting from global warming or El Niño events, is the direct cause of coral bleaching.” In contradiction of this presumption, they cited several studies of coral bleaching events that were not associated with any major sea surface temperature anomalies, and they explicitly stated, “it is not yet possible to determine conclusively that bleaching episodes and the consequent damage to reefs is due to global climate change.” Likewise, Toren *et al.* (1998) noted the extensive bleaching that occurred on the Great Barrier Reef during the summer of 1982 was also not associated with any major sea surface temperature increase; they stated, “several authors have reported on the patchy spatial distribution and spreading nature of coral bleaching,” which they correctly noted is inconsistent with the global-warming-induced coral bleaching hypothesis. Instead, they noted, “the progression of observable changes that take place during coral bleaching is reminiscent of that of developing microbial biofilms,” a point that will later be seen to be of great significance.

With respect to sedimentation, high rates have been conclusively demonstrated to lead to coral bleaching (Wesseling *et al.*, 1999); most historical increases in sedimentation rates are clearly human-induced. Umar *et al.* (1998), for example, listed such contributing anthropogenic activities as deforestation, agricultural practices, coastal development, construction, mining, drilling, dredging, and tourism. Nowlis *et al.* (1997) also discussed “how land development can increase the risk of severe damage to coral reefs by sediment runoff during storms.” But it has been difficult to determine just how much these phenomena have varied over the past few centuries.

Knowledge in this area took a quantum leap forward with the publication of a study by McCulloch *et al.* (2003) that provided a 250-year record of sediment transfer to Havannah Reef—a site on the inner Great Barrier Reef of northern Queensland, Australia—by flood plumes from the Burdekin River. According to the authors of that study, sediments

suspended in the Burdekin River contain barium (Ba), which is desorbed from the particles that carry it as they enter the ocean, where growing corals incorporate it into their skeletons along with calcium (Ca). Hence, when more sediments are carried to the sea by periodic flooding and more gradual longer-term changes in land use that lead to enhanced soil erosion, the resultant increases in sediment load are recorded in the Ba/Ca ratio of coral skeleton material. Inspired by these facts, McCulloch *et al.* measured Ba/Ca ratios in a 5.3-meter-long coral core from Havannah Reef that covered the period from about 1750 to 1985, as well as in some shorter cores from Havannah Reef and nearby Pandora Reef that extended the proxy sediment record to 1998.

Results of the analysis revealed that prior to the time of European settlement, which began in the Burdekin catchment in 1862, there was “surprisingly little evidence for flood-plume related activity from the coral Ba/Ca ratios.” Soon after, however, land clearance and domestic grazing intensified and the soil became more vulnerable to monsoon-rain-induced erosion. By 1870, baseline Ba/Ca ratios had risen by 30 percent and “within one to two decades after the arrival of European settlers in northern Queensland, there were already massive impacts on the river catchments that were being transmitted to the waters of the inner Great Barrier Reef.” During subsequent periods of flooding, in fact, the transport of suspended sediment to the reef increased by fully five- to ten-fold over what had been characteristic of pre-European settlement times.

In a companion article, Cole (2003) reported that corals from East Africa “tell a similar tale of erosion exacerbated by the imposition of colonial agricultural practices in the early decades of the twentieth century.” There, similar coral data from Malindi Reef, Kenya, indicate “a low and stable level of barium before about 1910 which rises dramatically by 1920, with a simultaneous increase in variance,” a phenomenon that was also evident in the Australian data.

What are the implications of these observations? Cole concludes that “human activity, in the form of changing land use, has added sedimentation to the list of stresses experienced by reefs.” Furthermore, as land-use intensification is a widespread phenomenon, she notes that “many reefs close to continents or large islands are likely to have experienced increased delivery of sediment over the past century,” which suggests the stress levels produced by this phenomenon are likely to have increased over the past

century as well. In addition, Cole logically concludes that as coastal populations continue to rise, “this phenomenon is likely to expand.”

Lastly, a number of poisonous substances are known to have the capacity to induce coral bleaching. Some of them are of human origin, such as herbicides, pesticides, and even excess nutrients that make their way from farmlands to the sea (Simkiss, 1964; Pittock, 1999). Other poisons originate in the sea itself, many the result of metabolic waste products of other creatures (Crossland and Barnes, 1974) and some a by-product of the coral host itself (Yonge, 1968). Each of these toxicants presents the coral community with its own distinct challenge.

Taken together, these findings suggest a number of sources of stress on coral survival and growth that have little or nothing to do with rising CO<sub>2</sub> concentrations or temperatures. It is also clear that human population growth and societal and economic development over the period of the Industrial Revolution have predisposed coral reefs to ever-increasing incidences of bleaching and subsequent mortality via a gradual intensification of near-coastal riverine sediment transport rates.

### 8.3.1.2. Adaptation

Considering the many threats to the health of coral reefs in today's world of extensive socioeconomic and environmental change, how can these incomparable repositories of underwater biodiversity be expected to escape irreversible bleaching and death? In response to this question, Glynn (1996) pointed out that "numerous reef-building coral species have endured three periods of global warming, from the Pliocene optimum (4.3-3.3 million years ago) through the Eemian interglacial (125 thousand years ago) and the mid-Holocene (6000-5000 years ago), when atmospheric CO<sub>2</sub> concentrations and sea temperatures often exceeded those of today." In fact, Glynn observed that "an increase in sea warming of less than 2°C would result

in a greatly increased diversity of corals in certain high latitude locations."

How does this happen? Living organisms are resilient. Various lifeforms can tolerate temperatures from below freezing to the boiling point of water; others inhabit niches where light intensity varies from complete darkness to full sunlight. One reason for this great versatility is that, given time to adapt, nearly all living organisms can learn to survive in conditions well outside their normal zones of environmental tolerance. As noted by Gates and Edmunds (1999), results of numerous studies indicate that "corals routinely occupy a physically heterogeneous environment," which "suggests they should possess a high degree of biological flexibility." And indeed they do, as evidenced by their successful responses to the different threats that cause coral bleaching, which are examined in the following subsections.

### 8.3.1.2.1. Response to Solar Radiation Stress

One example of adaptation to stress imposed by high solar irradiance comes from studies of corals that exhibit a "zonation" of their symbiont taxa with depth, where symbiont algae that are less tolerant of intense solar radiation grow on corals at greater depths below the ocean surface (Rowan and Knowlton, 1995; Rowan *et al.*, 1997). It has also been demonstrated that zooxanthellae in corals possess a number of light-quenching mechanisms that can be employed to reduce the negative impacts of excess light (Hoegh-Guldberg and Jones, 1999; Ralph *et al.*, 1999). Both the coral host and its symbionts also have the capacity to produce amino acids that act as natural "sunscreens" (Hoegh-Guldberg, 1999); and they can regulate their enzyme activities to enhance internal scavenging systems that remove noxious oxygen radicals produced in coral tissues as a result of high light intensities (Dyken and Shick, 1984; Lesser *et al.*, 1990; Matta and Trench, 1991; Shick *et al.*, 1996).

Another adaptive mechanism to lessen the stress of solar irradiance is coral tissue retraction, according to Brown *et al.* (1994), who studied the phenomenon in the scleractinian coral *Coeloseris mayeri* at coral reefs in Phuket, Thailand by examining the retraction and recovery of coral tissues over a tidal cycle. Results of their analysis showed that extreme tissue retraction was observed approximately 85 minutes after initial sub-aerial coral exposure. Tissue retraction, however, did not involve any reduction in chlorophyll concentration or algae symbiont abundance; the tissues expanded over the coral skeletons to pre-retraction conditions following the return of the tide. The adaptive benefits of tissue retraction, according to the authors, “include increased albedo, leading to a reduction in absorbed solar energy of 10%, ... and possible avoidance of photochemical damage or photoinhibition at high solar irradiance.”

Another intriguing idea was proposed by Nakamura and van Woesik (2001), who upon evaluating the bleaching of large and small coral colonies along the western coast of Okinawa, Japan during the summers of 1998 and 2001, argued that small coral colonies should survive thermal and light stress more readily than large coral colonies based on mass transfer theory, which suggests that rates of passive diffusion are more rapid for small colonies than for large colonies. Still another reason why large coral colonies suffer more than small colonies during environmental conditions conducive to bleaching is the fact that small *Acropora* recruits, according to Bena and van Woesik (2004), “contain high concentrations of fluorescent proteins (Papina *et al.*, 2002), which have photoprotective properties (Salih *et al.*, 2000),” and they note that “a high concentration of photoprotective pigments in early life, when planulae are near the surface and as newly settled recruits, may facilitate survival during this phase as well as during stress events involving both high irradiance and thermal anomalies (van Woesik, 2000).”

In addition to the adaptive phenomena described above, the earth appears to possess a natural “heat vent” over the tropics that suppresses the intensity of solar radiation to which corals are exposed whenever dangerously high water temperatures are approached. According to Hoegh-Guldberg (1999), 29.2°C is the threshold water temperature above which significant bleaching can be expected to occur in many tropical corals. However, as Sud *et al.* (1999) have demonstrated, deep atmospheric convection is

typically initiated whenever sea surface temperatures (SSTs) reach a value of about 28°C, so that an upper SST on the order of 30°C is rarely exceeded. As SSTs reach 28-29°C, the cloud-base airmass is charged with sufficient moist static energy for the clouds to reach the upper troposphere. At this point, the billowing cloud cover reduces the amount of solar radiation received at the surface of the sea, while cool and dry downdrafts produced by the moist convection tend to promote ocean surface cooling by increasing sensible and latent heat fluxes at the air-sea interface that cause temperatures there to decline. This “thermostat-like control,” as Sud *et al.* describe it, tends “to ventilate the tropical ocean efficiently and help contain the SST between 28-30°C,” which is essentially a fluctuating temperature band of  $\pm 1^\circ\text{C}$  centered on the bleaching threshold temperature of 29.2°C identified by Hoegh-Guldberg.

Some other intriguing observations also point to the existence of a natural phenomenon of this nature. Satheesh and Ramanathan (2000), for example, determined that polluted air from south and southeast Asia absorbs enough solar radiation over the northern Indian Ocean during the dry monsoon season to heat the atmosphere there by 1-3°C per day at solar noon, thereby greatly reducing the intensity of solar radiation received at the surface of the sea. Ackerman *et al.* (2000), however, calculated that this atmospheric heating would decrease cloud-layer relative humidity and reduce boundary-layer mixing, thereby leading to a 25 percent to 50 percent drop in daytime cloud cover relative to that of an aerosol-free atmosphere, which could well negate the surface cooling effect suggested by the findings of Satheesh and Ramanathan. But in a test of this hypothesis based on data obtained from the Extended Edited Cloud Report Archive, Norris (2001) determined that daytime low-level ocean cloud cover (which tends to cool the water surface) not only did not decrease from the 1950s to 1990s, it actually increased ... in both the Northern and Southern Hemispheres and at essentially all hours of the day.

Commenting on this finding, Norris remarked that “the observed all-hours increase in low-level cloud cover over the time period when soot aerosol has presumably greatly increased argues against a dominant effect of soot solar absorption contributing to cloud ‘burn-off’.” Hence, he says, “other processes must be compensating,” one of which, we suggest, could be the one described by Sud *et al.*

Another process is the “adaptive infrared iris” phenomenon described by Lindzen *et al.* (2001).

Working with upper-level cloudiness data obtained from the Japanese Geostationary Meteorological Satellite and SST data obtained from the National Centers for Environmental Prediction, the atmospheric scientists found a strong inverse relationship between upper-level cloud area and the mean SST of cloudy regions, such that the area of cirrus cloud coverage (which tends to warm the planet) normalized by a measure of the area of cumulus coverage (which tends to cool the planet) decreased about 22 percent for each 1°C increase in the SST of the cloudy regions.

“Essentially,” in the words of the scientists, “the cloudy-moist region appears to act as an infrared adaptive iris that opens up and closes down the regions free of upper-level clouds, which more effectively permit infrared cooling, in such a manner as to resist changes in tropical surface temperatures.” So substantial is this phenomenon, Lindzen *et al.* are confident it could “more than cancel all the positive feedbacks in the more sensitive current climate models,” which are routinely used to predict the climatic consequences of projected increases in atmospheric CO<sub>2</sub> concentration.

Is there any real-world evidence the natural thermostat discovered by Sud *et al.* and Lindzen *et al.* has actually been instrumental in preventing coral bleaching? Mumby *et al.* (2001) examined long-term meteorological records from the vicinity of the Society Islands, which provide what they call “the first empirical evidence that local patterns of cloud cover may influence the susceptibility of reefs to mass bleaching and subsequent coral mortality during periods of anomalously high SST.” With respect to the great El Niño of 1998, Mumby and his colleagues determined that SSTs in the Society Islands sector of French Polynesia were above the 29.2°C bleaching threshold for a longer period of time (two months) than in all prior bleaching years of the historical record. However, mass coral bleaching, which was extensive in certain other areas, was found to be “extremely mild in the Society Islands” and “patchy at a scale of 100s of km.” What provided the coral relief from extreme sun and heat? As Mumby and his associates describe it, “exceptionally high cloud cover significantly reduced the number of sun hours during the summer of 1998,” much as one would have expected earth’s natural thermostat to have done in the face of such anomalously high SSTs. The marine scientists also note that extensive spotty patterns of cloud cover, besides saving most of the coral they studied, “may partly account for spatial patchiness in

bleaching intensity and/or bleaching-induced mortality in other areas.”

In conclusion, although the natural thermostat cannot protect all of earth’s corals from life-threatening bleaching during all periods of anomalously high SSTs, it apparently protects enough of them enough of the time to ensure that sufficiently large numbers of corals survive to perpetuate their existence, since living reefs have persisted over the eons in spite of the continuing recurrence of these ever-present environmental threats. And perhaps that is how it has always been, although there are currently a host of unprecedented anthropogenic forces of site-specific origin that could well be weakening the abilities of some species to tolerate the types of thermal and solar stresses they have successfully “weathered” in the past.

### 8.3.1.2.2. Response to Temperature Stress

As living entities, corals are not only acted upon by the various elements of their environment, they also react or respond to them. And when changes in environmental factors pose a challenge to their continued existence, they sometimes take major defensive or adaptive actions to ensure their survival. A simple but pertinent example of one form of this phenomenon is thermal adaptation, which feature has been observed by several researchers to operate in corals.

Fang *et al.* (1997), for example, experimented with samples of the coral *Acropora grandis* that were taken from the hot water outlet of a nuclear power plant near Nanwan Bay, Taiwan. In 1988, the year the power plant began full operation, the coral samples were completely bleached within two days of exposure to a temperature of 33°C. Two years later, however, Fang *et al.* report that “samples taken from the same area did not even start bleaching until six days after exposure to 33°C temperatures.”

Similar findings have been reported by Middlebrook *et al.* (2008), who collected multiple upward-growing branch tips of the reef-building coral *Acropora aspera* from three large colonies at the southern end of Australia's Great Barrier Reef and placed them on racks immersed in running seawater within four 750-liter tanks that were maintained at the mean local ambient temperature (27°C) and exposed to natural reef-flat summer daily light levels. Then, two weeks prior to a simulated bleaching event—where water temperature was raised to a value of 34°C for a period of six days—they boosted the water temperature in one of the tanks to 31°C for 48 hours, while in another tank they boosted it to 31°C for 48 hours one week before the simulated bleaching event. In the third tank they had no pre-heating treatment, while in the fourth tank they had no pre-heating nor any simulated bleaching event. And at different points throughout the study, they measured photosystem II efficiency, xanthophyll and chlorophyll *a* concentrations, and *Symbiodinium* densities.

Results of the study indicated that the symbionts of the corals that were exposed to the 48-hour pre-bleaching thermal stress “were found to have more effective photoprotective mechanisms,” including

“changes in non-photochemical quenching and xanthophyll cycling,” and they further determined that “these differences in photoprotection were correlated with decreased loss of symbionts, with those corals that were not pre-stressed performing significantly worse, losing over 40% of their symbionts and having a greater reduction in photosynthetic efficiency,” whereas “pre-stressed coral symbiont densities were unchanged at the end of the bleaching.” In light of these findings, Middlebrook *et al.* say their study “conclusively demonstrates that thermal stress events two weeks and one week prior to a bleaching event provide significantly increased thermal tolerance to the coral holobiont, suggesting that short time-scale thermal adaptation can have profound effects on coral bleaching.”

Moving out of the laboratory and into the real world of nature, Adjeroud *et al.* (2005) initiated a monitoring program on 13 islands (eight atolls and five high volcanic islands) in four of the five archipelagoes of French Polynesia, with the goal of documenting the effects of natural perturbations on coral assemblages. For the period covered by their report (1992-2002), these reefs were subjected to three major coral bleaching events (1994, 1998, 2002) and three cyclones (1997), while prior to this period, the sites had experienced an additional seven bleaching events and 15 cyclones, as well as several *Acanthaster planci* outbreaks.

Results of the monitoring program revealed that the impacts of the bleaching events were variable among the different study locations. In their 10-year survey, for example, they observed three different temporal trends: “(1) ten sites where coral cover decreased in relation to the occurrence of major disturbances; (2) nine sites where coral cover increased, despite the occurrence of disturbances affecting seven of them; and (3) a site where no significant variation in coral cover was found.” In addition, they report that “an interannual survey of reef communities at Tiahura, Moorea, showed that the mortality of coral colonies following a bleaching event was decreasing with successive events, even if the latter have the same intensity (Adjeroud *et al.*, 2002).”

Commenting on their and other researchers’ observations, the seven French scientists say the “spatial and temporal variability of the impacts observed at several scales during the present and previous surveys may reflect an acclimation and/or adaptation of local populations,” such that “coral

colonies and/or their endosymbiotic zooxanthellae may be phenotypically (acclimation) and possibly genotypically (adaptation) resistant to bleaching events,” citing the work of Rowan *et al.* (1997), Hoegh-Guldberg (1999), Kinzie *et al.* (2001) and Coles and Brown (2003) in support of this conclusion.

Other researchers have also confirmed the phenomenon of thermal adaptation in coral reefs. Guzman and Cortes (2007) studied coral reefs of the eastern Pacific Ocean that “suffered unprecedented mass mortality at a regional scale as a consequence of the anomalous sea warming during the 1982-1983 El Niño.” At Cocos Island (5°32’N, 87°04’W), in particular, they found in a survey of three representative reefs, which they conducted in 1987, that remaining live coral cover was only 3 percent of what it had been prior to the occurrence of the great El Niño four years earlier (Guzman and Cortes, 1992). Based on this finding and the similar observations of other scientists at other reefs, they predicted that “the recovery of the reefs’ framework would take centuries, and recovery of live coral cover, decades.” In 2002, therefore, nearly 20 years after the disastrous coral-killing warming, they returned to see just how prescient they might have been after their initial assessment of the El Niño’s damage, quantifying “the live coral cover and species composition of five reefs, including the three previously assessed in 1987.” The two researchers report that overall mean live coral cover increased nearly five-fold, from 2.99 percent in 1987 to 14.87 percent in 2002, at the three sites studied during both periods, while the mean live coral cover of all five sites studied in 2002 was 22.7 percent. In addition, they found that “most new recruits and adults belonged to the main reef building species from pre-1982 ENSO, *Porites lobata*, suggesting that a disturbance as outstanding as El Niño was not sufficient to change the role or composition of the dominant species.”

With respect to the subject of thermal tolerance, however, the most interesting aspect of the study was the fact that a second major El Niño occurred between the two assessment periods; Guzman and Cortes state that “the 1997-1998 warming event around Cocos Island was more intense than all previous El Niño events,” noting that temperature anomalies “above 2°C lasted 4 months in 1997-1998 compared to 1 month in 1982-83.” Nevertheless, they report that “the coral communities suffered a lower and more selective mortality in 1997-1998, as was also observed in other areas of the eastern Pacific (Glynn

*et al.*, 2001; Cortes and Jimenez, 2003; Zapata and Vargas-Angel, 2003),” which is indicative of some type of thermal adaptation following the 1982-83 El Niño.

One year later in a paper published in *Marine Biology*, Maynard *et al.* (2008) described how they analyzed the bleaching severity of three genera of corals (*Acropora*, *Pocillopora* and *Porites*) via underwater video surveys of five sites in the central section of Australia’s Great Barrier Reef in late February and March of 1998 and 2002, while contemporary sea surface temperatures were acquired from satellite-based Advanced Very High Resolution Radiometer data that were calibrated to local ship- and drift buoy-obtained measurements, and surface irradiance data were obtained “using an approach modified from that of Pinker and Laszlo (1991).”

With respect to temperature, the four researchers report that “the amount of accumulated thermal stress (as degree heating days) in 2002 was more than double that in 1998 at four of the five sites,” and that “average surface irradiance during the 2002 thermal anomaly was 15.6-18.9% higher than during the 1998 anomaly.” Nevertheless, they found that “in 2002, bleaching severity was 30-100% lower than predicted from the relationship between severity and thermal stress in 1998, despite higher solar irradiances during the 2002 thermal event.” In addition, they found that the “coral genera most susceptible to thermal stress (*Pocillopora* and *Acropora*) showed the greatest increase in tolerance.”

In discussing their findings, Maynard *et al.* write that they are “consistent with previous studies documenting an increase in thermal tolerance between bleaching events (1982-1983 vs. 1997-1998) in the Galapagos Islands (Podesta and Glynn, 2001), the Gulf of Chiriqui, the Gulf of Panama (Glynn *et al.*, 2001), and on Costa Rican reefs (Jimenez *et al.*, 2001),” and they say that “Dunne and Brown (2001) found similar results to [theirs] in the Andaman Sea, in that bleaching severity was far reduced in 1998 compared to 1995 despite sea-temperature and light conditions being more conducive to widespread bleaching in 1998.”

As for the significance of these and other observations, the Australian scientists say that “the range in bleaching tolerances among corals inhabiting different thermal realms suggests that at least some coral symbioses have the ability to adapt to much higher temperatures than they currently experience in the central Great Barrier Reef,” citing the work of Coles and Brown (2003) and Riegl (1999, 2002). In

addition, they note that “even within reefs there is a significant variability in bleaching susceptibility for many species (Edmunds, 1994; Marshall and Baird, 2000), suggesting some potential for a shift in thermal tolerance based on selective mortality (Glynn *et al.*, 2001; Jimenez *et al.*, 2001) and local population growth alone.” Above and beyond that, however, they say their results additionally suggest “a capacity for acclimatization or adaptation.”

In concluding their paper, Maynard *et al.* say “there is emerging evidence of high genetic structure within coral species (Ayre and Hughes, 2004),” which suggests, in their words, that “the capacity for adaptation could be greater than is currently recognized.” Indeed, as stated by Skelly *et al.* (2007), “on the basis of the present knowledge of genetic variation in performance traits and species’ capacity for evolutionary response, it can be concluded that evolutionary change will often occur concomitantly with changes in climate as well as other environmental changes.”

One adaptive mechanism that corals have developed to survive the thermal stress of high water temperature is to replace the zooxanthellae expelled by the coral host during a stress-induced bleaching episode by one or more varieties of zooxanthellae that are more heat tolerant, a phenomenon we describe in greater detail in the next section of our report. Another mechanism is to produce heat shock proteins that help repair heat-damaged constituents of their bodies (Black *et al.*, 1995; Hayes and King, 1995; Fang *et al.*, 1997). Sharp *et al.* (1997), for example, demonstrated that sub-tidal specimens of *Goniopora djiboutiensis* typically have much lower constitutive levels of a 70-kD heat shock protein than do their intertidal con-specifics; and they have shown that corals transplanted from sub-tidal to intertidal locations (where temperature extremes are greater and more common) typically increase their expression of this heat shock protein.

Similar results have been reported by Roberts *et al.* (1997) in field work with *Mytilus californianus*. In addition, Gates and Edmunds (1999) have observed an increase in the 70-kD heat shock protein after six hours of exposure of *Montastraea franksi* to a 2-3°C increase in temperature, which is followed by another heat shock protein increase at the 48-hour point of exposure to elevated water temperature. They state that the first of these protein increases “provides strong evidence that changes in protein turnover during the initial exposure to elevated temperature provides this coral with the biological flexibility to

acclimatize to the elevation in sea water temperature,” and that the second increase “indicates another shift in protein turnover perhaps associated with an attempt to acclimatize to the more chronic level of temperature stress.”

How resilient are corals in this regard? No one knows for sure, but they’ve been around a very long time, during which climatic conditions have changed dramatically, from cold to warm and back again, over multiple glacial and interglacial cycles. Thermal adaptation by coral is a biological response that is overlooked or ignored by the IPCC.

### 8.3.1.2.3. Symbiont Shuffling

Although once considered to be members of the single species *Symbiodinium microadriaticum*, the zooxanthellae that reside within membrane-bound vacuoles in the cells of host corals are highly diverse, comprising perhaps hundreds of species, of which several are typically found in each species of coral (Trench, 1979; Rowan and Powers, 1991; Rowan *et al.*, 1997). One way coral respond to stress is to replace the zooxanthellae expelled by the coral host during a stress-induced bleaching episode with one or more varieties of zooxanthellae that are more tolerant of that particular stress.

Rowan *et al.* (1997) have suggested that this phenomenon occurs in many of the most successful Caribbean corals that act as hosts to dynamic multi-species communities of symbionts, and that “coral communities may adjust to climate change by recombining their existing host and symbiont genetic diversities,” thereby reducing the amount of damage that might subsequently be expected from another occurrence of anomalously high temperatures. Buddemeier and Fautin (1993) suggested coral bleaching is an adaptive strategy for “shuffling” symbiont genotypes to create associations better adapted to new environmental conditions. Kinzie (1999) suggested coral bleaching “might not be simply a breakdown of a stable relationship that serves as a symptom of degenerating environmental conditions,” but it “may be part of a mutualistic relationship on a larger temporal scale, wherein the identity of algal symbionts changes in response to a changing environment.”

This process of replacing less-stress-tolerant symbionts by more-stress-tolerant symbionts is also supported by the investigations of Rowan and Knowlton (1995) and Gates and Edmunds (1999). The strategy seems to be working, for as Glynn (1996) has observed, “despite recent incidences of severe coral reef bleaching and mortality, no species extinctions have yet been documented.”

These observations accord well with the experimental findings of Fagoonee *et al.* (1999), who suggest that coral bleaching events “may be frequent and part of the expected cycle.” Gates and Edmunds (1999) additionally report that “several of the prerequisites required to support this hypothesis have now been met,” and after describing them in some detail, they conclude “there is no doubt that the existence of multiple *Symbiodinium* clades, each potentially exhibiting a different physiological optima, provide corals with the opportunity to attain an expanded range of physiological flexibility which will ultimately be reflected in their response to environmental challenge.” In fact, this phenomenon may provide the explanation for the paradox posed by Pandolfi (1999); i.e., that “a large percentage of living coral reefs have been degraded, yet there are no known extinctions of any modern coral reef species.” Surely, this result is exactly what would be expected if periods of stress lead to the acquisition of more-stress-resistant zooxanthellae by coral hosts.

In spite of this early raft of compelling evidence for the phenomenon, Hoegh-Guldberg (1999) challenged the symbiont shuffling hypothesis on the

basis that the stress-induced replacement of less-stress-tolerant varieties of zooxanthellae by more-stress-tolerant varieties “has never been observed.” Although true at the time it was written, a subsequent series of studies has produced the long-sought proof that transforms the hypothesis into fact.

Baker (2001) conducted an experiment in which he transplanted corals of different combinations of host and algal symbiont from shallow (2-4 m) to deep (20-23 m) depths and vice versa. After eight weeks nearly half of the corals transplanted from deep to shallow depths had experienced partial or severe bleaching, whereas none of the corals transplanted from shallow to deep depths bleached. After one year, however, and despite even more bleaching at shallow depths, upward transplants showed no mortality, but nearly 20 percent of downward transplants had died. Why?

The symbiont shuffling hypothesis explains it this way. The corals that were transplanted upwards were presumed to have adjusted their algal symbiont distributions, via bleaching, to favor more-tolerant species, whereas the corals transplanted downward were assumed to not have done so, since they did not bleach. Baker suggested that these findings “support the view that coral bleaching can promote rapid response to environmental change by facilitating compensatory change in algal symbiont communities.” Without bleaching, he continued, “suboptimal host-symbiont combinations persist, leading eventually to significant host mortality.” Consequently, Baker proposed that coral bleaching may “ultimately help reef corals to survive.” And it may also explain why reefs, though depicted by the IPCC as environmentally fragile, have survived the large environmental changes experienced throughout geologic time.

One year later Adjeroud *et al.* (2002) provided additional evidence for the veracity of the symbiont shuffling hypothesis as a result of their assessment of the interannual variability of coral cover on the outer slope of the Tiahura sector of Moorea Island, French Polynesia, between 1991 and 1997, which focused on the impacts of bleaching events caused by thermal stress when sea surface temperatures rose above 29.2°C. Soon after the start of their study, they observed a severe decline in coral cover following a bleaching event that began in March 1991, which was followed by another bleaching event in March 1994. However, they report that the latter bleaching event “did not have an important impact on coral cover,” even though “the proportion of bleached colonies ...

and the order of susceptibility of coral genera were similar in 1991 and 1994 (Gleason, 1993; Hoegh-Guldberg and Salvat, 1995).” They report that between 1991 and 1992 total coral cover dropped from 51.0 percent to 24.2 percent, but that “coral cover did not decrease between 1994 and 1995.”

In discussing these observations, Adjeroud *et al.* write that a “possible explanation of the low mortality following the bleaching event in 1994 is that most of the colonies in place in 1994 were those that survived the 1991 event or were young recruits derived from those colonies,” noting that “one may assume that these coral colonies and/or their endosymbiotic zooxanthellae were phenotypically and possibly genotypically resistant to bleaching events,” which is exactly what the symbiont shuffling hypothesis would predict. They further state that “this result demonstrates the importance of understanding the ecological history of reefs (i.e., the chronology of disturbances) in interpreting the specific impacts of a particular disturbance.”

In the same year, Brown *et al.* (2002) published the results of an even longer 17-year study of coral reef flats at Ko Phuket, Thailand, in which they assessed coral reef changes in response to elevated water temperatures in 1991, 1995, 1997, and 1998. As they describe it, “many corals bleached during elevated sea temperatures in May 1991 and 1995, but no bleaching was recorded in 1997.” In addition, they report that “in May 1998 very limited bleaching occurred although sea temperatures were higher than previous events in 1991 and 1995 (Dunne and Brown, 2001).” What is more, when bleaching did take place, they say “it led only to partial mortality in coral colonies, with most corals recovering their color within 3-5 months of initial paling,” once again providing real-world evidence for what is predicted by the symbiont shuffling hypothesis.

The following year, Riegl (2003) reviewed what is known about the responses of real-world coral reefs to high-temperature-induced bleaching, focusing primarily on the Arabian Gulf, which experienced high-frequency recurrences of temperature-related bleaching in 1996, 1998, and 2002. In response to these high-temperature events, Riegl notes that *Acropora*, which during the 1996 and 1998 events always bleached first and suffered heaviest mortality, bleached less than all other corals in 2002 at Sir Abu Nuair (an offshore island of the United Arab Emirates) and actually recovered along the coast of Dubai between Jebel Ali and Ras Hasyan. As a result, Riegl states that “the unexpected resistance of Sir

Abu Nuair *Acropora* to bleaching in 2002 might indicate support for the hypothesis of Baker (2001) and Baker *et al.* (2002) that the symbiont communities on recovering reefs of the future might indeed be more resistant to subsequent bleaching,” and that “the Arabian Gulf perhaps provides us with some aspects which might be described as a ‘glimpse into the future,’ with ... hopes for at least some level of coral/zooxanthellae adaptation.”

In a contemporaneous paper, Kumaraguru *et al.* (2003) reported the results of a study wherein they assessed the degree of damage inflicted upon a number of coral reefs within Palk Bay (located on the southeast coast of India just north of the Gulf of Mannar) by a major warming event that produced monthly mean sea surface temperatures of 29.8 to 32.1°C from April through June 2002, after which they assessed the degree of recovery of the reefs. They determined that “a minimum of at least 50% and a maximum of 60% bleaching were noticed among the six different sites monitored.” However, as they continue, “the corals started to recover quickly in August 2002 and as much as 52% recovery could be noticed.” By comparison, they note that “recovery of corals after the 1998 bleaching phenomenon in the Gulf of Mannar was very slow, taking as much as one year to achieve similar recovery,” i.e., to achieve what was experienced in one *month* in 2002. Consequently, in words descriptive of the concept of symbiont shuffling, the Indian scientists say “the process of natural selection is in operation, with the growth of new coral colonies, and any disturbance in the system is only temporary.” Consequently, as they conclude in the final sentence of their paper, “the corals will resurge under the sea.”

Writing in *Nature*, Rowan (2004) described how he measured the photosynthetic responses of two zooxanthellae genotypes or clades—*Symbiodinium C* and *Symbiodinium D*—to increasing water temperature, finding that the photosynthetic prowess of the former decreased at higher temperatures while that of the latter increased. He then noted that “adaptation to higher temperature in *Symbiodinium D* can explain why *Pocillopora* spp. hosting them resist warm-water bleaching whereas corals hosting *Symbiodinium C* do not,” and that “it can also explain why *Pocillopora* spp. living in frequently warm habitats host only *Symbiodinium D*, and, perhaps, why those living in cooler habitats predominantly host *Symbiodinium C*,” concluding that these observations “indicate that symbiosis recombination

may be one mechanism by which corals adapt, in part, to global warming.”

Baker *et al.* (2004) “undertook molecular surveys of *Symbiodinium* in shallow scleractinian corals from five locations in the Indo-Pacific that had been differently affected by the 1997-98 El Niño-Southern Oscillation (ENSO) bleaching event.” Along the coasts of Panama, they surveyed ecologically dominant corals in the genus *Pocillopora* before, during, and after ENSO bleaching, finding that “colonies containing *Symbiodinium* in clade D were already common (43%) in 1995 and were unaffected by bleaching in 1997, while colonies containing clade C bleached severely.” Even more importantly, they found that “by 2001, colonies containing clade D had become dominant (63%) on these reefs.”

After describing similar observations in the Persian (Arabian) Gulf and the western Indian Ocean along the coast of Kenya, Baker *et al.* summarized their results by stating they indicate that “corals containing thermally tolerant *Symbiodinium* in clade D are more abundant on reefs after episodes of severe bleaching and mortality, and that surviving coral symbioses on these reefs more closely resemble those found in high-temperature environments,” where clade D predominates. They concluded their paper by noting that the symbiont changes they observed “are a common feature of severe bleaching and mortality events,” and by predicting that “these adaptive shifts will increase the resistance of these recovering reefs to future bleaching.”

Lewis and Coffroth (2004) described a controlled experiment in which they induced bleaching in a Caribbean octocoral (*Briareum* sp.) and then exposed it to exogenous *Symbiodinium* sp. containing rare variants of the chloroplast 23S ribosomal DNA (rDNA) domain V region (cp23S-genotype), after which they documented the symbionts’ repopulation of the coral, whose symbiont density had been reduced to less than 1 percent of its original level by the bleaching. Also, in a somewhat analogous study, Little *et al.* (2004) described how they investigated the acquisition of symbionts by juvenile *Acropora tenuis* corals growing on tiles they attached to different portions of reef at Nelly Bay, Magnetic Island (an inshore reef in the central section of Australia’s Great Barrier Reef).

Lewis and Coffroth wrote that the results of their study show “the repopulation of the symbiont community involved residual populations within *Briareum* sp., as well as symbionts from the surrounding water,” noting that “recovery of coral-

algal symbioses after a bleaching event is not solely dependent on the *Symbiodinium* complement initially acquired early in the host's ontogeny," but that "these symbioses also have the flexibility to establish new associations with symbionts from an environmental pool." Similarly, Little *et al.* reported that "initial uptake of zooxanthellae by juvenile corals during natural infection is nonspecific (a potentially adaptive trait)," and "the association is flexible and characterized by a change in (dominant) zooxanthella strains over time." Lewis and Coffroth concluded that "the ability of octocorals to reestablish symbiont populations from multiple sources provides a mechanism for resilience in the face of environmental change." Little *et al.* concluded that the "symbiont shuffling" observed by both groups "represents a mechanism for rapid acclimatization of the holobiont to environmental change."

Writing in the journal *Marine Ecology Progress Series*, Chen *et al.* (2005) reported their study of the seasonal dynamics of *Symbiodinium* algal phylotypes via bimonthly sampling over an 18-month period of *Acropora palifera* coral on a reef flat at Tantzel Bay, Kenting National Park, southern Taiwan, in an attempt to detect real-world symbiont shuffling. Results of the analysis revealed two levels of symbiont shuffling in host corals: (1) between *Symbiodinium* phylotypes C and D, and (2) among different variants within each phylotype. The most significant changes in symbiont composition occurred at times of significant increases in seawater temperature during late spring/early summer, perhaps as a consequence of enhanced stress experienced at that time, leading Chen *et al.* to state their work revealed "the first evidence that the symbiont community within coral colonies is dynamic ... involving changes in *Symbiodinium* phylotypes."

Also in 2005, Van Oppen *et al.* (2005) sampled zooxanthellae from three common species of scleractinian corals at 17 sites along a latitudinal and cross-shelf gradient in the central and southern sections of the Great Barrier Reef some four to five months after the major bleaching event of 2002, recording the health status of each colony at the time of its collection and identifying its zooxanthella genotypes, of which there are eight distinct clades (A-H) with clade D being the most heat-tolerant. Results of the analysis revealed that "there were no simple correlations between symbiont types and either the level of bleaching of individual colonies or indicators of heat stress at individual sites." However, they say "there was a very high post-bleaching abundance of

the heat tolerant symbiont type D in one coral population at the most heat-stressed site."

With respect to the post-bleaching abundance of clade D zooxanthellae at the high heat-stress site, the Australian researchers say they suspect it was due to "a proliferation in the absolute abundance of clade D within existing colonies that were previously dominated by clade C zooxanthellae," and that in the four to five months before sampling them, "mixed C-D colonies that had bleached but survived may have shifted (shuffling) from C-dominance to D-dominance, and/or C-dominated colonies may have suffered higher mortality during the 2002 bleaching event" and subsequently been repopulated by a predominance of clade D genotypes.

Working within Australia's Great Barrier Reef system, Berkelmans and van Oppen (2006) investigated the thermal acclimatization potential of *Acropora millepora* corals to rising temperatures through transplantation and experimental manipulation, finding that the adult corals "are capable of acquiring increased thermal tolerance and that the increased tolerance is a direct result of a change in the symbiont type dominating their tissues from *Symbiodinium* type C to D." Two years later, working with an expanded group of authors (Jones *et al.*, 2008), the same two researchers reported similar findings following the occurrence of a natural bleaching event.

Prior to the bleaching event, Jones *et al.* report that "*A. millepora* at Miall reef associated predominantly with *Symbiodinium* type C2 (93.5%) and to a much lesser extent with *Symbiodinium* clade D (3.5%) or mixtures of C2 and D (3.0%)." During the bleaching event, they report "the relative difference in bleaching susceptibility between corals predominated by C2 and D was clearly evident, with the former bleaching white and the latter normally pigmented," while corals harboring a mix of *Symbiodinium* C2 and D were "mostly pale in appearance." Then, three months after the bleaching event, they observed "a major shift to thermally tolerant type D and C1 symbiont communities ... in the surviving colonies," the latter of which types had not been detected in any of the corals prior to bleaching. They report "this shift resulted partly from a change of symbionts within coral colonies that survived the bleaching event (42%) and partly from selective mortality of the more bleaching-sensitive C2-predominant colonies (37%)." In addition, they report that all of the colonies that harbored low levels of D-type symbionts prior to the bleaching event

survived and changed from clade C2 to D predominance.

In conclusion, Jones *et al.* say that “as a direct result of the shift in symbiont community, the Miall Island *A. millepora* population is likely to have become more thermo-tolerant,” as they note that “a shift from bleaching-sensitive type C2 to clade D increased the thermal tolerance of this species by 1–1.5°C.” They say their results “strongly support the reinterpreted adaptive bleaching hypothesis of Buddemeier *et al.* (2004), which postulates that a continuum of changing environmental states stimulates the loss of bleaching-sensitive symbionts in favor of symbionts that make the new holobiont more thermally tolerant.” They state that their observations “provide the first extensive colony-specific documentation and quantification of temporal symbiont community change in the field in response to temperature stress, suggesting a population-wide acclimatization to increased water temperature.”

In a much larger geographical study, Lien *et al.* (2007) examined the symbiont diversity in a scleractinian coral, *Oulastrea crispata*, throughout its entire latitudinal distribution range in the West Pacific, i.e., from tropical peninsular Thailand (<10°N) to high-latitude outlying coral communities in Japan (>35°N), convincingly demonstrating in the words of the six scientists who conducted the study, “that phylotype D is the dominant *Symbiodinium* in scleractinian corals throughout tropical reefs and marginal outlying non-reefal coral communities.” In addition, they learned that this particular symbiont clade “favors ‘marginal habitats’ where other symbionts are poorly suited to the stresses, such as irradiance, temperature fluctuations, sedimentation, etc.” Being a major component of the symbiont repertoire of most scleractinian corals in most places, the apparent near-universal presence of *Symbiodinium* phylotype D thus provides, according to Lien *et al.*, “a flexible means for corals to *routinely cope* [our italics] with environmental heterogeneities and survive the consequences (e.g., recover from coral bleaching).”

Also in 2007, Mieog *et al.* (2007) utilized a newly developed real-time polymerase chain reaction assay, which they say “is able to detect *Symbiodinium* clades C and D with >100-fold higher sensitivity compared to conventional techniques,” to test 82 colonies of four common scleractinian corals (*Acropora millepora*, *Acropora tenuis*, *Stylophora pistillata* and *Turbinaria reniformis*) from eleven different locations on Australia’s Great Barrier Reef

for evidence of the presence of background *Symbiodinium* clades. Results of the analysis showed that “ninety-three percent of the colonies tested were dominated by clade C and 76% of these had a D background,” the latter of which symbionts, in their words, “are amongst the most thermo-tolerant types known to date,” being found “on reefs that chronically experience unusually high temperatures or that have recently been impacted by bleaching events, suggesting that temperature stress can favor clade D.” Consequently, Mieog *et al.* concluded that the clade D symbiont backgrounds detected in their study can potentially act as safety-parachutes, “allowing corals to become more thermo-tolerant through symbiont shuffling as seawater temperatures rise due to global warming.” As a result, they suggest that symbiont shuffling is likely to play a role in the way “corals cope with global warming conditions,” leading to new competitive hierarchies and, ultimately, “the coral community assemblages of the future.”

In spite of the hope symbiont shuffling provides—that the world’s corals will indeed be able to successfully cope with the possibility of future global warming, be it anthropogenic-induced or natural—some researchers have claimed that few coral symbioses host more than one type of symbiont, which has led some commentators to argue that symbiont shuffling is not an option for most coral species to survive the coming thermal onslaught of global warming. But is this claim correct? Not according to the results of Apprill and Gates (2007).

Working with samples of the widely distributed massive corals *Porites lobata* and *Porites lutea*—which they collected from Kaneohe Bay, Hawaii—Apprill and Gates compared the identity and diversity of *Symbiodinium* symbiont types obtained using cloning and sequencing of internal transcribed spacer region 2 (ITS2) with that obtained using the more commonly applied downstream analytical techniques of denaturing gradient gel electrophoresis (DGGE).

Results of the analysis revealed “a total of 11 ITS2 types in *Porites lobata* and 17 in *Porites lutea* with individual colonies hosting from one to six and three to eight ITS2 types for *P. lobata* and *P. lutea*, respectively.” In addition, the two authors report that “of the clones examined, 93% of the *P. lobata* and 83% of the *P. lutea* sequences are not listed in GenBank,” noting that they resolved “sixfold to eightfold greater diversity per coral species than previously reported.”

In a “perspective” that accompanied Apprill and Gates’ important paper, van Oppen (2007) wrote that

“the current perception of coral-inhabiting symbiont diversity at nuclear ribosomal DNA is shown [by Apprill and Gates] to be a significant underestimate of the wide diversity that in fact exists.” These findings, in her words, “have potentially far-reaching consequences in terms of our understanding of *Symbiodinium* diversity, host-symbiont specificity and the potential of corals to acclimatize to environmental perturbations through changes in the composition of their algal endosymbiont community,” which assessment, it is almost unnecessary to say, suggests a greater than previously believed ability to do just that in response to any further global warming that might occur.

In a contemporaneous study, Baird *et al.* (2007) also discount the argument that symbiont shuffling is not an option for most coral species, because, “as they see it,” it is the sub-clade that must be considered within this context, citing studies that indicate “there are both heat tolerant and heat susceptible sub-clades within both clades C and D *Symbiodinium*.” Hence, the more relevant question becomes: How many coral species can host more than one sub-clade? The answer, of course, is that most if not all of them likely do; Baird *et al.* note that “biogeographical data suggest that when species need to respond to novel environments, they have the flexibility to do so.”

So how and when might such sub-clade changes occur? Although most prior research in this area has been on adult colonies switching symbionts in response to warming-induced bleaching episodes, Baird *et al.* suggest that “change is more likely to occur between generations,” for initial coral infection typically occurs in larvae or early juveniles, which are much more flexible than adults. In this regard, for example, they note that “juveniles of *Acropora tenuis* regularly harbor mixed assemblages of symbionts, whereas adults of the species almost invariably host a single clade,” and they indicate that larvae of *Fungia scutaria* ingest symbionts from multiple hosts, although they generally harbor but one symbiont as adults.

Because of these facts, the Australian researchers say there is no need for an acute disturbance, such as bleaching, to induce clade or sub-clade change. Instead, if ocean temperatures rise to new heights in the future, they foresee juveniles naturally hosting more heat-tolerant sub-clades and maintaining them into adulthood.

In a further assessment of the size of the symbiont diversity reservoir, especially among juvenile coral species, Pochon *et al.* (2007) collected more than

1,000 soritid specimens over a depth of 40 meters on a single reef at Gun Beach on the island of Guam, Micronesia, throughout the course of an entire year, which they then studied by means of molecular techniques to identify unique *internal transcribed spacer-2* (ITS-2) types of *ribosomal DNA* (rDNA), in a project self-described as “the most targeted and exhaustive sampling effort ever undertaken for any group of *Symbiodinium*-bearing hosts.”

Throughout the course of their analysis, Pochon *et al.* identified 61 unique symbiont types in only three soritid host genera, making the Guam *Symbiodinium* assemblage the most diverse derived to date from a single reef. In addition, they report that “the majority of mixed genotypes observed during this survey were usually harbored by the smallest hosts.” As a result, the authors speculate that “juvenile foraminifera may be better able to switch or shuffle heterogeneous symbiont communities than adults,” so that as juveniles grow, “their symbiont communities become ‘optimized’ for the prevailing environmental conditions,” suggesting that this phenomenon “may be a key element in the continued evolutionary success of these protests in coral reef ecosystems worldwide.”

In support of the above statement, we additionally cite the work of Mumby (1999), who analyzed the population dynamics of juvenile corals in Belize, both prior to, and after, a massive coral bleaching event in 1998. Although 70 percent to 90 percent of adult coral colonies were severely bleached during the event, only 25 percent of coral recruits exhibited signs of bleaching. What is more, one month after the event, it was concluded that “net bleaching-induced mortality of coral recruits ... was insignificant,” demonstrating the ability of juvenile corals to successfully weather such bleaching events.

In light of these several observations, earth’s corals will likely be able to successfully cope with the possibility of further increases in water temperatures, be they anthropogenic-induced or natural. Corals have survived such warmth—and worse—many times in the past, including the Medieval Warm Period, Roman Warm Period, and Holocene Optimum, as well as throughout numerous similar periods during a number of prior interglacial periods; there is no reason to believe they cannot do it again, if the need arises.

Additional information on this topic, including reviews of newer publications as they become available, can be found at <http://www.co2science.org/subject/c/bleachrespsymb.php>.

#### 8.3.1.2.4. Bacterial Shuffling

One final adaptive bleaching mechanism is discussed by Reshef *et al.*, (2006), who developed a case for what they call the coral probiotic hypothesis, and what we call “bacterial shuffling.” This concept, in their words, “posits that a dynamic relationship exists between symbiotic microorganisms and environmental conditions which brings about the selection of the most advantageous coral holobiont.”

This concept is analogous to the adaptive bleaching hypothesis of Buddemeier and Fautin (1993), or what was referred to in the preceding section as symbiont shuffling, wherein corals exposed to some type of stress—such as that induced by exposure to unusually high water temperatures or solar irradiance—first lose their dinoflagellate symbionts (bleach) and then regain a new mixture of zooxanthellae that are better suited to the stress

conditions. In fact, the two phenomena work in precisely the same way, in one case by the corals rearranging their zooxanthellae populations (symbiont shuffling) and in the other case by the corals rearranging their bacterial populations (bacterial shuffling).

In seeking evidence for their hypothesis, the team of Israeli researchers concentrated their efforts on looking for examples of corals developing resistance to emerging diseases. This approach makes sense, because corals lack an adaptive immune system; i.e., they possess no antibodies (Nair *et al.*, 2005), and they therefore can protect themselves against specific diseases in no other way than to adjust the relative sizes of the diverse bacterial populations associated with their mucus and tissues so as to promote the growth of those types of bacteria that tend to mitigate most effectively against the specific disease that happens to be troubling them.

Reshef *et al.* begin by describing the discovery that bleaching of *Oculina patagonica* corals in the Mediterranean Sea was caused by the bacterium *Vibrio shiloi*, together with the finding that bleaching of *Pocillopora damicornis* corals in the Indian Ocean and Red Sea was the result of an infection with *Vibrio coralliilyticus*. But they then report that (1) “during the last two years *O. patagonica* has developed resistance to the infection by *V. shiloi*,” (2) “*V. shiloi* can no longer be found on the corals,” and (3) “*V. shiloi* that previously infected corals are unable to infect the existing corals.” They say “by some unknown mechanism, the coral is now able to lyse the intracellular *V. shiloi* and avoid the disease,” and because corals lack the ability to produce antibodies and have no adaptive immune system, the only logical conclusion to be drawn from these observations is that bacterial shuffling must be what produced the welcome results.

With respect to the future of earth’s corals in the context of global warming, the Israeli scientists note that “Hoegh-Guldberg (1999, 2004) has predicted that coral reefs will have only remnant populations of reef-building corals by the middle of this century,” based on “the assumption that corals cannot adapt rapidly enough to the predicted temperatures in order to survive.” However, they report that considerable evidence has been collected in support of the adaptive bleaching hypothesis, and they emphasize that the hundreds of different bacterial species associated with corals “give the coral holobiont an enormous genetic potential to adapt rapidly to changing environmental conditions.” They say “it is not unreasonable to

predict that under appropriate selection conditions, the change could take place in days or weeks, rather than decades required for classical Darwinian mutation and selection,” and that “these rapid changes may allow the coral holobiont to use nutrients more efficiently, prevent colonization by specific pathogens and avoid death during bleaching by providing carbon and energy from photosynthetic prokaryotes,” of which they say there is “a metabolically active, diverse pool” in most corals.

Additional information on this topic, including reviews of newer publications as they become available, can be found at <http://www.co2science.org/subject/c/bacterialsuffling.php>.

### 8.3.1.3. Widespread Coral Bleaching

#### 8.3.1.3.1. Not Caused by Global Warming

Hoegh-Guldberg (1999) concluded that “coral bleaching is due to warmer than normal temperatures” and that “increased sea temperature is the primary reason for why coral bleaching has occurred with increasing intensity and frequency over the past two decades.” As outlined in the preceding sections, there is some evidence that points toward these conclusions, but there is much other evidence that points to alternative possibilities.

Consider, for example, the persistence of coral reefs through geologic time, which provides

substantive evidence that these ecological entities can successfully adapt to a dramatically changing global environment (Veron, 1995). What can their history tell us about bleaching and global warming in our day?

The earliest coral reefs date to the Palaeozoic Era, over 450 million years ago (Hill, 1956). The scleractinian corals, which are the major builders of the reefs of today (Achtuv and Dubinsky, 1990), appeared in the mid-Triassic some 240 million years later (Hill, 1956), when the earth was considerably warmer than it is currently (Chadwick-Furman, 1996). Although reef-building ceased for a time following the extinctions at the end of the Triassic, the Scleractinia came back with a vengeance during the Jurassic (Newell, 1971; Veron, 1995); they continued to exhibit great robustness throughout the Cretaceous, even when temperatures were as much as 8-15°C higher (Chadwick-Furman, 1996; Veizer *et al.*, 1999), and atmospheric CO<sub>2</sub> concentrations two to seven times higher (Berner and Kothavala, 2001), than present.

At the end of the Cretaceous, 70 percent of the genera and one-third of the families of scleractinian corals disappeared (Veron, 1995) in the greatest biospheric extinction event in geological history, which may possibly have been caused by a large asteroid impact (Alvarez *et al.*, 1980, 1984). They developed again, however, throughout the Cenozoic, particularly the Oligocene and Miocene (Chadwick-Furman, 1996). Finally, throughout the past two million years of the Pleistocene, they survived at least seventeen glacial-interglacial cycles of dramatic climate change and sea-level fluctuation, successfully adapting, over and over again, to these enormous environmental challenges (Pandolfi, 1999). In the words of Benzie (1999), this evidence suggests that “coral reef communities are relatively resilient, have survived previous global climate change, and appear likely to survive future changes.” This conclusion leads us to wonder why corals should be succumbing to global warming now.

To answer such an inquiry we must first address the question of what is “normal” for coral reefs in our day. Is it what they look like now? Or what they looked like 30 years ago? Or 300 years ago? Kinzie (1999) has emphatically stated that “it is clear that the definition of a healthy reef as ‘what it looked like when I started diving’ is fraught not only with hubris but strong temporal bias.” Indeed, as Greenstein *et al.* (1998a) have observed, “it must be demonstrated that the classic reef coral zonation pattern described in the

early days of coral reef ecology, and upon which ‘healthy’ versus ‘unhealthy’ reefs are determined, are themselves representative of reefs that existed prior to any human influence.” Only when this criterion is met will we have, in the words of Greenstein *et al.* (1998b), a good replacement for “the temporally myopic view afforded by monitoring studies that rarely span a scientific career.” Clearly, therefore, there should be no argument over the key fact that we need a proper understanding of the past to correctly judge the present if we ever are to foretell the future.

In an attempt to obtain a true picture of pristine coral conditions in the western North Atlantic and Caribbean, Greenstein *et al.* (1998a, 1998b) conducted systematic censuses of “life assemblages” and “death assemblages” of corals on healthy modern patch reefs and compared the results with similar censuses they conducted on “fossil assemblages” preserved in Pleistocene limestones in close proximity to the modern reefs. The data revealed a recent decline in thickets of *Acropora cervicornis*, as evidenced by their abundance in the death assemblage, and a concurrent increase in *Porites porites*, as evidenced by their abundance in the life assemblage. In comparing these results with those obtained from the fossil assemblage, they found that the present Caribbean-wide decline of *A. cervicornis* is “without historical precedent” and that it is a dramatic departure from “the long-term persistence of this taxon during Pleistocene and Holocene Optimum time,” when “intensifying cycles in climate and sea level” recurred throughout a roughly one-million-year time period.

These observations, along with the similar findings of Jackson (1992) and Aronson and Precht (1997), suggest that if little change in coral community structure occurred throughout the Pleistocene—when it was often warmer than it is now (Petit *et al.*, 1999)—the recent die-off of *A. cervicornis* cannot be due to global warming alone, or even primarily, for this particular coral has clearly weathered several major episodes of global warming and elevated water temperatures in the past with no adverse consequences. Neither can the coral’s die-off be due to the CO<sub>2</sub>-induced decrease in seawater calcium carbonate saturation state that might possibly be occurring at the present time (see the section later in this chapter on coral calcification); for the air’s CO<sub>2</sub> content has not risen sufficiently to have caused this parameter to decline enough to significantly impact reef coral calcification rates (Gattuso *et al.*, 1998, 1999), as is also demonstrated by the

opportunistic replacement of *A. cervicornis* by *P. porites*. In addition, in their detailed reconstruction of the history of calcification rates in massive *Porites* colonies from Australia’s Great Barrier Reef, Lough and Barnes (1997) report that the mid-twentieth century had the second highest coral growth rate of the past 237 years. Hence, although *A. cervicornis* has indeed suffered an extreme decrease in abundance throughout the Caribbean in recent years (Hughes, 1994), its precipitous decline cannot be attributed to either global warming or the direct effects of rising CO<sub>2</sub>.

In light of these data-driven considerations, Greenstein *et al.* (1998a, 1998b) have attributed the increasing coral bleaching of the past two decades to a host of local anthropogenic impacts. This conclusion is accepted in a much wider context as well, as Buddemeier and Smith (1999) have noted that “reviews of the problems facing coral reefs have consistently emphasized that local and regional anthropogenic impacts are a far greater immediate threat to coral reefs than Greenhouse-enhanced climate change.”

### 8.3.1.3.2. An Alternative Hypothesis

The preceding considerations clearly indicate global warming cannot be the primary cause of the massive coral bleaching the earth has experienced in recent years. However, the IPCC tenaciously clings to this hypothesis because (1) no significant massive and widespread coral bleaching was reported in the 1970s and (2) the global warming hypothesis can account for this observation. Specifically, Hoegh-Guldberg (1999) has suggested that the reason “why mass bleaching events are not seen prior to 1980” is that “increases in sea temperatures have only become critical since in the 1980s, when El Niño disturbances began to exceed the thermal tolerances of corals and their zooxanthellae” as a result of global warming increasing the background temperature to which El Niño thermal effects are added.

This reasoning assumes no other theory is capable of accounting for the fact that modern mass bleaching events did not begin to occur until 1980. On the basis of this *assumption*, Hoegh-Guldberg (1999) concludes that the global warming hypothesis must be correct, even in light of the many problems associated with it. This assumption, however, is not true, for there are other ways of satisfying this critical criterion that do account for the lack of bleaching episodes before 1980, which we describe below.

The North Atlantic Oscillation (NAO) is responsible for multiannual to decadal variability in Northern Hemispheric climate that is numerically represented by the pressure difference between the Azores high and the Icelandic low (Dugam *et al.*, 1997). It has been documented over the past 350 years in Greenland ice core reconstructions (Appenzeller *et al.*, 1998) and explicitly quantified from 1864 through 1994 via actual pressure records

(Hurrell, 1995), which have been updated through 1998 by Uppenbrink (1999).

Plots of these NAO datasets reveal a shift from strong negative index values in the 1950s and 1960s to what Hurrell (1995) describes as “unprecedented strongly positive NAO index values since 1980.” This observation is especially important, for during times of high NAO index values, there is a significant reduction in atmospheric moisture transport across southern Europe, the Mediterranean, and north Africa (Hurrell, 1995); and Richardson *et al.* (1999) note that this phenomenon has led to the development of prolonged drought in the Sahel region of Africa since the NAO shift to positive index values in 1980.

One consequence of this drought has been a gradual increase in the dust content of the atmosphere, which in some areas has grown to five-fold what was deemed normal prior to this climatic transition (Richardson *et al.*, 1999). Of particular significance to corals is the fact that this airborne dust carries bacteria, viruses, and fungi that can kill them. Pearce (1999) notes that outbreaks of a number of coral diseases “have coincided with years when the dust load in the atmosphere was highest.” In 1983, for example—when the NAO index reached its highest value since 1864 (Hurrell, 1995) and the atmosphere was exceptionally dusty—a soil fungus of the *Aspergillus* genus appeared in the Caribbean, initiating an onslaught of soft coral sea fans that has now destroyed more than 90 percent of them. Pearce (1999) notes there are solid scientific reasons for concluding that “the speed and pattern of the fungus’s spread indicates that it could only have arrived on the trade winds from Africa.”

In addition to carrying its deadly biological cargo, the positive-NAO-induced airborne dust is rich in iron, which extra supply, in the words of R.T. Barber as quoted by Pearce (1999), “may have spurred the worldwide growth of a variety of invader organisms harmful to coral ecosystems.” Such iron-rich dust has the capacity to fertilize algae that compete with zooxanthellae for other scarce nutrients and reef living space. Abram *et al.* (2003), for example, reported that a massive coral bleaching event that killed close to 100 percent of the coral and fish in the reef ecosystem of the Mentawai Islands (located southwest of Sumatra, Indonesia, in the equatorial eastern Indian Ocean) in 1997-1998 was brought about by an anomalous influx of iron provided by atmospheric fallout from the 1997 Indonesian wildfires, which they describe as being “the worst wildfires in the recorded history of southeast Asia.”

The enhanced burden of iron, in turn, spawned a large phytoplankton bloom that likely caused the coral and fish death via asphyxiation. In concluding their paper, Abram *et al.* warn that “widespread tropical wildfire is a recent phenomenon, the magnitude and frequency of which are increasing as population rises and terrestrial biomass continues to be disrupted,” and “reefs are likely to become increasingly susceptible to large algal blooms triggered by episodic nutrient enrichment from wildfires,” which phenomenon, in their words, “may pose a new threat to coastal marine ecosystems that could escalate into the 21<sup>st</sup> century.”

The timeline for the appearance and progression of these several related phenomena matches perfectly with the timeline of the historical buildup of modern coral reef bleaching throughout the 1980s and 1990s. This is not to say, however, that these aggregate phenomena comprise the entire answer to the problem to the exclusion of all other possible causes, even including global warming. We only suggest that they, too, must be seriously considered in attempts to identify the true cause or causes of this development in coral reef history.

Although one can make the case for coral bleaching being caused by global warming, there are too many pieces of evidence that contradict this hypothesis for it to be deemed the sole, or even primary, cause of this modern problem. There is at least one alternative explanation—the unprecedented, strongly positive NAO since 1980—during the past two decades.

#### 8.3.1.4. Sea-level Rise

Many people believe rising sea levels, by gradually reducing the amount of life-sustaining light that reaches their algal symbionts, will decimate earth's corals. This assumption is a major concern often expressed in discussions of reef responses to global climate change (Hopley and Kinsey, 1988). But it is probably not valid, for a number of reasons.

First, the 18- to 59-cm warming-induced sea-level rise that is predicted for the coming century (IPCC, 2007)—which could be greatly exaggerated if predictions of CO<sub>2</sub>-induced global warming are wrong—falls well within the range (2 to 6 mm per year) of typical coral vertical extension rates, which exhibited a modal value of 7 to 8 mm per year during the Holocene and can be more than double that value in certain branching corals (Hopley and Kinsey, 1988; Done, 1999). Second, most coral reefs are known to have successfully responded to the sea-level rises that occurred between 14,000 and 6,000 years ago—which were accompanied by large changes in “CO<sub>2</sub> concentrations, ... rainfall, cloud cover, storms and currents” (Wilkinson, 1996)—and which were more than twice as rapid as what is being predicted for the coming century (Digerfeldt and Hendry, 1987). Third, earth's oceans have undergone—and their coral reefs have survived (Chadwick-Furman, 1996)—at least 17 major cycles of sea-level rise and fall during the Pleistocene, the most recent low phase of which ended 18,000 years ago with a global sea level some 120-135 meters below where it is now (Grigg and Epp, 1989). Fourth, most coral reefs handle increases in sea level—even *rapid* increases—much better than decreases (White *et al.*, 1998). Yet even if reef vertical growth rates could not keep up with rising sea levels, that would not spell their doom.

One of the important characteristics of essentially all reef cnidarians is their ability to produce free-swimming planulae, spores, or dispersive larval stages. Kinzie (1999) notes that “no matter how quickly sea level might rise, propagules of the species could keep pace and settle at suitable depths each generation,” thereby creating what he calls jump-up reefs that “might well contain most of the species present in the original community.” Done (1999) notes that “coral communities have a history of tracking their preferred environmental niche which may suggest that as an entity, they will be predisposed to ‘adapt’ to prospective changes in environment over the next century,” citing precedents that clearly demonstrate that “coral communities have historically had a good capacity to track their re-distributed preferred physical niches.”

It is not at all surprising, therefore, as Kinzie and Buddemeier (1996) recount, that coral reefs have survived many periods of “massive environmental changes” throughout the geologic record. Reefs are survivors, they state, “because they do not simply tolerate environmental changes” but “exhibit an impressive array of acclimations” that allow them to deal with a variety of challenges to their continued existence in any given area. Hence, it is highly unlikely that anticipated increases in sea level would spell the doom of earth's coral reefs.

Strange as it may seem, rising sea levels may have a *positive* effect on earth's coral reefs (Roberts, 1993). Over the past 6,000 years, relatively stable sea levels have limited upward reef growth, resulting in the development of extensive reef flats; as Buddemeier and Smith (1988) and Wilkinson (1996) have noted, the sea-level rises predicted to result from CO<sub>2</sub>-induced global warming should actually be beneficial, permitting increased growth in these growth-restricted areas. In the words of Chadwick-Furman (1996), “many coral reefs have already reached their upward limit of growth at present sea level (Buddemeier, 1992), and may be released from this vertical constraint by a rise in sea level.” She also notes that rising sea levels may allow more water to circulate between segregated lagoons and outer reef slopes, which could “increase the exchange of coral propagules between reef habitats and lead to higher coral diversity in inner reef areas.” She, too, concludes that “coral reefs are likely to survive predicted rates of global change.”

## 8.3.2. Direct Threats

In addition to the CO<sub>2</sub>-induced indirect threats postulated to harm the world's coral reefs, as discussed in Section 8.3.1. of this document, the global increase in the atmosphere's CO<sub>2</sub> content has been hypothesized to possess the potential to harm coral reefs directly. By inducing changes in ocean water chemistry that can lead to reductions in the calcium carbonate saturation state of seawater, it has been predicted that elevated levels of atmospheric CO<sub>2</sub> may reduce rates of coral calcification, possibly leading to slower-growing—and, therefore, weaker—coral skeletons, and in some cases even death.

We begin this next section by discussing the important role biology plays in driving the physical-chemical process of coral calcification, followed by a discussion of several real-world observations that depict increasing rates of coral calcification in the face of rising temperatures and atmospheric CO<sub>2</sub> concentrations.

### 8.3.2.1. Ocean Acidification

The rate of deposition of calcium carbonate on coral reefs, or coral calcification rate, is controlled at the cellular level by the saturation state of calcium carbonate in seawater. Oceanic surface waters have likely been saturated or supersaturated in this regard—providing a good environment for coral reef growth—since early Precambrian times (Holland, 1984). Currently, however, as the air's CO<sub>2</sub> content rises in response to anthropogenic CO<sub>2</sub> emissions, more carbon dioxide dissolves in the surface waters of the world's oceans, and the pH values of the planet's oceanic waters are, or should be, gradually dropping, leading to a reduction in the calcium carbonate saturation state of seawater.

This phenomenon has been theorized to be leading to a corresponding reduction in coral calcification rates (Smith and Buddemeier, 1992; Buddemeier, 1994; Buddemeier and Fautin, 1996a,b; Holligan and Robertson, 1996; Gattuso *et al.*, 1998; Buddemeier and Smith, 1999; IPCC, 2007-I, 2007-II; De'ath *et al.*, 2009), which reduction has been hypothesized to be rendering corals more susceptible to a number of other environmental stresses, including “sea-level rise, extreme temperatures, human damage (from mining, dredging, fishing and tourism), and changes in salinity and pollutant concentrations (nutrients, pesticides, herbicides and

particulates), and in ocean currents, ENSO, and storm damage” (Pittock, 1999). Kleypas *et al.* (1999), for example, have calculated that calcification rates of tropical corals should already have declined by 6 percent to 11 percent or more since 1880, as a result of the concomitant increase in atmospheric CO<sub>2</sub> concentration, and they predict that the reductions could reach 17 percent to 35 percent by 2100. Likewise, Langdon *et al.* (2000) calculated a decrease in coral calcification rate of up to 40 percent between 1880 and 2065.

The ocean chemistry aspect of this theory is rather straightforward, but it certainly is not as solid as some commentators make it out to be. In evaluating global seawater impacts of model-predicted global warming and direct seawater chemical consequences of a doubling of the air’s CO<sub>2</sub> content, Loaiciga (2006) used a mass-balance approach to “estimate the change in average seawater salinity caused by the melting of terrestrial ice and permanent snow in a warming earth.” He applied “a chemical equilibrium model for the concentration of carbonate species in seawater open to the atmosphere” in order to “estimate the effect of changes in atmospheric CO<sub>2</sub> on the acidity of seawater.” Assuming that the rise in the planet’s mean surface air temperature continues unabated, and that it eventually causes the melting of all terrestrial ice and permanent snow, Loaiciga calculated that “the average seawater salinity would be lowered not more than 0.61% from its current 35%.” He also reports that across the range of seawater temperature considered (0° to 30°C), “a doubling of CO<sub>2</sub> from 380 ppm to 760 ppm increases the seawater acidity [lowers its pH] approximately 0.19 pH units.” He thus concludes that “on a global scale and over the time scales considered (hundreds of years), there would not be accentuated changes in either seawater salinity or acidity from the rising concentration of atmospheric CO<sub>2</sub>.”

Furthermore, with more CO<sub>2</sub> in the air, additional weathering of terrestrial carbonates is likely to occur, which would increase delivery of Ca<sup>2+</sup> to the oceans and partly compensate for the CO<sub>2</sub>-induced decrease in oceanic calcium carbonate saturation state (Riding, 1996). And as with all phenomena involving living organisms, the introduction of *life* into the ocean acidification picture greatly complicates things. Considerations of a suite of interrelated biological phenomena, for example, also make it much more difficult to draw such sweeping negative conclusions as are currently being discussed. Indeed, as shown in

the next section, they even suggest that the rising CO<sub>2</sub> content of earth’s atmosphere may be a positive phenomenon, enhancing the growth rates of coral reefs and helping them to better withstand the many environmental stresses that truly are inimical to their well-being.

### 8.3.2.1.1. Role of Biology

Over half a century ago, Kawaguti and Sakumoto (1948) illustrated the important role played by photosynthesis in the construction of coral reefs. They analyzed numerous datasets recorded in several earlier publications, demonstrating that coral calcification rates are considerably higher in the daylight (when photosynthesis by coral symbionts occurs) than they are in the dark (when the symbionts lose carbon via respiration). A number of more modern studies have also demonstrated that symbiont photosynthesis enhances coral calcification (Barnes and Chalker, 1990; Yamashiro, 1995); and they have further demonstrated that long-term reef calcification rates generally rise in direct proportion to increases in rates of reef primary production (Frankignoulle *et al.*, 1996; Gattuso *et al.*, 1996, 1999). The work of Muscatine (1990) suggests that “the photosynthetic activity of zooxanthellae is the chief source of energy for the energetically expensive process of calcification” (Hoegh-Guldberg, 1999). Consequently, if an anthropogenic-induced increase in the transfer of CO<sub>2</sub> from the atmosphere to the world’s oceans, i.e., hydrospheric CO<sub>2</sub> enrichment, were to lead to increases in coral symbiont photosynthesis—as atmospheric CO<sub>2</sub> enrichment does for essentially all terrestrial plants (Kimball, 1983; Idso, 1992)—it is likely that increases in coral calcification rates would occur as well.

There are several reasons for expecting a positive coral calcification response to CO<sub>2</sub>-enhanced symbiont photosynthesis. One of the first mechanisms to come to mind is the opposite of the phenomenon that has been proffered as a cause of future declines in coral calcification rates. This reverse phenomenon is the decrease in extracellular CO<sub>2</sub> partial pressure in coral tissues that is driven by the drawdown of aqueous CO<sub>2</sub> caused by the photosynthetic process. With CO<sub>2</sub> being removed from the water in intimate contact with the coral host via its fixation by photosynthesis (which CO<sub>2</sub> drawdown is of greater significance to the coral than the increase in the CO<sub>2</sub> content of the surrounding bulk water that is affected by the ongoing rise in the air’s CO<sub>2</sub> content), the pH and calcium carbonate saturation state of the water immediately surrounding the coral host should *rise* (Goreau, 1959), enhancing the coral’s calcification rate (Gattuso *et al.*, 1999). If hydrospheric CO<sub>2</sub> enrichment stimulates zooxanthellae photosynthesis to the same degree that atmospheric CO<sub>2</sub> enrichment stimulates photosynthesis in terrestrial plants, i.e., by 30 percent to 50 percent for a 300 ppm increase in CO<sub>2</sub> concentration (Kimball, 1983; Idso 1992, Idso and Idso, 1994), this phenomenon alone would more than compensate for the drop in the calcium carbonate saturation state of the bulk-water of the world’s oceans produced by the ongoing rise in the air’s CO<sub>2</sub> content, which Gattuso *et al.* (1999) have calculated could lead to a 15 percent reduction in coral calcification rate for a doubling of the pre-industrial atmospheric CO<sub>2</sub> concentration.

Another reason why coral calcification may proceed at a higher rate in the presence of CO<sub>2</sub>-stimulated symbiont photosynthesis is that, while growing more robustly, the zooxanthellae may take up more of the metabolic waste products of the coral host, which, if present in too great quantities, can prove detrimental to the health of the host, as well as the health of the entire coral plant-animal assemblage (Yonge, 1968; Crossland and Barnes, 1974). There are also a number of other substances that are known to directly interfere with calcium carbonate precipitation; they too can be actively removed from the water by coral symbionts in much the same way that symbionts remove host waste products (Simkiss, 1964). More importantly, perhaps, a greater amount of symbiont-produced photosynthates may provide more fuel for the active transport processes involved in coral calcification (Chalker and Taylor, 1975), as well as more raw materials for the synthesis of the coral organic matrix (Wainwright, 1963; Muscatine,

1967; Battey and Patton, 1984). Finally, the photosynthetic process helps to maintain a healthy aerobic or oxic environment for the optimal growth of the coral animals (Rinkevich and Loya, 1984; Rands *et al.*, 1992); greater CO<sub>2</sub>-induced rates of symbiont photosynthesis would enhance this important “environmental protection activity.”

Such observations invoke a number of questions. With ever more CO<sub>2</sub> going into the air, driving ever more CO<sub>2</sub> into the oceans, might we not logically expect to see increasingly greater rates of coral symbiont photosynthesis, due to the photosynthesis-stimulating effect of hydrospheric CO<sub>2</sub> enrichment? Would not this phenomenon, in turn, increasingly enhance all of the many positive photosynthesis-dependent phenomena we have described and thereby increase coral calcification rates? And might it not increase these rates well beyond the point of overpowering the modest negative effect of the purely chemical consequences of elevated dissolved CO<sub>2</sub> on ocean pH and calcium carbonate saturation state?

The answers to these several questions are probably all “yes,” but arriving at these conclusions is not as simple as it sounds. For one thing, although many types of marine plant life do indeed respond to hydrospheric CO<sub>2</sub> enrichment (Raven *et al.*, 1985)—including seagrasses (Zimmerman *et al.*, 1997), certain diatoms (Riebesell *et al.*, 1993; Chen and Gao, 2004; Sobrino *et al.*, 2008), macroalgae (Borowitzka and Larkum, 1976; Gao *et al.*, 1993), and microalgae or phytoplankton (Raven, 1991; Nimer and Merrett, 1993)—the photosynthesis of many marine autotrophs is normally not considered to be carbon-limited, because of the large supply of bicarbonate in the world’s oceans (Raven, 1997). However, as Gattuso *et al.* (1999) explain, this situation is true only for autotrophs that possess an effective carbon-concentrating mechanism; it is believed that many coral symbionts are of this type (Burris *et al.*, 1983; Al-Moghrabi *et al.*, 1996; Goiran *et al.*, 1996).

Nevertheless, in yet another positive twist to this complex story, Gattuso *et al.* (1999) report that coral zooxanthellae are able to change their mechanism of carbon supply in response to various environmental stimuli. Furthermore, Beardall *et al.* (1998) suggest that an increased concentration of dissolved CO<sub>2</sub>, together with an increase in the rate of CO<sub>2</sub> generation by bicarbonate dehydration in host cells, may favor a transition to the diffusional mode of carbon supply, which *is* sensitive to hydrospheric CO<sub>2</sub> concentration. Consequently, if such a change in mode of carbon supply were to occur—prompted,

perhaps, by hydrospheric CO<sub>2</sub> enrichment itself—this shift in CO<sub>2</sub> fixation strategy would indeed allow the several biological mechanisms we have described to operate to enhance reef calcification rates in response to a rise in the air’s CO<sub>2</sub> content.

In one final example that demonstrates the importance of biology in driving the physical-chemical process of coral calcification, Muscatine *et al.* (2005) note that the “photosynthetic activity of zooxanthellae is the chief source of energy for the energetically expensive process of calcification,” and that long-term reef calcification rates have generally been observed to rise in direct proportion to increases in rates of reef primary production, which they say may well be *enhanced* by increases in the air’s CO<sub>2</sub> concentration.

Muscatine *et al.* begin the report of their investigation of the subject by stating much the same thing, i.e., that endosymbiotic algae “release products of photosynthesis to animal cells ... and augment the rate of skeletal calcification.” Then, noting that the “natural abundance of stable isotopes ( $\delta^{13}\text{C}$  and  $\delta^{15}\text{N}$ ) has answered paleobiological and modern questions about the effect of photosymbiosis on sources of carbon and oxygen in coral skeletal calcium carbonate,” they go on to investigate the natural abundance of these isotopes in another coral skeletal compartment—the skeletal organic matrix (OM)—in 17 species of modern scleractinian corals, after which they compare the results for symbiotic and nonsymbiotic forms to determine the role played by algae in OM development.

Why is this study an important scientific undertaking? It is because, in the words of Muscatine *et al.*, “the scleractinian coral skeleton is a two-phase composite structure consisting of fiber-like crystals of aragonitic calcium carbonate intimately associated with an intrinsic OM,” and although the OM generally comprises less than 0.1 percent of the total weight of the coral skeleton, it is, in their words, “believed to initiate nucleation of calcium carbonate and provide a framework for crystallographic orientation and species-specific architecture.” In fact, they say inhibition of OM synthesis “brings coral calcification to a halt.”

So what did Muscatine *et al.* learn from their experiments? They say their “most striking observation is the significant difference in mean OM  $\delta^{15}\text{N}$  between symbiotic and nonsymbiotic corals,” which makes OM  $\delta^{15}\text{N}$  an important proxy for photosymbiosis. As an example of its usefulness, they applied the technique to a fossil coral (*Pachytheclis*

*major*) from the Triassic (which prevailed some 240 million years ago), finding that the ancient coral was indeed photosymbiotic. Even more importantly, however, they conclude in the final sentence of their paper that “it now seems that symbiotic algae may control calcification by both modification of physico-chemical parameters within the coral polyps (Gautret *et al.*, 1997; Cuif *et al.*, 1999) and augmenting the synthesis of OM (Allemand *et al.*, 1998).”

Although lacking the research to absolutely identify the “what” and definitively describe the “how” of the hypothesis of hydrospheric CO<sub>2</sub> enhancement of coral calcification, it is clear that something of the nature described above can indeed act to overcome the negative effect of the high-CO<sub>2</sub>-induced decrease in calcium carbonate saturation state on coral calcification rate. It has been clearly demonstrated, for example, that corals can grow quite well in aquariums containing water of very high dissolved CO<sub>2</sub> concentration (Atkinson *et al.*, 1995); and Carlson (1999) has stated that the fact that corals often thrive in such water “seems to contradict conclusions ... that high CO<sub>2</sub> may inhibit calcification.” There are numerous other examples of such phenomena in the real world of nature, which we examine next.

### 8.3.2.1.2. Coral Calcification

Many people have predicted that rates of coral calcification, as well as the photosynthetic rates of their symbiotic algae, will dramatically decline in response to what they typically refer to as an acidification of the world's oceans, as the atmosphere's CO<sub>2</sub> concentration continues to rise in

the years, decades, and centuries to come. As ever more pertinent evidence accumulates, however, the true story appears to be just the opposite.

Herfort *et al.* (2008) note that an increase in atmospheric CO<sub>2</sub> will cause an increase in the abundance of HCO<sub>3</sub><sup>-</sup> (bicarbonate) ions and dissolved CO<sub>2</sub>, and they also report that several studies on marine plants have observed “increased photosynthesis with higher than ambient DIC [dissolved inorganic carbon] concentrations,” citing the works of Gao *et al.* (1993), Weis (1993), Beer and Rehnberg (1997), Marubini and Thake (1998), Mercado *et al.* (2001, 2003), Herfort *et al.* (2002), and Zou *et al.* (2003).

To further explore this subject, and to see what it might imply for coral calcification, the three researchers employed a wide range of bicarbonate concentrations “to monitor the kinetics of bicarbonate use in both photosynthesis and calcification in two reef-building corals, *Porites porites* and *Acropora* sp.” This work revealed that additions of HCO<sub>3</sub><sup>-</sup> to synthetic seawater continued to increase the calcification rate of *Porites porites* until the bicarbonate concentration exceeded three times that of seawater, while photosynthetic rates of the coral’s symbiotic algae were stimulated by HCO<sub>3</sub><sup>-</sup> addition until they became saturated at twice the normal HCO<sub>3</sub><sup>-</sup> concentration of seawater.

Similar experiments conducted on Indo-Pacific *Acropora* sp. showed that calcification and photosynthetic rates in these corals were enhanced to an even greater extent, with calcification continuing to increase above a quadrupling of the HCO<sub>3</sub><sup>-</sup> concentration and photosynthesis saturating at triple the concentration of seawater. In addition, they monitored calcification rates of the *Acropora* sp. in the dark, and, in their words, “although these were lower than in the light for a given HCO<sub>3</sub><sup>-</sup> concentration, they still increased dramatically with HCO<sub>3</sub><sup>-</sup> addition, showing that calcification in this coral is light stimulated but not light dependent.”

In discussing the significance of their findings, Herfort *et al.* suggest that “hermatypic corals incubated in the light achieve high rates of calcification by the synergistic action of photosynthesis,” which, as they have shown, is enhanced by elevated concentrations of HCO<sub>3</sub><sup>-</sup> ions that come courtesy of the ongoing rise in the air’s CO<sub>2</sub> content. As for the real-world implications of their work, the three researchers note that over the next century the predicted increase in atmospheric CO<sub>2</sub> concentration “will result in about a 15%

increase in oceanic HCO<sub>3</sub><sup>-</sup>,” and they say that this development “could stimulate photosynthesis and calcification in a wide variety of hermatypic corals,” a conclusion that stands in stark contrast to the contention of the IPCC.

In another study, Pelejero *et al.* (2005) developed a reconstruction of seawater pH spanning the period 1708-1988, based on the boron isotopic composition (δ<sup>11</sup>B) of a long-lived massive coral (*Porites*) from Flinders Reef in the western Coral Sea of the southwestern Pacific. Results indicated that “there [was] no notable trend toward lower δ<sup>11</sup>B values” over the 300-year period investigated. Instead, they say that “the dominant feature of the coral δ<sup>11</sup>B record is a clear interdecadal oscillation of pH, with δ<sup>11</sup>B values ranging between 23 and 25 per mil (7.9 and 8.2 pH units),” which “is synchronous with the Interdecadal Pacific Oscillation.” Furthermore, they calculated changes in aragonite saturation state from the Flinders pH record that varied between ~3 and 4.5, which values encompass “the lower and upper limits of aragonite saturation state within which corals can survive.” Despite this fact, they report that “skeletal extension and calcification rates for the Flinders Reef coral fall within the normal range for *Porites* and are not correlated with aragonite saturation state or pH.”

Thus, contrary to claims that historical anthropogenic CO<sub>2</sub> emissions have already resulted in a significant decline in ocean water pH and aragonite saturation state, Pelejero *et al.*’s 300-year record of these parameters (which, in their words, began “well before the start of the Industrial Revolution”) provides no evidence of such a decline. What is more, and also contrary to what one would expect from claims of how sensitive coral calcification rate is to changes in pH and aragonite saturation state, they found that huge cyclical changes in these parameters had essentially no detectable effect on either coral calcification or skeletal extension rates.

Moving a little backward in time, in a study of historical calcification rates determined from coral cores retrieved from 35 sites on the Great Barrier Reef, Lough and Barnes (1997) observed a statistically significant correlation between coral calcification rate and local water temperature, such that a 1°C increase in mean annual water temperature increased mean annual coral calcification rate by about 3.5 percent. Nevertheless, they report there were “declines in calcification in *Porites* on the Great Barrier Reef over recent decades.” They are quick to point out, however, that their data depict several

extended periods of time when coral growth rates were either above or below the long-term mean, cautioning that “it would be unwise to rely on short-term values (say averages over less than 30 years) to assess mean conditions.”

As an example of this fact, they report that “a decline in calcification equivalent to the recent decline occurred earlier this century and much greater declines occurred in the 18th and 19th centuries,” long before anthropogenic CO<sub>2</sub> emissions made much of an impact on the air’s CO<sub>2</sub> concentration. Over the entire expanse of their dataset, Lough and Barnes say “the 20th century has witnessed the second highest period of above average calcification in the past 237 years,” which is not exactly what one would expect in light of (1) how dangerous high water temperatures are often said to be for corals, (2) the claim that earth is currently warmer than it has been at any other time during the entire past millennium, and (3) the fact that the air’s CO<sub>2</sub> content is currently much higher than it has been for far longer than a mere thousand years.

Similar findings were reported by Bessat and Buigues (2001), who derived a history of coral calcification rates from a core extracted from a massive *Porites* coral head on the French Polynesian island of Moorea that covered the period 1801-1990. They performed this work, they say, because “recent coral-growth models highlight the enhanced greenhouse effect on the decrease of calcification rate,” and rather than relying on theoretical calculations, they wanted to work with real-world data, stating that the records preserved in ancient corals “may provide information about long-term variability in the performance of coral reefs, allowing unnatural changes to be distinguished from natural variability.”

Bessat and Buigues found that a 1°C increase in water temperature *increased* coral calcification rates at the site they studied by 4.5 percent. Then, they found that “instead of a 6-14% decline in calcification over the past 100 years computed by the Kleypas group, the calcification has increased, in accordance with [the results of] Australian scientists Lough and Barnes.” They also observed patterns of “jumps or stages” in the record, which were characterized by an increase in the annual rate of calcification, particularly at the beginning of the past century “and in a more marked way around 1940, 1960 and 1976,” stating once again that their results “do not confirm those predicted by the Kleypas *et al.* (1999) model.”

Another major blow to the Kleypas *et al.* model was provided by the work of Lough and Barnes

(2000), who assembled and analyzed the calcification characteristics of 245 similar-sized massive colonies of *Porites* corals obtained from 29 reef sites located along the length, and across the breadth, of Australia’s Great Barrier Reef (GBR), which data spanned a latitudinal range of approximately 9° and an annual average sea surface temperature (SST) range of 25-27°C. To these data they added other published data from the Hawaiian Archipelago (Grigg, 1981, 1997) and Phuket, Thailand (Scoffin *et al.*, 1992), thereby extending the latitudinal range of the expanded dataset to 20° and the annual average SST range to 23-29°C.

This analysis revealed that the GBR calcification data were linearly related to the average annual SST data, such that “a 1°C rise in average annual SST increased average annual calcification by 0.39 g cm<sup>-2</sup> year<sup>-1</sup>.” Results were much the same for the extended dataset; Lough and Barnes report that “the regression equation [calcification = 0.33(SST)—7.07] explained 83.6% of the variance in average annual calcification (F = 213.59, p less than 0.00),” noting that “this equation provides for a change in calcification rate of 0.33 g cm<sup>-2</sup> year<sup>-1</sup> for each 1°C change in average annual SST.”

With respect to the significance of their findings, Lough and Barnes say they “allow assessment of possible impacts of global climate change on coral reef ecosystems,” and between the two 50-year periods 1880-1929 and 1930-1979, they calculate a calcification increase of 0.06 g cm<sup>-2</sup> year<sup>-1</sup>, noting that “this increase of ~4% in calcification rate conflicts with the estimated decrease in coral calcification rate of 6-14% over the same time period suggested by Kleypas *et al.* (1999) as a response to changes in ocean chemistry.” Even more stunning is their observation that between the two 20-year periods 1903-1922 and 1979-1998, “the SST-associated increase in calcification is estimated to be less than 5% in the northern GBR, ~12% in the central GBR, ~20% in the southern GBR and to increase dramatically (up to ~50%) to the south of the GBR.”

In light of these real-world observations, and in stark contrast to the doom-and-gloom prognostications of the IPCC, Lough and Barnes conclude that coral calcification rates “may have already significantly increased along the GBR in response to global climate change.”

But in *Nature*, Caldeira and Wickett (2003) kept the catastrophe ball rolling. Based on a geochemical model, an ocean general-circulation model, an IPCC CO<sub>2</sub> emissions scenario for the twenty-first century,

and a logistic function for the burning of earth's post-twenty-first century fossil-fuel reserves, they calculated the maximum level to which the air's CO<sub>2</sub> concentration might rise, the point in time when that might happen, and the related decline that might be expected to occur in ocean-surface pH. These calculations indicated that earth's atmospheric CO<sub>2</sub> concentration could approach 2,000 ppm around the year 2300, leading to an ocean-surface pH reduction of 0.7 units, a change described by Caldeira and Wickett as being much more rapid and considerably greater "than any experienced in the past 300 million years," which, of course, proves deadly for earth's corals in their scenario.

The following year, similar concerns were aroused by a report prepared for the Pew Center on Global Climate Change, a group advocating immediate action on global warming. In that document, Buddemeier *et al.* (2004) claimed the projected increase in the air's CO<sub>2</sub> content and the simulated decline in ocean-surface pH would dramatically decrease coral calcification rates, which they predicted would lead to "a slow-down or reversal of reef-building and the potential loss of reef structures." Even Buddemeier *et al.* (2004), however, were forced to admit that "calcification rates of large heads of the massive coral *Porites* increased rather than decreased over the latter half of the 20th century," further noting that "temperature and calcification rates are correlated, and these corals have so far responded more to increases in water temperature (growing faster through increased metabolism and the increased photosynthetic rates of their zooxanthellae) than to decreases in carbonate ion concentration."

The most recent claims of impending coral doom derive from the 2009 *Science* study of De'ath *et al.* (2009), who examined coral calcification rates on the Great Barrier Reef over the past 400 years. Results of their analysis indicate that there was a 14 percent decline in *Porites* calcification rate between 1990 and 2005, which observation the authors claim "is unprecedented in at least the past 400 years." As one might expect, the media's coverage of these findings included some ominous declarations. The headline of a BBC News report, for example, proclaimed "coral reef growth is slowest ever," while a Sky News headline read "Barrier Reef coral growth 'will stop'." ABC News went so far as to state *when* it might stop, concluding their report by quoting the research paper's senior author as saying "coral growth could hit zero by 2050."

How correct are such claims? Beginning with the first media claim that "coral reef growth is slowest ever," it can't possibly be right. The scleractinian corals, which are the major builders of the reefs of today, have been around some 200 million years, during most of which time the atmosphere's CO<sub>2</sub> concentration was greater and its temperature was higher than today, which should immediately raise a red flag about the proffered cause of the recent decline in reef growth.

In regard to the recent decline in calcification being unprecedented in the past 400 years, this is a good example of cherry-picking a time frame to make a sensational claim. All one needs to do is follow the published De'ath *et al.* calcification history back in time a mere 33 years more, from 1605 to 1572, to see the coral calcification rate during that earlier time was approximately 23 percent lower than what it was at its twentieth century peak, and the air's CO<sub>2</sub> concentration was more than 100 ppm less than what it is today.

Another way of looking at De'ath *et al.*'s data is to realize that from 1572 to the twentieth century peak, *Porites* calcification rates on the Great Barrier Reef rose by about 29 percent as atmospheric CO<sub>2</sub> concentration and air temperature rose concurrently, after which calcification rates declined, but by a smaller 14 percent. Why would anyone believe that the recent calcification decline implies that *Porites* coral growth "will stop," and that the end will come "by 2050"? They believe it because certain scientists (such as James Hansen) and politicians (such as Al Gore) imply much the same thing, as even De'ath *et al.* do. But when scientists feel compelled to be as correct and as true to their data as possible, such as when writing in *Science*, the three researchers from the Australian Institute of Marine Science clearly state that "the causes for the Great Barrier Reef-wide decline in coral calcification of massive *Porites* remain unknown." And when the causes of the recent decline in coral calcification rate are admitted to be unknown, it seems foolish indeed to predict, not only that the decline will continue, but that it will lead all the way to the demise of the studied coral, and especially at a specified future date, which, we might add, De'ath *et al.* appropriately do not do in their *Science* paper.

A second good reason for not believing that the ongoing rise in the air's CO<sub>2</sub> content will lead to reduced oceanic pH and, therefore, lower calcification rates in the world's coral reefs, is that the same phenomenon that powers the twin processes of coral

calcification and phytoplanktonic growth (photosynthesis) tends to increase the pH of marine waters (Gnaiger *et al.*, 1978; Santhanam *et al.*, 1994; Brussaard *et al.*, 1996; Lindholm and Nummelin, 1999; Macedo *et al.*, 2001; Hansen, 2002). This phenomenon has been shown to have the ability to dramatically increase the pH of marine bays, lagoons, and tidal pools (Gnaiger *et al.*, 1978; Macedo *et al.*, 2001; Hansen, 2002) as well as to significantly enhance the surface water pH of areas as large as the North Sea (Brussaard *et al.*, 1996).

In one recent example, Middelboe and Hansen (2007) studied the pH of a wave-exposed boulder reef in Aalsgaarde on the northern coast of Zealand, Denmark, and a sheltered shallow-water area in Kildebakkerne in the estuary Roskilde Fjord, Denmark, reporting that, in line with what one would expect if photosynthesis tends to increase surface-water pH, (1) “daytime pH was significantly higher in spring, summer and autumn than in winter at both study sites,” often reaching values of 9 or more during peak summer growth periods vs. 8 or less in winter, (2) “diurnal measurements at the most exposed site showed significantly higher pH during the day than during the night,” reaching values that sometimes exceeded 9 during daylight hours but that typically dipped below 8 at night, and (3) that “diurnal variations were largest in the shallow water and decreased with increasing water depth.”

In addition to their own findings, Middelboe and Hansen cite those of Pearson *et al.* (1998), who found that pH averaged about 9 during the summer in populations of *Fucus vesiculosus* in the Baltic Sea; Menendez *et al.* (2001), who found that maximum pH was 9 to 9.5 in dense floating macroalgae in a brackish coastal lagoon in the Ebro River Delta; and Bjork *et al.* (2004), who found pH values as high as 9.8 to 10.1 in isolated rock pools in Sweden. Noting that “pH in the sea is usually considered to be stable at around 8 to 8.2,” the two Danish researchers thus concluded that “pH is higher in natural shallow-water habitats than previously thought.”

With each succeeding year, the physical evidence against the CO<sub>2</sub>-reduced calcification theory continues to grow ever more compelling, while support for the positive view promoted here continues to accumulate. Working in the laboratory, for example, Reynaud *et al.* (2004) grew nubbins of the branching zooxanthellate scleractinian coral *Acropora verweyi* in aquariums maintained at 20°, 25°, and 29°C, while weighing them once a week over a period of four weeks. This exercise revealed that coral

calcification rates increased in nearly perfect linear fashion with increasing water temperature, yielding values of 0.06 percent, 0.22 percent, and 0.35 percent per day at 20°, 25°, and 29°C, respectively. These data reveal an approximate 480 percent increase in calcification rate in response to a 9°C increase in water temperature and a 160 percent increase in response to a 3°C increase in temperature, the latter of which temperature increases is somewhere in the low to midrange of global warming that the IPCC claims will result from a 300 ppm increase in the air’s CO<sub>2</sub> concentration. This positive temperature effect outweighs the negative effect of rising CO<sub>2</sub> concentrations on coral calcification via ocean acidification.

Carricart-Ganivet (2004) developed relationships between coral calcification rate and annual average SST based on data collected from colonies of the reef-building coral *Montastraea annularis* at 12 localities in the Gulf of Mexico and the Caribbean Sea, finding that calcification rate in the Gulf of Mexico increased 0.55 g cm<sup>-2</sup> year<sup>-1</sup> for each 1°C increase, while in the Caribbean Sea it increased 0.58 g cm<sup>-2</sup> year<sup>-1</sup> for each 1°C increase. Pooling these data with those of *M. annularis* and *M. faveolata* growing to a depth of 10 m at Carrie Bow Cay, Belize, those from reefs at St. Croix in the US Virgin Islands, and those of *M. faveolata* growing to a depth of 10 m at Curacao, Antilles, Carricart-Ganivet reports he obtained a mean increase in calcification rate of ~0.5 g cm<sup>-2</sup> year<sup>-1</sup> for each 1°C increase in annual average SST, which is even greater than what was found by Lough and Barnes for *Porites* corals.

In another important study, McNeil *et al.* (2004) used a coupled atmosphere-ice-ocean carbon cycle model to calculate annual mean SST increases within the world’s current coral reef habitat from 1995 to 2100 for increases in the air’s CO<sub>2</sub> concentration specified by the IPCC’s IS92a scenario, after which concomitant changes in coral reef calcification rates were estimated by combining the output of the climate model with empirical relationships between coral calcification rate and (1) aragonite saturation state (the negative CO<sub>2</sub> effect) and (2) annual SST (the positive temperature effect). Their choice for the first of these two relationships was that derived by Langdon *et al.* (2000), which leads to an even greater reduction in calcification than was predicted in the study of Kleypas *et al.* Their choice for the second relationship was that derived by Lough and Barnes (2000), which leads to an increase in calcification that is only half as large as that derived by Carricart-

Ganivet (2004). As a result, it can be appreciated that the net result of the two phenomena was doubly weighted in favor of reduced coral calcification. Nevertheless, McNeil *et al.* found that the increase in coral reef calcification associated with ocean warming outweighed the decrease associated with the CO<sub>2</sub>-induced decrease in aragonite saturate state. They calculated that coral calcification in 2100 would be 35 percent higher than what it was in pre-industrial times at the very least. And they found that the area of coral reef habitat expands in association with the projected ocean warming.

Finally, in a study devoted to corals that involves a much longer period of time than all of the others we have discussed, Crabbe *et al.* (2006) determined the original growth rates of long-dead Quaternary corals found in limestone deposits on islands in the Wakatobi Marine National Park of Indonesia, after which they compared them to the growth rates of present-day corals of the same genera living in the same area. This work revealed that the Quaternary corals grew “in a comparable environment to modern reefs”—except, of course, for the air’s CO<sub>2</sub> concentration, which is currently higher than it has been at any other time throughout the Quaternary, which spans the past 1.8 million years. Most interestingly, therefore, their measurements indicated that the radial growth rates of the modern corals were 31 percent greater than those of their ancient predecessors in the case of *Porites* species, and 34 percent greater in the case of *Favites* species.

To these papers we could add many others (Clausen and Roth, 1975; Coles and Jokiel, 1977; Kajiwara *et al.*, 1995; Nie *et al.*, 1997; Reynaud-Vaganay *et al.*, 1999; Reynaud *et al.*, 2007) that also depict increasing rates of coral calcification in the face of rising temperatures and atmospheric CO<sub>2</sub> concentrations. Clearly, the net impact of twentieth century increases in atmospheric CO<sub>2</sub> and temperature has not been anywhere near as catastrophically disruptive to earth’s corals as the IPCC suggests it should have been. Quite to the contrary, the temperature and CO<sub>2</sub> increases appear to not have been hurtful at all, and in fact appear to have been helpful.

Additional information on this topic, including reviews of newer publications as they become available, can be found at <http://www.co2science.org/subject/c/calcification.php>.

### 8.3.2.1.3. Other Marine Organisms

In a paper recently published in *Limnology and Oceanography*, Richardson and Gibbons (2008) say there has been a drop of 0.1 pH unit in the global ocean since the start of the Industrial Revolution, and that “such acidification of the ocean may make calcification more difficult for calcareous organisms,” resulting in the “opening [of] ecological space for non-calcifying species.” In line with this thinking, they report that Attrill *et al.* (2007) have argued that “jellyfish may take advantage of the vacant niches made available by the negative effects of acidification on calcifying plankton,” causing jellyfish to become more abundant, and they note that the latter researchers provided some evidence for this effect in the west-central North Sea over the period 1971-1995. Hence, they undertook a study to see if Attrill *et al.*'s findings (which were claimed to be the first of their kind) could be replicated on a much larger scale.

Working with data from a larger portion of the North Sea, as well as throughout most of the much vaster Northeast Atlantic Ocean, Richardson and Gibbons used coelenterate (jellyfish) records from the Continuous Plankton Recorder (CPR) and pH data from the International Council for the Exploration of the Sea (ICES) for the period 1946-2003 to explore

the possibility of a relationship between jellyfish abundance and acidic ocean conditions. This work revealed that there were, as they describe it, “no significant relationships between jellyfish abundance and acidic conditions in any of the regions investigated.”

In harmony with their findings, the two researchers note that “no observed declines in the abundance of calcifiers with lowering pH have yet been reported.” In addition, they write that the “larvae of sea urchins form skeletal parts comprising magnesium-bearing calcite, which is 30 times more soluble than calcite without magnesium,” and, therefore, that “lower ocean pH should drastically inhibit the formation of these soluble calcite precursors.” Yet they report that “there is no observable negative effect of pH.” In fact, they say that echinoderm larvae in the North Sea have actually exhibited “a 10-fold increase [our italics] in recent times,” which they say has been “linked predominantly to warming (Kirby *et al.*, 2007).” Likewise, they further note that even in the most recent IPCC report, “there was no empirical evidence reported for the effect of acidification on marine biological systems (Rosenzweig *et al.*, 2007).” In light of this body of real-world evidence, Richardson and Gibbons conclude (rather generously, we think) that “the role of pH in structuring zooplankton communities in the North Sea and further afield at present is tenuous.”

In another study, Vogt *et al.* (2008) examined the effects of atmospheric CO<sub>2</sub> enrichment on various marine microorganisms in nine marine mesocosms in a fjord adjacent to the Large-Scale Facilities of the Biological Station of the University of Bergen in Espesgrend, Norway. Three of the mesocosms were maintained at ambient levels of CO<sub>2</sub> (~375 ppm), three were maintained at levels expected to prevail at the end of the current century (760 ppm or 2x CO<sub>2</sub>), and three were maintained at levels predicted for the middle of the next century (1,150 ppm or 3x CO<sub>2</sub>), while measurements of numerous ecosystem parameters were made over a period of 24 days.

Results of the analysis showed no significant phytoplankton species shifts between treatments, and that “the ecosystem composition, bacterial and phytoplankton abundances and productivity, grazing rates and total grazer abundance and reproduction were not significantly affected by CO<sub>2</sub> induced effects,” citing in support of this statement the work of Riebesell *et al.* (2007), Riebesell *et al.* (2008), Egge *et al.* (2007), Paulino *et al.* (2007), Larsen *et al.*

(2007), Suffrian *et al.* (2008), and Carotenuto *et al.* (2007). With respect to their many findings, the eight researchers say their observations suggest that “the system under study was surprisingly resilient to abrupt and large pH changes.”

Expanding the subject of CO<sub>2</sub> effects on other marine organisms, Gutowska *et al.* (2008) studied the cephalopod mollusk *Sepia officinalis* and found that it “is capable of not only maintaining calcification, but also growth rates and metabolism when exposed to elevated partial pressures of carbon dioxide.” Over a six-week test period, for example, they found that “juvenile *S. officinalis* maintained calcification under ~4000 and ~6000 ppm CO<sub>2</sub>, and grew at the same rate with the same gross growth efficiency as did control animals,” gaining approximately 4 percent body mass daily and increasing the mass of their calcified cuttlebone by more than 500 percent. These findings thus led them to specifically conclude that “active cephalopods possess a certain level of pre-adaptation to long-term increments in carbon dioxide levels,” and to generally conclude that our “understanding of the mechanistic processes that limit calcification must improve before we can begin to predict what effects future ocean acidification will have on calcifying marine invertebrates.”

In another study, Berge *et al.* (2006) continuously supplied five 5-liter aquariums with low-food-content sea water that was extracted from the top meter of the Oslofjord outside the Marine Research Station Solbergstrand in Norway, while CO<sub>2</sub> was continuously added to the waters of the aquaria so as to maintain them at five different pH values (means of 8.1, 7.6, 7.4, 7.1, and 6.7) for a period of 44 days. Prior to the start of the study, blue mussels (*Mytilus edulis*) of two different size classes (mean lengths of either 11 or 21 mm) were collected from the outer part of the Oslofjord, and 50 of each size class were introduced into each aquarium, where they were examined almost daily for any deaths that may have occurred, after which shell lengths at either the time of death or at the end of the study were determined and compared to lengths measured at the start of the study. Simultaneously, water temperature rose slowly from 16° to 19°C during the initial 23 days of the experiment, but then declined slightly to day 31, after which it rose rapidly to attain a maximum value of 24°C on day 39.

A lack of mortality during the first 23 days of the study showed, in the words of the researchers, that “the increased concentration of CO<sub>2</sub> in the water and the correspondingly reduced pH had no acute effects

on the mussels.” Thereafter, however, some mortality was observed in the highest CO<sub>2</sub> (lowest pH) treatment from day 23 to day 37, after which deaths could also be observed in some of the other treatments, which mortality Berge *et al.* attributed to the rapid increase in water temperature that occurred between days 31 and 39.

With respect to growth, the Norwegian researchers report that “mean increments of shell length were much lower for the two largest CO<sub>2</sub> additions compared to the values in the controls, while for the two smallest doses the growth [was] about the same as in the control, or in one case even higher (small shells at pH = 7.6),” such that there were “no significant differences between the three aquaria within the pH range 7.4-8.1.”

Berge *et al.* say their results “indicate that future reductions in pH caused by increased concentrations of anthropogenic CO<sub>2</sub> in the sea may have an impact on blue mussels,” but that “comparison of estimates of future pH reduction in the sea (Caldeira and Wickett, 2003) and the observed threshold for negative effects on growth of blue mussels [which they determined to lie somewhere between a pH of 7.4 and 7.1] do however indicate that this will probably not happen in this century.” Indeed, Caldeira and Wickett’s calculation of the maximum level to which the air’s CO<sub>2</sub> concentration might rise yields a value that approaches 2,000 ppm around the year 2300, representing a surface oceanic pH reduction of 0.7 units, which drops the pH only to the upper limit of the “threshold for negative effects on growth of blue mussels” found by Berge *et al.*, i.e., 7.4. Consequently, blue mussels will likely never be bothered by the tendency for atmospheric CO<sub>2</sub> enrichment to lower oceanic pH values.

In a study of a very different creature, Langer *et al.* (2006) conducted batch-culture experiments on two coccolithophores, *Calcidiscus leptoporus* and *Coccolithus pelagicus*, in which they observed a “deterioration of coccolith production above as well as below present-day CO<sub>2</sub> concentrations in *C. leptoporus*,” and a “lack of a CO<sub>2</sub> sensitivity of calcification in *C. pelagicus*” over an atmospheric CO<sub>2</sub> concentration range of 98-915 ppm. Both of these observations, in their words, “refute the notion of a linear relationship of calcification with the carbonate ion concentration and carbonate saturation state.” In an apparent negative finding, however, particularly in the case of *C. leptoporus*, Langer *et al.* observed that although their experiments revealed that “at 360 ppm CO<sub>2</sub> most coccoliths show normal

morphology,” at both “higher and lower CO<sub>2</sub> concentrations the proportion of coccoliths showing incomplete growth and malformation increases notably.”

To determine if such deleterious responses might also have occurred in the real world at different times in the past, the researchers studied coccolith morphologies in six sediment cores obtained along a range of latitudes in the Atlantic Ocean. This work revealed that changes in coccolith morphology similar to those “occurring in response to the abrupt CO<sub>2</sub> perturbation applied in experimental treatments are *not* [our italics] mirrored in the sedimentary record.” This finding indicates, as they suggest, that “in the natural environment *C. leptoporus* has adjusted to the 80-ppm CO<sub>2</sub> and 180-ppm CO<sub>2</sub> difference between present [and] preindustrial and glacial times, respectively.”

In further discussing these observations, Langer *et al.* say “it is reasonable to assume that *C. leptoporus* has adapted its calcification mechanism to the change in carbonate chemistry having occurred since the last glacial maximum,” suggesting as a possible explanation for this phenomenon that “the population is genetically diverse, containing strains with diverse physiological and genetic traits, as already demonstrated for *E. huxleyi* (Brand, 1981, 1982, 1984; Conte *et al.*, 1998; Medlin *et al.*, 1996; Paasche, 2002; Stolte *et al.*, 2000).” They also state that this adaptive ability “is not likely to be confined to *C. leptoporus* but can be assumed to play a role in other coccolithophore species as well,” which leads them to conclude that such populations “may be able to evolve so that the optimal CO<sub>2</sub> level for calcification of the species tracks the environmental value.” With respect to the future, therefore, Langer *et al.* end on a strongly positive note, stating that “genetic diversity, both between and within species, may allow calcifying organisms to prevail in a high CO<sub>2</sub> ocean.”

Focusing on another coccolithophore species, Riebesell (2004) notes that “a moderate increase in CO<sub>2</sub> facilitates photosynthetic carbon fixation of some phytoplankton groups,” including “the coccolithophorids *Emiliana huxleyi* and *Gephyrocapsa oceanica*.” Hence, in a major challenge to the claim that atmospheric CO<sub>2</sub> enrichment will definitely harm such marine organisms, Riebesell suggests that “CO<sub>2</sub>-sensitive taxa, such as the calcifying coccolithophorids, should therefore *benefit more* [our italics] from the present

increase in atmospheric CO<sub>2</sub> compared to the non-calcifying diatoms.”

In support of this suggestion, Riebesell describes the results of some CO<sub>2</sub> perturbation experiments conducted south of Bergen, Norway, where nine 11-m<sup>3</sup> enclosures moored to a floating raft were aerated with CO<sub>2</sub>-depleted, normal and CO<sub>2</sub>-enriched air to achieve CO<sub>2</sub> levels of 190, 370, and 710 ppm, simulating glacial, present-day, and predicted conditions for the end of the century, respectively. In the course of the study, a bloom consisting of a mixed phytoplankton community developed, and, in Riebesell’s words, “significantly higher net community production was observed under elevated CO<sub>2</sub> levels during the build-up of the bloom.” He further reports that “CO<sub>2</sub>-related differences in primary production continued after nutrient exhaustion, leading to higher production of transparent exopolymer particles under high CO<sub>2</sub> conditions,” something that has also been observed by Engel (2002) in a natural plankton assemblage and by Heemann (2002) in monospecific cultures of both diatoms and coccolithophores.

Another important finding of this experiment was that the community that developed under the high CO<sub>2</sub> conditions expected for the end of this century was dominated by *Emiliana huxleyi*. Consequently, Riebesell finds even more reason to believe that “coccolithophores may benefit from the present increase in atmospheric CO<sub>2</sub> and related changes in seawater carbonate chemistry,” in contrast to the many negative predictions that have been made about rising atmospheric CO<sub>2</sub> concentrations in this regard. Finally, in further commentary on the topic, Riebesell states that “increasing CO<sub>2</sub> availability may improve the overall resource utilization of *E. huxleyi* and possibly of other fast-growing coccolithophore species,” concluding that “if this provides an ecological advantage for coccolithophores, rising atmospheric CO<sub>2</sub> could potentially increase the contribution of calcifying phytoplankton to overall primary production.” In fact, noting that “a moderate increase in CO<sub>2</sub> facilitates photosynthetic carbon fixation of some phytoplankton groups,” including “the coccolithophorids *Emiliana huxleyi* and *Gephyrocapsa oceanica*,” Riebesell suggests that “CO<sub>2</sub>-sensitive taxa, such as the calcifying coccolithophorids, should therefore benefit *more* [our italics] from the present increase in atmospheric CO<sub>2</sub> compared to the non-calcifying diatoms.”

Support of Riebesell’s findings was recently provided by an international team of 13 researchers

(Iglesias-Rodriguez *et al.*, 2008), who bubbled air of a number of different atmospheric CO<sub>2</sub> concentrations through culture media containing the phytoplanktonic coccolithophore species *Emiliana huxleyi*, while determining the amounts of particulate organic and inorganic carbon they produced. In addition, they determined the real-world change in average coccolithophore mass over the past 220 years in the subpolar North Atlantic Ocean, based on data obtained from a sediment core, over which period of time the atmosphere's CO<sub>2</sub> concentration rose by approximately 90 ppm and the earth emerged from the frigid depths of the Little Ice Age to experience the supposedly unprecedented high temperatures of the Current Warm Period.

Results of their analysis revealed an approximate doubling of both particulate organic and inorganic carbon between the culture media in equilibrium with air of today's CO<sub>2</sub> concentration and the culture media in equilibrium with air of 750 ppm CO<sub>2</sub>. In addition, they say the field evidence they obtained from the deep-ocean sediment core they studied "is consistent with these laboratory conclusions," and that it indicates that "over the past 220 years there has been a 40% increase in average coccolith mass."

Focusing more on the future, a third independent team of seven scientists (Feng *et al.*, 2008) studied *Emiliana huxleyi* coccoliths that they isolated from the Sargasso Sea, and which they grew in semi-continuous culture media at low and high light intensities, low and high temperatures (20 and 24°C), and low and high CO<sub>2</sub> concentrations (375 and 750 ppm). This work revealed that in the low-light environment, the maximum photosynthetic rate was lowest in the low-temperature, low-CO<sub>2</sub> or ambient treatment, but was increased by 55 percent by elevated temperature alone and by 95 percent by elevated CO<sub>2</sub> alone, while in the high-temperature, high-CO<sub>2</sub> or greenhouse treatment it was increased by 150 percent relative to the ambient treatment. Likewise, in the high-light environment, there were maximum photosynthetic rate increases of 58 percent, 67 percent, and 92 percent for the elevated temperature alone, elevated CO<sub>2</sub> alone, and greenhouse treatments, respectively. Consequently, the researchers concluded that "future trends of CO<sub>2</sub> enrichment, sea-surface warming and exposure to higher mean irradiances from intensified stratification will have a large influence on the growth of *Emiliana huxleyi*."

Clearly, claims of impending marine species extinctions due to ocean acidification are not

supported by real-world evidence—they are refuted by it.

Additional information on this topic, including reviews of newer publications as they become available, can be found at <http://www.co2science.org/subject/c/calcificationother.php>.

#### 8.4. Polar Bears

According to the IPCC, global warming is “inducing declining survival rates, smaller size, and cannibalism among polar bears (Amstrup *et al.*, 2006; Regehr *et al.*, 2006)” (IPCC, 2007-II, p. 88). “Reproductive success in polar bears,” the IPCC also claims, “has declined, resulting in a drop in body condition, which in turn is due to melting Arctic Sea ice. Without ice, polar bears cannot hunt seals, their favourite prey (Derocher *et al.*, 2004)” (p. 103). Later in the same report, the IPCC claims to have “very high confidence” that “substantial loss of sea ice will reduce habitat for dependent species (e.g., polar bears)” (p. 213).

As was the case with coral reefs, the IPCC's claims and predictions are based on computer models and untested theories rather than real-world data. They are at odds with much of what is known about sea ice, polar bear populations and behaviors, and the natural ability of wildlife to adapt to climate change.

In this section we review the evidence and conclude polar bears are not endangered by global warming, whether it is caused by human activity or any other causes. Since our findings once again contradict those of the IPCC, we summarize them here:

- There is little or no evidence of global warming-induced reduction in the extent or thickness of Arctic sea ice in the second-half of the twentieth century, particularly during those seasons when polar bears rely on it to reach their favorite food supply (seals), despite what the IPCC calls the “unprecedented warming” of the past century.
- Polar bears have survived changes in climate that exceed those that occurred during the twentieth century or are forecast by the IPCC's computer models.
- Temperatures in Greenland and other Arctic areas exhibit considerable variability described by one group of scientists as “a long term cooling and shorter warming periods.”
- Most populations of polar bears are growing, not shrinking, and the biggest influence on polar bear populations is not temperature but hunting by humans, which historically has taken too large a toll on polar bear populations.
- Forecasts of dwindling polar bear populations assume trends in sea ice and temperature that are counterfactual, rely on computer climate models that are known to be unreliable, and violate most of the principles of scientific forecasting.

### 8.4.1. Arctic Sea Ice

Global warming is thought to endanger polar bears (*Ursus maritimus*) by melting sea ice. According to Derocher *et al.* (2004), “it is unlikely that polar bears will survive as a species if the sea ice disappears completely as has been predicted by some.” (We note that even the IPCC's computer models do not predict the “disappearance” of all sea ice, so this widely cited warning is essentially meaningless.) Amstrup *et al.* (2007) say “Our modeling suggests that realization of the sea ice future which is currently projected, would mean loss of  $\approx 2/3$  of the world's current polar bear population by mid-century.”

These dire predictions are based entirely on computer simulations of the effects of warming temperatures on the extent of sea ice in the Arctic region. One way to test the reliability of those simulations is to see what effect the warming of the twentieth century had on the extent and thickness of sea ice. If the warming of the twentieth century hasn't produced trends toward less sea ice extent and thickness, why should we believe computer models that claim future warming would have a different effect? This section summarizes a more comprehensive analysis of Arctic sea ice that appeared in Chapter 4 of this report.

#### 8.4.1.1. Extent

The popular media is filled with reports about the disappearance of sea ice at the North Pole and the possibility of an ice-free summer in the region. The IPCC also focuses on summer (August and September) minimum Arctic sea ice extent (see Figures 4.8, 4.9, and 4.10 on pp. 351-352 of IPCC, 2007-I) and downplays evidence showing relatively little change in sea ice extent at other times of the year (e.g., Figure 4.10 shows relatively stable March sea ice extent but it receives no comment in the text).

Summer sea ice losses are part of an eons-long natural cycle to which polar bears have adapted in order to survive. Polar bears are able to fast for more than four months at a time while fully awake and mobile, without hibernating as other bears do (Watts and Hansen, 1987; Ramsay and Stirling, 1988; Ramsay and Hobson, 1991; Lennox and Goodship, 2008). During their winter feeding season, polar bears rely on sea ice to reach ringed seals (*Phoca hispida*) and in some regions bearded seals (*Erignathus barbatus*), their main sources of food (Derocher *et al.*, 2002; Stirling and Øritsland, 1995). Therefore, the measure of sea ice extent that is most relevant to the survival of polar bears is not summer minimums but multi-year. According to numerous studies described below, multi-year sea ice extent is growing in some parts of the Arctic and declining in others, sometimes changing sign over the course of a single year or two, making it difficult to discern an overall trend. The data show low-frequency oscillations that are not what one would predict based on the greenhouse warming theory and gradually increasing atmospheric CO<sub>2</sub> concentrations.

Johannessen *et al.* (1999) analyzed Arctic sea ice extent over the period 1978-1998 and found it to have decreased by about 14 percent. This finding led them to suggest that “the balance of evidence,” as small as it then was, indicates “an ice cover in transition,” and that “if this apparent transformation continues, it may lead to a markedly different ice regime in the Arctic,” as also was suggested by Vinnikov *et al.* (1999). However, the plots of sea ice area presented by Johannessen *et al.* reveal that essentially all of the drop occurred abruptly over a single period of not more than three years (1987/88-1990/91) and possibly

only one year (1989/90-1990/91). Furthermore, it appears from their data that from 1990/91 onward, sea ice area in the Arctic may have *increased*.

More recently, Kwok (2004) estimated the coverage of Arctic multi-year sea ice at the beginning of each year of the study was 3774 x 10<sup>3</sup> km<sup>2</sup> in 2000, 3896 x 10<sup>3</sup> km<sup>2</sup> in 2001, 4475 x 10<sup>3</sup> km<sup>2</sup> in 2002, and 4122 x 10<sup>3</sup> km<sup>2</sup> in 2003, representing an *increase* in sea ice coverage of 9 percent over a third of a decade. Belchansky *et al.* (2004) report that from 1988 to 2001, total January multi-year ice area declined at a mean rate of 1.4 percent per year. They note, however, that in the autumn of 1996 “a large multiyear ice recruitment of over 10<sup>6</sup> km<sup>2</sup> fully replenished the previous 8-year decline in total area.” They add that the replenishment “was followed by an accelerated and compensatory decline during the subsequent 4 years.” In addition, they learned that 75 percent of the interannual variation in January multi-year sea area “was explained by linear regression on two atmospheric parameters: the previous winter’s Arctic Oscillation index as a proxy to melt duration and the previous year’s average sea level pressure gradient across the Fram Strait as a proxy to annual ice export.”

Belchansky *et al.* conclude that their 14-year analysis of multi-year ice dynamics is “insufficient to project long-term trends.” They also conclude it is insufficient to reveal “whether recent declines in multiyear ice area and thickness are indicators of anthropogenic exacerbations to positive feedbacks that will lead the Arctic to an unprecedented future of reduced ice cover, or whether they are simply ephemeral expressions of natural low frequency oscillations.”

Heide-Jorgensen and Laidre (2004) examined changes in the fraction of open-water found within various pack-ice microhabitats of Foxe Basin, Hudson Bay, Hudson Strait, Baffin Bay-Davis Strait, northern Baffin Bay, and Lancaster Sound over a 23-year interval (1979-2001) using remotely sensed microwave measurements of sea-ice extent, after which the trends they documented were “related to the relative importance of each wintering microhabitat for eight marine indicator species and potential impacts on winter success and survival were examined.” Foxe Basin, Hudson Bay, and Hudson Strait showed small increasing trends in the fraction of open water, with the upward trends at all microhabitats studied ranging from 0.2 to 0.7 percent per decade. In Baffin Bay-Davis Strait and northern Baffin Bay, on the other hand, the open-water trend

was downward, and at a mean rate for all open-water microhabitats studied of fully 1 percent per decade, while the trend in all Lancaster Sound open-water microhabitats was also downward, in this case at a mean rate of 0.6 percent per decade.

Heide-Jorgensen and Laidre report that “increasing trends in sea ice coverage in Baffin Bay and Davis Strait (resulting in declining open-water) were as high as 7.5 percent per decade between 1979-1999 (Parkinson *et al.*, 1999; Deser *et al.*, 2000; Parkinson, 2000a,b; Parkinson and Cavalieri, 2002) and comparable significant increases have been detected back to 1953 (Stern and Heide-Jorgensen, 2003).” They additionally note that “similar trends in sea ice have also been detected locally along the West Greenland coast, with slightly lower increases of 2.8 percent per decade (Stern and Heide-Jorgensen, 2003).”

Grumet *et al.* (2001) warned that recent trends in Arctic sea ice cover “can be viewed out of context because their brevity does not account for interdecadal variability, nor are the records sufficiently long to clearly establish a climate trend.” In an effort to overcome this “short-sightedness,” they developed a 1,000-year record of spring sea ice conditions in the Arctic region of Baffin Bay based on sea-salt records from an ice core obtained from the Penny Ice Cap on Baffin Island. They determined that after a period of reduced sea ice during the eleventh through fourteenth centuries, enhanced sea ice conditions prevailed during the following 600 years. For the final (twentieth) century of this period, they report that “despite warmer temperatures during the turn of the century, sea-ice conditions in the Baffin Bay/Labrador Sea region, at least during the last 50 years, are within ‘Little Ice Age’ variability,” suggesting that sea ice extent there has not yet emerged from the range of conditions characteristic of the Little Ice Age.

In an adjacent sector of the Arctic, this latter period of time also was studied by Comiso *et al.* (2001), who used satellite imagery to analyze and quantify a number of attributes of the Odden ice tongue—a winter ice-cover phenomenon that occurs in the Greenland Sea with a length of about 1,300 km and an aerial coverage of as much as 330,000 square kilometers—over the period 1979-1998. By utilizing surface air temperature data from Jan Mayen Island, which is located within the region of study, Comiso and colleagues were able to infer the behavior of this phenomenon over the past 75 years. Trend analyses revealed that the ice tongue has exhibited no

statistically significant change in any of the parameters studied over the past 20 years; but the proxy reconstruction of the Odden ice tongue for the past 75 years revealed the ice phenomenon to have been “a relatively smaller feature several decades ago,” due to the warmer temperatures that prevailed at that time.

In another study of Arctic climate variability, Omstedt and Chen (2001) obtained a proxy record of the annual maximum extent of sea ice in the region of the Baltic Sea over the period 1720-1997. In analyzing this record, they found that a significant decline in sea ice occurred around 1877. In addition, they reported finding greater variability in sea ice extent in the colder 1720-1877 period than in the warmer 1878-1997 period, suggesting that air temperatures are not the main force at work in determining sea ice extent.

Jevrejeva (2001) reconstructed an even longer record of sea ice duration (and, therefore, extent) in the Baltic Sea region by examining historical data for the observed time of ice break-up between 1529 and 1990 in the northern port of Riga, Latvia. The long date-of-ice-break-up time series was best described by a fifth-order polynomial, which identified four distinct periods of climatic transition: (1) 1530-1640, warming with a tendency toward earlier ice break-up of nine days/century, (2) 1640-1770, cooling with a tendency toward later ice break-up of five days/century, (3) 1770-1920, warming with a tendency toward earlier ice break-up of 15 days/century, and (4) 1920-1990, *cooling* with a tendency toward later ice break-up of 12 days/century.

On the other hand, in a study of the Nordic Seas (the Greenland, Iceland, Norwegian, Barents, and Western Kara Seas), Vinje (2001) determined that “the extent of ice in the Nordic Seas measured in April has decreased by 33% over the past 135 years.” He notes, however, that “nearly half of this reduction is observed over the period 1860-1900,” during a period, we note, when the atmosphere’s CO<sub>2</sub> concentration rose by only 7 ppm, whereas the second half of the sea-ice decline occurred over a period of time when the air’s CO<sub>2</sub> concentration rose by more than 70 ppm. If the historical rise in the air’s CO<sub>2</sub> content has been responsible for the historical decrease in sea-ice extent, its impact over the last century has declined to less than a tenth of what its impact was over the preceding four decades. This in turn suggests that the increase in the air’s CO<sub>2</sub> content

over the past 135 years has likely had nothing to do with the concomitant decline in sea-ice cover.

In a similar study of the Kara, Laptev, East Siberian, and Chukchi Seas, based on newly available long-term Russian observations, Polyakov *et al.* (2002) found “smaller than expected” trends in sea ice cover that, in their words, “do not support the hypothesized polar amplification of global warming.” Likewise, in a study published the following year, Polyakov *et al.* (2003) report that “over the entire Siberian marginal-ice zone the century-long trend is only -0.5% per decade,” while “in the Kara, Laptev, East Siberian, and Chukchi Seas the ice extent trends are not large either: -1.1%, -0.4%, +0.3%, and -1.0% per decade, respectively.” Moreover, they say “these trends, except for the Chukchi Sea, are not statistically significant.”

Divine and Dick (2006) used historical April through August ice observations made in the Nordic Seas—comprised of the Iceland, Greenland, Norwegian, and Barents Seas, extending from 30°W to 70°E—to construct time series of ice-edge position anomalies spanning the period 1750-2002, which they analyzed for evidence of long-term trend and oscillatory behavior. The authors report that “evidence was found of oscillations in ice cover with periods of about 60 to 80 years and 20 to 30 years, superimposed on a continuous negative trend,” which observations are indicative of a “persistent ice retreat since the second half of the 19th century” that began well before anthropogenic CO<sub>2</sub> emissions could have had much effect on earth’s climate.

Noting that the last cold period observed in the Arctic occurred at the end of the 1960s, the two Norwegian researchers say their results suggest that “the Arctic ice pack is now at the periodical apogee of the low-frequency variability,” and that “this could explain the strong negative trend in ice extent during the last decades as a possible superposition of natural low frequency variability and greenhouse gas induced warming of the last decades.” However, as they immediately caution, “a similar shrinkage of ice cover was observed in the 1920s-1930s, during the previous warm phase of the low frequency oscillation, when any anthropogenic influence is believed to have still been negligible.” They suggest, therefore, “that during decades to come ... the retreat of ice cover may change to an expansion.”

The oscillatory behavior observed in so many of the sea ice studies suggests, in the words of Parkinson (2000b), “the possibility of close connections between the sea ice cover and major oscillatory patterns in the

atmosphere and oceans,” including connections with: “(1) the North Atlantic Oscillation (e.g., Hurrell and van Loon, 1997; Johannessen *et al.*, 1999; Kwok and Rothrock, 1999; Deser *et al.*, 2000; Kwok, 2000; Vinje, 2001) and the spatially broader Arctic Oscillation (e.g., Deser *et al.*, 2000; Wang and Ikeda, 2000); (2) the Arctic Ocean Oscillation (Polyakov *et al.*, 1999; Proshutinsky *et al.*, 1999); (3) a ‘see-saw’ in winter temperatures between Greenland and northern Europe (Rogers and van Loon, 1979); and (4) an interdecadal Arctic climate cycle (Mysak *et al.*, 1990; Mysak and Power, 1992).” The likelihood that Arctic sea ice trends are the product of such natural oscillations, Parkinson continues, “provides a strong rationale for considerable caution when extrapolating into the future the widely reported decreases in the Arctic ice cover over the past few decades or when attributing the decreases primarily to global warming.”

The latest observations on Greenland’s outlet glaciers, reported in January 2009 by a writer for *Science* who attended a December 2008 meeting of the American Geophysical Union, amply confirm Parkinson’s conclusion. They show the acceleration of melting that had occurred between 2003-2005 had “come to an end” and “nearly everywhere around southeast Greenland, outlet glacier flows have returned to the levels of 2000” (Anonymous, 2009). The article quotes a team of researchers led by glacial modeler Faezeh Nick of Durham University in the United Kingdom as saying “our results imply that the recent rates of mass loss in Greenland’s outlet glaciers are transient and should not be extrapolated into the future” (Ibid.)

In conclusion, there is little or no evidence of a consistent, global warming-induced reduction in the extent of Arctic sea ice, especially during those seasons when polar bears rely on it to reach their favorite food supply (seals), despite what the IPCC calls the “unprecedented warming” of the past century. This is a key finding that undermines the claim that global warming would have a harmful effect on polar bears in the future.

Additional information on this topic, including reviews of newer publications as they become available, can be found at <http://www.co2science.org/subject/s/seaicearctic.php>.

#### 8.4.1.2. Thickness

In addition to its extent, the thickness of Arctic sea ice is of concern since it must support the weight of hunting polar bears. Male polar bears can weigh up to 800 kg (1,764 pounds) (DeMaster and Stirling, 1981), and there is anecdotal evidence of bears larger than this (Dowsley, 2005). Thick sea ice can negatively affect populations of marine mammals by reducing the size and number of airholes, thereby suffocating some species of whales and seals and reducing the number of hunting areas for polar bears (Stirling, 2002; Laidre *et al.*, 2008; Harington, 2008). Trends in the thickness of sea ice might also be precursors of changes in sea ice extent.

Based on analyses of submarine sonar data, Rothrock *et al.* (1999) suggested that Arctic sea ice in

the mid 1990s had thinned by about 42 percent of the average 1958-1977 thickness. The IPCC reports this finding but also reports that other more recent studies found “the reduction in ice thickness was not gradual, but occurred abruptly before 1991,” and acknowledges that “ice thickness varies considerably from year to year at a given location and so the rather sparse temporal sampling provided by submarine data makes inferences regarding long term change difficult” (IPCC 2007, p. 353). Johannessen *et al.* (1999), for example, found that essentially all of the drop occurred rather abruptly over a single period of not more than three years (1987/88-1990/91) and possibly only one year (1989/90-1990/91).

Two years after Johannessen *et al.*, Winsor (2001) analyzed a more comprehensive set of Arctic sea-ice data obtained from six submarine cruises conducted between 1991 and 1997 that had covered the central Arctic Basin from 76°N to 90°N, as well as two areas that had been particularly densely sampled, one centered at the North Pole (>87°N) and one in the central part of the Beaufort Sea (centered at approximately 76°N, 145°W). The transect data across the entire Arctic Basin revealed that the mean Arctic sea-ice thickness had remained “almost constant” over the period of study. Data from the North Pole also showed little variability, and a linear regression of the data revealed a “slight increasing trend for the whole period.” As for the Beaufort Sea region, annual variability in sea ice thickness was greater than at the North Pole but once again, in Winsor’s words, “no significant trend” in mean sea-ice thickness was found. Combining the North Pole results with the results of an earlier study, Winsor concluded that “mean ice thickness has remained on a near-constant level around the North Pole from 1986 to 1997.”

The following year, Holloway and Sou (2002) explored “how observations, theory, and modeling work together to clarify perceived changes to Arctic sea ice,” incorporating data from “the atmosphere, rivers, and ocean along with dynamics expressed in an ocean-ice-snow model.” On the basis of a number of different data-fed model runs, they found that for the last half of the past century, “no linear trend [in Arctic sea ice volume] over 50 years is appropriate,” noting their results indicated “increasing volume to the mid-1960s, decadal variability without significant trend from the mid-1960s to the mid-1980s, then a loss of volume from the mid-1980s to the mid-1990s.” The net effect of this behavior, in their words, was that “the volume estimated in 2000 is close to the

volume estimated in 1950.” They suggest that the initial inferred rapid thinning of Arctic sea ice was, as they put it, “unlikely,” due to problems arising from under-sampling. They also report that “varying winds that readily redistribute Arctic ice create a recurring pattern whereby ice shifts between the central Arctic and peripheral regions, especially in the Canadian sector,” and that the “timing and tracks of the submarine surveys missed this dominant mode of variability.”

In the same year, Polyakov *et al.* (2002) employed newly available long-term Russian landfast-ice data obtained from the Kara, Laptev, East Siberian, and Chuckchi Seas to investigate trends and variability in the Arctic environment poleward of 62°N. This study revealed that fast-ice thickness trends in the different seas were “relatively small, positive or negative in sign at different locations, and not statistically significant at the 95% level.” A year later, these results were reconfirmed by Polyakov *et al.* (2003), who reported that the available fast-ice records “do not show a significant trend,” while noting that “in the Kara and Chukchi Seas trends are positive, and in the Laptev and East Siberian Seas trends are negative,” but stating that “these trends are not statistically significant at the 95% confidence level.”

Laxon *et al.* (2003) used an eight-year time series (1993-2001) of Arctic sea-ice thickness data derived from measurements of ice freeboard made by radar altimeters carried aboard ERS-1 and 2 satellites to determine the mean thickness and variability of Arctic sea ice between latitudes 65°N and 81.5°N, which region covers the entire circumference of the Arctic Ocean, including the Beaufort, Chukchi, East Siberian, Kara, Laptev, Barents, and Greenland Seas. These real-world observations (1) revealed “an interannual variability in ice thickness at higher frequency, and of greater amplitude, than simulated by regional Arctic models,” (2) undermined “the conclusion from numerical models that changes in ice thickness occur on much longer timescales than changes in ice extent,” and (3) showed that “sea ice mass can change by up to 16% within one year,” which finding “contrasts with the concept of a slowly dwindling ice pack, produced by greenhouse warming.” Laxon *et al.* concluded that “errors are present in current simulations of Arctic sea ice,” stating in their closing sentence that “until models properly reproduce the observed high-frequency, and thermodynamically driven, variability in sea ice

thickness, simulations of both recent, and future, changes in Arctic ice cover will be open to question.”

In a paper on landfast ice in Canada’s Hudson Bay, Gagnon and Gough (2006) cite nine different studies of sea-ice cover, duration, and thickness in the Northern Hemisphere, noting that the Hudson Bay region “has been omitted from those studies with the exception of Parkinson *et al.* (1999).” For 13 stations located on the shores of Hudson Bay (seven) and surrounding nearby lakes (six), Gagnon and Gough then analyzed long-term weekly measurements of ice thickness and associated weather conditions that began and ended, in the mean, in 1963 and 1993, respectively. The study revealed that a “statistically significant thickening of the ice cover over time was detected on the western side of Hudson Bay, while a slight thinning lacking statistical significance was observed on the eastern side.” This asymmetry, in their words, was “related to the variability of air temperature, snow depth, and the dates of ice freeze-up and break-up,” with “increasing maximum ice thickness at a number of stations” being “correlated to earlier freeze-up due to negative temperature trends in autumn,” and with high snow accumulation being associated with low ice thickness, “because the snow cover insulates the ice surface, reducing heat conduction and thereby ice growth.” Noting that their findings “are in contrast to the projections from general circulation models, and to the reduction in sea-ice extent and thickness observed in other regions of the Arctic,” Gagnon and Gough say “this contradiction must be addressed in regional climate change impact assessments.”

Finally, the relationship between sea ice thickness and polar bear survival is not so simple that any reduction in the one leads to a reduction in the other. As mentioned previously, research has found that expanding sea ice extent and thickness can negatively affect populations of marine mammals, including polar bears (Stirling, 2002; Laidre *et al.*, 2008; Harington, 2008). Laidre and Heide-Jørgensen (2005) report that “cetacean occurrence is generally negatively correlated with dense or complete ice cover due to the need to breathe at the surface,” and that “lacking the ability to break holes in the ice,” narwhals are vulnerable to reductions in the amount of open water available to them, as has been demonstrated by ice entrapment events “where hundreds of narwhals died during rapid sea ice formation caused by sudden cold periods (Siegstad and Heide-Jørgensen, 1994; Heide-Jørgensen *et al.*, 2002). Such events were becoming ever more likely

as temperatures continued to decline and sea ice cover and variability increased.” They concluded that “with the evidence of changes in sea ice conditions that could impact foraging, prey availability, and of utmost importance, access to the surface to breathe, it is unclear how narwhal sub-populations will fare in light of changes in the high Arctic.”

While the negative effects of too much or too thick ice are well known and documented, the evidence is less clear that thinner ice is a major impediment to hunting by polar bears. The bears are known to hunt on new ice that is less than 30 cm (about 1 foot) thick and to use first-year ice that is greater than 120 cm (about 4 feet) thick for overwintering and denning (Ferguson *et al.*, 1997; Ferguson *et al.*, 2000). For context, consider that first-year ice in March 2008 was about 160 cm (about 5 feet) thick (NSIDC 2008). Polar bears also are able to migrate to other areas in response to changes in sea ice, as they have been observed to do in response to competition for food, contact with human development, and other environmental impacts (Messier *et al.*, 2001; Dyke *et al.*, 2007).

These observations suggest there has not been a steady or continuing thinning of Arctic sea ice that can be attributed to CO<sub>2</sub>-induced global warming. Rather, and as was the case with changes in the extent of Arctic sea ice, changes in sea ice thickness appear to be a consequence of changes in ice dynamics caused by periodic climate oscillations having nothing to do with changes in the air’s CO<sub>2</sub> content. Consequently, there is once again no evidence that polar bears are endangered by global warming, whether it results from human activities or other causes.

Additional information on this topic, including reviews of newer publications as they become available, can be found at <http://www.co2science.org/subject/s/seaicearcticthick.php>.

#### 8.4.2. Temperatures

Polar bears evolved from brown bears (*Ursus arctos*) sometime in the last 400,000 years and probably no more than 200,000 years ago (Amnason *et al.*, 1995; Davis *et al.*, 2008; Harington, 2008). This means they have survived whatever changes in the Arctic climate took place over the course of many millennia, including two major warming periods over the last 11,000 years, the Early Holocene Climatic Optimum and the Medieval Warm Period.

In this section we review evidence of these warm periods first in Greenland and then in the rest of the Arctic. Then we look at more recent temperature trends in Greenland and the rest of the Arctic and find

considerable variability, recently described by one group of scientists as “a long term cooling and shorter warming periods” (Chylek *et al.*, 2006). These topics are addressed in greater detail in Chapter 3 of this report.

##### 8.4.2.1. Prehistoric Greenland

Dahl-Jensen *et al.* (1998) used data from two ice sheet boreholes to reconstruct the temperature history of Greenland over the past 50,000 years. Their analysis indicated that temperatures on the Greenland Ice Sheet during the Last Glacial Maximum (about 25,000 years ago) were  $23 \pm 2$  °C colder than at present. After the termination of the glacial period, however, temperatures increased steadily to a value that was 2.5°C warmer than at present, during the Climatic Optimum of 4,000 to 7,000 years ago. The Medieval Warm Period and Little Ice Age were also evident in the borehole data, with temperatures 1°C warmer and 0.5-0.7°C cooler than at present, respectively. Then, after the Little Ice Age, the scientists report “temperatures reached a maximum around 1930 AD” and that “temperatures have decreased during the last decades.”

In another study of Greenland climate, Bard (2002) describes glacial-period millennial-scale episodes of dramatic warming called Dansgaard-Oeschger events (with temperature increases “of more than 10°C”), which are evident in Greenland ice core records, as well as episodes of “drastic cooling” called Heinrich events (with temperature drops “of up to about 5°C”), which are evident in sea surface temperature records derived from the study of North

Atlantic deep-sea sediment cores. In the Greenland record, according to Bard, the progression of these events is such that “the temperature warms abruptly to reach a maximum and then slowly decreases for a few centuries before reaching a threshold, after which it drops back to the cold values that prevailed before the warm event.”

Wagner and Melles (2001) retrieved a sediment core from a lake on an island situated just off Liverpool Land on the east coast of Greenland. Analyzing it for a number of properties related to the past presence of seabirds there, they obtained a 10,000-year record that tells us much about the region’s climatic history. Key to the study were certain biogeochemical data that reflected variations in seabird breeding colonies in the catchment area of the lake. These data revealed high levels of the various parameters measured by Wagner and Melles between about 1,100 and 700 years before present (BP) that were indicative of the summer presence of significant numbers of seabirds during that “medieval warm period,” as they describe it, which had been preceded by a several-hundred-year period of little to no inferred bird presence. Then, after the Medieval Warm Period, the data suggested another absence of birds during what they refer to as “a subsequent Little Ice Age,” which they note was “the coldest period since the early Holocene in East Greenland.” Their data also showed signs of a “resettlement of seabirds during the last 100 years, indicated by an increase of organic matter in the lake sediment and confirmed by bird observations.” However, values of the most recent data were not as great as those obtained from the earlier Medieval Warm Period; and temperatures derived from two Greenland ice cores led to the same conclusion: It was warmer at various times between 1,100 to 700 years BP than it was over the twentieth century.

Kaplan *et al.* (2002) also worked with data obtained from a small lake, this one in southern Greenland, analyzing sediment physical-chemical properties, including magnetic susceptibility, density, water content, and biogenic silica and organic matter concentrations. They discovered that “the interval from 6000 to 3000 cal yr BP was marked by warmth and stability.” Thereafter, however, the climate cooled “until its culmination during the Little Ice Age,” but from 1,300-900 years BP, there was a partial amelioration of climate (the Medieval Warm Period) that was associated with an approximate 1.5°C rise in temperature.

Following another brief warming between AD 1500 and 1750, the second and more severe portion of the Little Ice Age occurred, which was in turn followed by “naturally initiated post-Little Ice Age warming since AD 1850, which is recorded throughout the Arctic.” They report that Viking “colonization around the northwestern North Atlantic occurred during peak Medieval Warm Period conditions that ended in southern Greenland by AD 1100,” noting that Norse movements around the region thereafter “occurred at perhaps the worst time in the last 10,000 years, in terms of the overall stability of the environment for sustained plant and animal husbandry.”

These many studies of the temperature history of Greenland depict long-term oscillatory cooling ever since the Climatic Optimum of the mid-Holocene, when it was perhaps 2.5°C warmer than it is now, within which cooling trend is included the Medieval Warm Period, when it was about 1°C warmer than it is currently, and the Little Ice Age, when it was 0.5 to 0.7°C cooler than now, after which temperatures rebounded to a new maximum in the 1930s and 1940s, only to fall steadily thereafter.

Polar bears obviously survived these large-scale and often sudden climate changes in Greenland, otherwise none would be found living in Greenland today. This does not mean the population of polar bears remained constant throughout this period; more likely they flourished in some periods and declined in numbers in others. But changes in climate did not lead to their extinction. This history begs the question: Why would temperature changes that are predicted to be of the same scale or less than those that occurred naturally, before there was any human impact on climate, be expected to cause the extinction of polar bears, when early natural cycles did not?

Additional information on this topic, including reviews of newer publications as they become available, can be found at <http://www.co2science.org/subject/g/greenland.php>.

#### 8.4.2.2. Rest of the Prehistoric Arctic

Polar bears faced similar temperature changes in the rest of the Arctic region. Naurzbaev and Vaganov (2000) developed a 2,200-year temperature history using tree-ring data obtained from 118 trees near the upper-timberline in Siberia for the period 212 BC to AD 1996, as well as a similar history covering the period of the Holocene Climatic Optimum (3300 to 2600 BC). They reported that several warm and cool periods prevailed for several multi-century periods throughout the last two millennia: a cool period in the first two centuries AD, a warm period from AD 200 to 600, cooling again from 600 to 800 AD, followed by the Medieval Warm Period from about AD 850 to 1150, the cooling of the Little Ice Age from AD 1200 through 1800, followed by the recovery warming of the twentieth century. In regard to this latter temperature rise, however, the two scientists say it was “not extraordinary” and that “the warming at the border of the first and second millennia [AD 1000] was longer in time and similar in amplitude.” In addition, their reconstructed temperatures for the Holocene Climatic Optimum revealed there was an even warmer period about 5,000 years ago, when temperatures averaged 3.3°C more than they did over the past two millennia.

Moore *et al.* (2001) analyzed sediment cores extracted from Donard Lake, Baffin Island, Canada (~66.25°N, 62°W) to produce a 1,240-year record of mean summer temperature for this region that averaged 2.9°C over the period AD 750-1990. Within this period there were several anomalously warm decades with temperatures that were as high as 4°C around AD 1000 and 1100, while at the beginning of the thirteenth century Donard Lake witnessed what they called “one of the largest climatic transitions in over a millennium,” as “average summer temperatures rose rapidly by nearly 2°C from AD 1195-1220, ending in the warmest decade in the record,” with temperatures near 4.5°C. This latter temperature rise was then followed by a period of extended warmth that lasted until an abrupt cooling

event occurred around AD 1375, resulting in the following decade being one of the coldest in the record and signaling the onset of the Little Ice Age on Baffin Island, which lasted 400 years. At the modern end of the record, a gradual warming trend occurred over the period 1800-1900, followed by a dramatic cooling event that brought temperatures back to levels characteristic of the Little Ice Age, which chilliness lasted until about 1950. Thereafter, temperatures rose once more throughout the 1950s and 1960s, whereupon they trended downwards toward cooler conditions to the end of the record in 1990.

Gedalof and Smith (2001) compiled a transect of six tree ring-width chronologies from stands of mountain hemlock growing near the treeline that extends from southern Oregon to the Kenai Peninsula, Alaska. Over the period of their study (AD 1599-1983), they determined that “much of the pre-instrumental record in the Pacific Northwest region of North America [was] characterized by alternating regimes of relatively warmer and cooler SST [sea surface temperature] in the North Pacific, punctuated by abrupt shifts in the mean background state,” which were found to be “relatively common occurrences.” They concluded, “regime shifts in the North Pacific have occurred 11 times since 1650.” A significant aspect of these findings is the fact that the abrupt 1976-77 shift in this Pacific Decadal Oscillation, as it is generally called, is what was responsible for the vast majority of the past half-century’s warming in Alaska, which some commentators wrongly point to as evidence of CO<sub>2</sub>-induced global warming.

Kasper and Allard (2001) examined soil deformations caused by ice wedges (a widespread and abundant form of ground ice in permafrost regions that can grow during colder periods and deform and crack the soil). Working near Salluit, northern Québec (approx. 62°N, 75.75°W), they found evidence of ice wedge activity prior to AD 140, reflecting cold climatic conditions. Between AD 140 and 1030, however, this activity decreased, reflective of warmer conditions. Then, from AD 1030 to 1500, conditions cooled; and from 1500 to 1900 ice wedge activity was at its peak, when the Little Ice Age ruled, suggesting this climatic interval exhibited the coldest conditions of the past 4,000 years. Thereafter, a warmer period prevailed, from about 1900 to 1946, which was followed by a return to cold conditions during the last five decades of the twentieth century, during which time more than 90 percent of the ice wedges studied reactivated and grew by 20-30 cm, in harmony with a

reported temperature decline of 1.1°C observed at the meteorological station in Salluit.

Naurzbaev *et al.* (2002) developed a 2,427-year proxy temperature history for the part of the Taimyr Peninsula, northern Russia, lying between 70°30' and 72°28' North latitude, based on a study of ring-widths of living and preserved larch trees, noting that it has been shown that “the main driver of tree-ring variability at the polar timber-line [where they worked] is temperature (Vaganov *et al.*, 1996; Briffa *et al.*, 1998; Schweingruber and Briffa, 1996).” This work revealed that “the warmest periods over the last two millennia in this region were clearly in the third [Roman Warm Period], tenth to twelfth [Medieval Warm Period] and during the twentieth [Current Warm Period] centuries.” With respect to the second of these three periods, they emphasize that “the warmth of the two centuries AD 1058-1157 and 950-1049 attests to the reality of relative mediaeval warmth in this region.” Their data also reveal three other important pieces of information: (1) the Roman and Medieval Warm Periods were both warmer than the Current Warm Period has been to date, (2) the beginning of the end of the Little Ice Age was somewhere in the vicinity of 1830, and (3) the Current Warm Period peaked somewhere in the vicinity of 1940.

These studies demonstrate that polar bears throughout the Arctic region experienced periods of warming and cooling in the past that exceed the variability observed in the twentieth century and likely to occur in the twenty-first century. Additional information on this topic, including reviews of newer publications as they become available, can be found at [http://www.co2science.org/subject/a/arctictemp\\_trends.php](http://www.co2science.org/subject/a/arctictemp_trends.php).

### 8.4.2.3. Twentieth Century

The IPCC theorizes that warming temperatures in the twentieth century have had a harmful effect on polar bears, but it overlooks evidence that temperatures in Greenland and the rest of the Arctic region peaked in the 1930s. We review that research in this section.

Starting in Greenland, Hanna and Cappelen (2003) determined the air temperature history of coastal southern Greenland from 1958-2001, based on data from eight Danish Meteorological Institute stations in coastal and near-coastal southern Greenland, as well as the concomitant sea surface temperature (SST) history of the Labrador Sea off southwest Greenland, based on three previously published and subsequently extended SST datasets (Parker *et al.*, 1995; Rayner *et al.*, 1996; Kalnay *et al.*, 1996). The coastal temperature data showed a cooling of 1.29°C over the period of study, while two of the three SST databases also depicted cooling: by 0.44°C in one case and by 0.80°C in the other. Both the land-based air temperature and SST series followed similar patterns and were strongly correlated, but with no obvious lead/lag either way. In addition, it was determined that the cooling was “significantly inversely correlated with an increased phase of the North Atlantic Oscillation (NAO) over

the past few decades.” The two researchers say this “NAO-temperature link doesn’t explain what caused the observed cooling in coastal southern Greenland but it does lend it credibility.”

Several other studies also have reported late-twentieth century cooling on Greenland. Based on mean monthly temperatures of 37 Arctic and seven sub-Arctic stations, as well as temperature anomalies of 30 grid-boxes from the updated dataset of Jones, for example, Przybylak (2000) found that “the level of temperature in Greenland in the last 10-20 years is similar to that observed in the 19th century.” Likewise, in a study that utilized satellite imagery of the Odden ice tongue (a winter ice cover that occurs in the Greenland Sea with a length of about 1,300 km and an aerial coverage of as much as 330,000 square kilometers) plus surface air temperature data from adjacent Jan Mayen Island, Comiso *et al.* (2001) determined that the ice phenomenon was “a relatively smaller feature several decades ago,” due to the warmer temperatures that were prevalent at that time. In addition, they report that observational evidence from Jan Mayen Island indicates temperatures there cooled at a rate of  $0.15 \pm 0.03^\circ\text{C}$  per decade during the past 75 years.

Taurisano *et al.* (2004) examined the temperature history of the Nuuk fjord during the last century, where their analyses of all pertinent regional data led them to conclude that “at all stations in the Nuuk fjord, both the annual mean and the average temperature of the three summer months (June, July and August) exhibit a pattern in agreement with the trends observed at other stations in south and west Greenland (Humlum 1999; Hanna and Cappelen, 2003).” As they describe it, the temperature data “show that a warming trend occurred in the Nuuk fjord during the first 50 years of the 1900s, followed by a cooling over the second part of the century, when the average annual temperatures decreased by approximately  $1.5^\circ\text{C}$ .” Coincident with this cooling trend there was also what they describe as “a remarkable increase in the number of snowfall days (+59 days).” What is more, they report that “not only did the cooling affect the winter months, as suggested by Hanna and Cappelen (2002), but also the summer mean,” noting that “the summer cooling is rather important information for glaciological studies, due to the ablation-temperature relations.”

In a study of three coastal stations in southern and central Greenland that possess almost uninterrupted temperature records between 1950 and 2000, Chylek *et al.* (2004) discovered that “summer temperatures,

which are most relevant to Greenland ice sheet melting rates, do not show any persistent increase during the last fifty years.” In fact, working with the two stations with the longest records (both over a century in length), they determined that coastal Greenland’s peak temperatures occurred between 1930 and 1940, and that the subsequent decrease in temperature was so substantial and sustained that current coastal temperatures “are about  $1^\circ\text{C}$  below their 1940 values.” Furthermore, they note that “at the summit of the Greenland ice sheet the summer average temperature has decreased at the rate of  $2.2^\circ\text{C}$  per decade since the beginning of the measurements in 1987.” Hence, as with the Arctic as a whole, it would appear that Greenland has not experienced any net warming over the most dramatic period of atmospheric  $\text{CO}_2$  increase on record. In fact, it has *cooled* during this period.

At the start of the twentieth century, however, Greenland was warming, as it emerged, along with the rest of the world, from the depths of the Little Ice Age. Between 1920 and 1930, when the atmosphere’s  $\text{CO}_2$  concentration rose by a mere 3 to 4 ppm, there was a phenomenal warming at all five coastal locations for which contemporary temperature records are available. In the words of Chylek *et al.*, “average annual temperature rose between  $2$  and  $4^\circ\text{C}$  [and by as much as  $6^\circ\text{C}$  in the winter] in less than ten years.” And this warming, as they note, “is also seen in the  $^{18}\text{O}/^{16}\text{O}$  record of the Summit ice core (Steig *et al.*, 1994; Stuiver *et al.*, 1995; White *et al.*, 1997).”

In commenting on this dramatic temperature rise, which they call the “great Greenland warming of the 1920s,” Chylek *et al.* conclude that “since there was no significant increase in the atmospheric greenhouse gas concentration during that time, the Greenland warming of the 1920s demonstrates that a large and rapid temperature increase can occur over Greenland, and perhaps in other regions of the Arctic, due to internal climate variability such as the NAM/NAO [Northern Annular Mode/North Atlantic Oscillation], without a significant anthropogenic influence.” These facts led them to speculate that “the NAO may play a crucial role in determining local Greenland climate during the 21st century, resulting in a local climate that may defy the global climate change.”

Two years later, Chylek and another team of researchers compared average summer temperatures recorded at Ammassalik, on Greenland’s southeast coast, and Godthab Nuuk on the island’s southwestern coast, for the period 1905 to 2005 (Chylek *et al.*, 2006). They found “the 1955 to 2005

averages of the summer temperatures and the temperatures of the warmest month at both Godthab Nuuk and Ammassalik are significantly lower than the corresponding averages for the previous 50 years (1905-1955). The summers at both the southwestern and the southeastern coast of Greenland were significantly colder within the 1955-2005 period compared to the 1905-1955.”

Chylek *et al.* also compared temperatures for the 10-year periods of 1920-1930 and 1995-2005. They found the average summer temperature for 2003 in Ammassalik was a record high since 1895, but “the years 2004 and 2005 were closer to normal being well below temperatures reached in the 1930s and 1940s.” Similarly, the record from Godthab Nuuk showed that while temperatures there “were also increasing during the 1995-2005 period, they stayed generally below the values typical for the 1920-1940 period.” The authors conclude that “reports of Greenland temperature changes are .... diverse suggesting a long term cooling and shorter warming periods.”

Moving to the rest of the Arctic region, Overpeck *et al.* (1997) combined paleoclimatic records obtained from lake and marine sediments, trees, and glaciers to develop a 400-year history of circum-Arctic surface air temperature. From this record they determined that the most dramatic warming of the last four centuries of the past millennium (1.5°C) occurred between 1840 and 1955. Then, from 1955 to the end of the record (about 1990), the mean circum-Arctic air temperature declined by 0.4°C.

Zeeberg and Forman (2001) analyzed twentieth century changes in glacier terminus positions on north Novaya Zemlya, a Russian island located between the Barents and Kara Seas in the Arctic Ocean, providing in the process a quantitative assessment of the effects of temperature and precipitation on glacial mass balance. This work revealed a significant and accelerated post-Little Ice Age glacial retreat in the first and second decades of the twentieth century; but by 1952, the region’s glaciers had experienced between 75 to 100 percent of their net twentieth century retreat. During the next 50 years, the recession of more than half of the glaciers stopped, and many tidewater glaciers actually began to advance. These glacial stabilizations and advances were attributed by the two scientists to observed increases in precipitation and/or decreases in temperature. In the four decades since 1961, for example, weather stations at Novaya Zemlya show summer temperatures to have been 0.3° to 0.5°C colder than they were over the prior 40 years, while

winter temperatures were 2.3° to 2.8°C colder than they were over the prior 40-year period. Such observations, in Zeeberg and Forman’s words, are “counter to warming of the Eurasian Arctic predicted for the twenty-first century by climate models, particularly for the winter season.”

Comiso *et al.* (2000) utilized satellite imagery to analyze and quantify a number of attributes of the Odden ice tongue, including its average concentration, maximum area, and maximum extent over the period 1979-1998. They used surface air temperature data from Jan Mayen Island, located within the region of study, to infer the behavior of the phenomenon over the past 75 years. The Odden ice tongue was found to vary in size, shape, and length of occurrence during the 20-year period, displaying a fair amount of interannual variability. Quantitatively, trend analyses revealed that the ice tongue had exhibited no statistically significant change in any of the parameters studied over the short 20-year period. However, a proxy reconstruction of the Odden ice tongue for the past 75 years revealed the ice phenomenon to have been “a relatively smaller feature several decades ago,” due to the significantly warmer temperatures that prevailed at that time. The fact that the Odden ice tongue has persisted, virtually unchanged in the mean during the past 20 years, is in direct contrast with predictions of rapid and increasing warmth in earth’s polar regions as a result of CO<sub>2</sub>-induced global warming. This observation, along with the observational evidence from Jan Mayen Island that temperatures there actually cooled at a rate of  $0.15 \pm 0.03^\circ\text{C}$  per decade during the past 75 years, bolsters the view that there has been little to no warming in this part of the Arctic, as well as most of its other parts, over the past seven decades.

Przybylak (2002) conducted a detailed analysis of intraseasonal and interannual variability in maximum, minimum, and average air temperature and diurnal air temperature range for the entire Arctic—as delineated by Treshnikov (1985)—for the period 1951-1990, based on data from 10 stations “representing the majority of the climatic regions in the Arctic.” This work indicated that trends in both the intraseasonal and interannual variability of the temperatures studied did not show any significant changes, leading Przybylak to conclude that “this aspect of climate change, as well as trends in average seasonal and annual values of temperature investigated earlier (Przybylak, 1997, 2000), proves that, in the Arctic in the period 1951-90, no tangible manifestations of the greenhouse effect can be identified.”

Isaksson *et al.* (2003) retrieved two ice cores (one from Lomonosovfonna and one from Austfonna) far above the Arctic Circle in Svalbard, Norway, after which the 12 cooperating scientists from Norway, Finland, Sweden, Canada, Japan, Estonia, and the Netherlands used  $\delta^{18}\text{O}$  data to reconstruct a 600-year temperature history of the region. As would be expected—in light of the earth’s transition from the Little Ice Age to the Current Warm Period—the international group of scientists reported that “the  $\delta^{18}\text{O}$  data from both Lomonosovfonna and Austfonna ice cores suggest that the twentieth century was the warmest during at least the past 600 years.” However, the warmest decade of the twentieth century was centered on approximately 1930, while the instrumental temperature record at Longyearbyen also shows the decade of the 1930s to have been the warmest. In addition, the authors remark, “as on Svalbard, the 1930s were the warmest decade in the Trondheim record.” Consequently, there was no net warming over the last seven decades of the twentieth century in the parts of Norway cited in this study.

In the same year, Polyakov *et al.* (2003) derived a surface air temperature history that stretched from 1875 to 2000, based on measurements carried out at 75 land stations and a number of drifting buoys located poleward of 62°N latitude. From 1875 to about 1917, the team of eight U.S. and Russian scientists found the surface air temperature of the huge northern region rose hardly at all; but then it climbed 1.7°C in just 20 years to reach a peak in 1937 that was not eclipsed over the remainder of the record. During this 20-year period of rapidly rising air temperature, the atmosphere’s CO<sub>2</sub> concentration rose by a mere 8 ppm. But then, over the next six decades, when the air’s CO<sub>2</sub> concentration rose by approximately 55 ppm, or nearly seven times more than it did throughout the 20-year period of dramatic warming that preceded it, the surface air temperature of the region poleward of 62°N experienced no net warming and, in fact, may have cooled.

Laidre and Heide-Jorgensen (2005), using a combination of long-term satellite tracking data, climate data, and remotely sensed sea ice concentrations to detect localized habitat trends of narwhals—a species of whale that polar bears are known to hunt—in Baffin Bay between Greenland and Canada, home to the largest narwhal population in the world. They found “since 1970, the climate in West Greenland has cooled, reflected in both oceanographic and biological conditions (Hanna and Cappelen, 2003),” with the result that “Baffin Bay

and Davis Strait display strong significant increasing trends in ice concentrations and extent, as high as 7.5 percent per decade between 1979 and 1996, with comparable increases detected back to 1953 (Parkinson *et al.*, 1999; Deser *et al.*, 2000; Parkinson, 2000a,b; Parkinson and Cavalieri, 2002; Stern and Heide-Jorgensen, 2003).”

Groisman *et al.* (2006) reported using “a new Global Synoptic Data Network consisting of 2100 stations within the boundaries of the former Soviet Union created jointly by the [U.S.] National Climatic Data Center and Russian Institute for Hydrometeorological Information ... to assess the climatology of snow cover, frozen and unfrozen ground reports, and their temporal variability for the period from 1936 to 2004.” They determined that “during the past 69 years (1936-2004 period), an increase in duration of the period with snow on the ground over Russia and the Russian polar region north of the Arctic circle has been documented by 5 days or 3% and 12 days or 5%, respectively,” and they note this result “is in agreement with other findings.” In commenting on this development, plus the similar findings of others, the five researchers say “changes in snow cover extent during the 1936-2004 period cannot be linked with ‘warming’ (particularly with the Arctic warming).” Why? Because, as they continue, “in this particular period the Arctic warming was absent.”

Karlén (2005), focusing on Svalbard Lufthavn (located at 78°N latitude), which he later shows to be representative of much of the Arctic, reports that “the Svalbard mean annual temperature increased rapidly from the 1910s to the late 1930s,” that “the temperature thereafter became lower, and a minimum was reached around 1970,” and that “Svalbard thereafter became warmer, but the mean temperature in the late 1990s was still slightly cooler than it was in the late 1930s,” indicative of a cooling trend of 0.11°C per decade over the last 70 years of the twentieth century.

In support of his contention that cooling was truly the norm in the Arctic over this period, Karlén goes on to say (1) “the observed warming during the 1930s is supported by data from several stations along the Arctic coasts and on islands in the Arctic, e.g. *Nordklim* data from Bjornoya and Jan Mayen in the north Atlantic, Vardo and Tromso in northern Norway, Sodankylae and Karasjoki in northern Finland, and Stykkisholmur in Iceland,” and (2) “there is also [similar] data from other reports; e.g. Godthaab, Jakobshavn, and Egedesminde in

Greenland, Ostrov Dikson on the north coast of Siberia, Salehard in inland Siberia, and Nome in western Alaska.” All of these stations, to quote him further, “indicate the same pattern of changes in annual mean temperature: a warm 1930s, a cooling until around 1970, and thereafter a warming, although the temperature remains slightly below the level of the late 1930s.” In addition, he says “many stations with records starting later than the 1930s also indicate cooling, e.g. Vize in the Arctic Sea north of the Siberian coast and Frobisher Bay and Clyde on Baffin Island.” Finally, Karlén reports that the 250-year temperature record of Stockholm “shows that the fluctuations of the 1900s are not unique,” and that “changes of the same magnitude as in the 1900s occurred between 1770 and 1800, and distinct but smaller fluctuations occurred around 1825.”

Karlén notes that “during the 50 years in which the atmospheric concentration of CO<sub>2</sub> has increased considerably, the temperature has decreased,” which leads him to conclude that “the Arctic temperature data do not support the models predicting that there will be a critical future warming of the climate because of an increased concentration of CO<sub>2</sub> in the atmosphere.” And this is especially important, in Karlén’s words, because the model-based prediction “is that changes will be strongest and first noticeable in the Arctic.”

All these studies suggest that concern over the effect of the “unprecedented warming” of the twentieth century on polar bears has overlooked a key fact: In the areas where polar bears actually live, there has not been a consistent or unprecedented warming trend in the past 50 years. Consequently, changing temperatures cannot be blamed for changes in polar bear populations, the subject of the next section.

### 8.4.3. Population

The world's polar bear populations live in the wild only in the Northern Hemisphere on land and sea ice in the area surrounding the North Pole. Polar bears tend to stay in, or return to, local areas (Taylor and Lee, 1995; Bethke *et al.*, 1996; Taylor *et al.*, 2001), although some migration is known to occur (Messier *et al.*, 2001; Amstrup *et al.*, 2004). Their range expands and contracts with the accretion and contraction of sea ice with the seasons, with bears moving south during the winter as sea ice advances (Amstrup *et al.*, 2000). In some areas (e.g., Hudson Bay, Foxe Basin, Baffin Bay, and James Bay) polar bears move from sea ice to land for several months during the summer open-water season (Ferguson *et al.*, 1997; Lunn *et al.*, 1997; Taylor *et al.*, 2001, 2005).

The total polar bear population is unknown, since its numbers in the huge central Arctic Basin have never been counted (Aars *et al.*, 2006), although polar bears have been reported there (Van Meurs and Splettstoesser, 2003). A common estimate is of approximately 23,000, with a range of 17,600 to 28,500 (Aars *et al.*, 2006). There is even less certainty regarding the number of polar bears in the 1950s and 1960s, with most estimates around 5,000 to 10,000. Virtually all scientists agree that polar bear populations have grown since the 1970s. For example, Derocher has said "after the signing of the International Agreement on Polar Bears in the 1970s, harvests were controlled and the numbers increased. There is no argument from anyone on this point" (Derocher, 2009).

Even though polar bear populations grew during the second half of the twentieth century, a time when the IPCC claims there was a rapid increase in global temperatures and loss of sea ice, Derocher and others say this population growth is evidence of the effects of hunting bans and quotas and does not contradict their claim that warming temperatures and melting sea ice have hurt polar bear populations. They point, with apparent merit, to negative demographic impacts on polar bear populations identified in the Southern

Beaufort Sea and in Western Hudson Bay, and possible adverse nutritional impacts in the Northern Beaufort Sea and Southern Hudson Bay, due to changes in local sea ice conditions. But this is not evidence that global warming threatens polar bears with extinction. If anthropogenic global warming were a real threat to polar bears, its effects should be observable throughout the Current Warming Period, not just the last few years, and the warming would have to affect more than only a small number of subpopulations, as appears to have been the case (see discussion below). The modified argument—that global warming *only in recent years* is negatively affecting *some subpopulations* of polar bears *but not others*—is not what is being reported in daily newspapers or even what the IPCC claims. The real-world long-term trends in polar bear populations contradict what would be expected if the theory of anthropogenic global warming were true.

The polar bear population is divided into 19 subpopulations for management purposes. According to the IUCN Polar Bear Specialist Group, five subpopulations are declining, five are stable, two are increasing, and seven have insufficient data on which to base a decision. (Aars *et al.*, 2006). Significantly, four of the five subpopulations listed as declining are at risk due to hunting, not reduced sea ice (Aars *et al.*, 2006). This is hardly a picture of a species in steep decline, or even in decline at all. It certainly does not provide an empirical basis for predictions of imminent extinction.

Hunting historically has been the greatest threat to polar bear populations. The arrival of snowmobiles, helicopters, and high-powered rifles led to “harvest” levels that were not sustainable (Taylor *et al.*, 2002; Taylor *et al.*, 2006; Taylor *et al.*, 2008). Hunting was largely unregulated until passage of the 1974 International Agreement for the Conservation of Polar Bears and Their Habitat. Greenland didn’t institute a quota for polar bear hunting until 2006 (Polar Bear Technical Committee, 2006). Annual kills for most populations now have been substantially reduced, but it will take at least 20 years for populations to recover.

The range of polar bears is affected by changes in climate but not in a linear fashion with temperature or the extent or thickness of sea ice. As explained previously, sea ice extent and thickness are only indirectly related to polar bear populations. Only two subpopulations—the Western Hudson Bay (WH) and Southern Beaufort Sea (SB) populations—probably have declined due to climate change effects (Ferguson

*et al.*, 2005; Regehr *et al.*, 2006, 2007a,b; Rode *et al.*, 2007; Hunter *et al.*, 2007), and even one of these (WH) is disputed (Dyck *et al.*, 2007).

Taylor and Dowsley (2008) summarized recent population surveys as follows:

Of six polar bear populations recently evaluated during the climate warming period, two populations appear to have been reduced (WH, SB), 2 populations appear to have remained constant (SH, NB), and one population appears to have increased (DS), and one was abundant but the information was not sufficient to estimate trend (BS). Seven other populations (VM, LS, NW, BB, KB, MC, GB) surveyed during the period of climate warming had vital rates sufficient to sustain substantial rates of harvest [i.e., hunting] at the time they were studied. Information from a Foxe Basin (FB) population survey was sufficient to document that the population had remained abundant although it had been harvested at a relatively high rate, although the survival and recruitment estimates necessary to determine trend were not available. The biological information on the remaining four populations (CS, LS, KS, EG) and the few bears that may inhabit the Arctic Basin is insufficient to suggest anything about current numbers or trend.

Taylor and Dowsley go on to say “the increase to current high numbers of polar bears in the Davis Strait has occurred during the current warming period, and has occurred with declining sea ice conditions that are sometimes less than 40% coverage at winter maximum (Stirling and Parkinson, 2006). Clearly the DS bears do manage to hunt successfully in unconsolidated pack ice.” They comment, as do Dyck *et al.* (2007), that polar bears have been observed to successfully hunt seals in tidal flats along shores during ice-free periods.

“Considered together,” Taylor and Dowsley conclude, “these demographic data do not suggest that polar bears as a species are headed for extinction in the next three generations (45 years) or the foreseeable future. The demographic data do support increased monitoring, and augmenting periodic population surveys with ecological and behavioral studies.” They also observe that “to date, no population has been expatriated due to climate change effects, so the effect of decreased densities, alternative food sources, or behavioral adaptation to less ice on population persistence is not known.”

The fact that polar bear populations are not declining should come as no surprise once it is

understood that sea ice is not receding (at least not in all areas inhabited by polar bears or during their feeding season) or getting thinner, and that temperatures in the circumpolar region in recent years have not been unusually warm. Polar bears are adapted to the extremes of warming and cooling that can and do occur. Polar bears will move out of affected areas and return when conditions improve and when the sea ice is neither too thick nor too ephemeral. Transition will stress some populations and if warming continues for whatever reason, some populations may be expatriated. However, polar bears as a species are not in danger of depletion, let alone extinction.

#### 8.4.4. Forecasts

Since most polar bear subpopulations are either growing or stable, and since there is little evidence that global warming is causing a loss of sea ice that is affecting most polar bear populations, the IPCC is left only with computer models that predict future declines in polar bear populations. In this section we ask whether those predictions are reliable. The reliability of computer climate models is addressed in greater detail in Chapter 1 of this report.

Green and Armstrong (2007) make the important point that forecasting is a practice and a discipline that is separate from physics, biology, geology, and the other sciences that are often applied to the question of climate change. Physicists, biologists, and other scientists often do not know how to make accurate forecasts, and consequently their predictions of the future are no more reliable than those made by nonexperts (Tetlock, 2005; Ascher, 1978). It is telling that Green and Armstrong's search of the IPCC Working Group I report (2007) "found no references ... to the primary sources of information on forecasting methods" and "the forecasting procedures that were described [in sufficient detail to be

evaluated] violated 72 principles. Many of the violations were, by themselves, critical." In other words, the forecasts contained in the IPCC report are unscientific regardless of the scientific qualifications of the report's many contributors.

Scientists working in fields characterized by complexity and uncertainty are apt to confuse the output of *models*—which are nothing more than a statement of how the modeler believes a part of the world works—with real-world trends and forecasts (Bryson, 1993). Computer climate models certainly fall into this class, and they have been severely criticized for their failure to replicate real-world phenomena by many scientists, including Balling (2005), Christy (2005), Frauenfeld (2005), Posmentier and Soon (2005), and Pilkey and Pilkey-Jarvis (2007). Many of these writers observe that computer models can be "tweaked" to reconstruct climate histories after the fact, but this provides no assurance that the new model will do a better job forecasting future climates. Individual climate models often have widely differing assumptions about basic climate mechanisms but are then "tweaked" to produce similar forecasts. This is nothing at all like how real scientific forecasting is done.

Turning to predictions of the possible extinction of polar bears due to anthropogenic global warming, in response to calls to list polar bears as a threatened species under the U.S. Endangered Species Act, the U.S. Geological Survey commissioned nine administrative reports to forecast future polar bear populations. The reports eventually produced were Amstrup *et al.* (2007), Bergen *et al.* (2007), DeWeaver (2007), Durner *et al.* (2007), Hunter *et al.* (2007), Obbard *et al.* (2007), Regehr *et al.* (2007), Rode *et al.* (2007), and Stirling *et al.* (2007). Two of those studies—Anstrup *et al.* (2007) and Hunter *et al.* (2007), thought to give the strongest support for listing polar bears as endangered—were subsequently analyzed by J. Scott Armstrong, Kesten C. Green, and Willie Soon (2008) experts on forecasting at the Wharton School at the University of Pennsylvania and Monash University in Victoria, Australia, and an astrophysicist at the Harvard-Smithsonian Center for Astrophysics in Cambridge, Massachusetts, respectively. The three researchers gave the two studies failing grades for the following reasons:

- Both studies assumed things that are untrue or unknown, such as that "global warming will occur and will reduce the amount of summer sea ice" and "polar bears will not adapt; thus, they

will obtain less food than they do now by hunting from the sea ice platform.”

- Amstrup *et al.* (2007) “definitely contravened 41 principles and apparently contravened an additional 32 principles,” referring to scientific forecasting principles established by the Forecasting Principles Project and set forth in a book titled *Principles of Forecasting* (Armstrong, 2001). “Of the 116 relevant principles, we could find evidence that [Amstrup *et al.* (2007)] properly applied only 17 (14.7 percent).”
- Hunter *et al.* (2007) “clearly contravened 61 principles and probably contravened an additional 19 principles ... the authors properly applied only 10 (9.5 percent) of the 105 relevant principles.”

Among the many errors they identified in Amstrup *et al.* (2007) were (1) relying on a single polar bear expert, (2) choosing an extreme forecast rather than a conservative one despite the presence of complex interactions and instability, and (3) failure to include all important variables. Mistakes made by Hunter *et al.* (2007) included (1) heavy reliance on five years of data with unknown measurement errors, (2) failure to include newly available data, (3) failure to give other researchers access to their data, and (4) failure to list possible outcomes and their likelihoods. According to Armstrong, Green, and Soon, the failure of these forecasters to adhere to the principles of scientific forecasting makes their forecasts “of no value to decisionmakers.”

More generally, forecasts of the possible extinction of polar bears fail to explain how a decline in population (or some subpopulations) necessarily raises the prospect of species extinction. For example, the IUCN/SSC Polar Bear Specialists Group forecast that climate change might reduce polar bear stocks by as much as 30 percent over the next three generations. Such a reduction, should it occur (and we have given ample reasons to doubt it would), would be unfortunate, but it is not extinction and would not necessarily lead to extinction. It suggests the number of polar bears would decline from approximately 24,000 to approximately 17,000. For the sake of comparison, the National Wildlife Federation supports removing grizzly bears in Yellowstone Park USA from the endangered species list even though that population is estimated to be only 600 (Taylor and Dowsley, 2007).

As Crockford (2008) explains, “even if substantial declines in polar bears and their prey do occur because of anthropogenic global warming ... this does not doom them to extinction: Many species have recovered from far more dramatic declines in population than predicted by even the most pessimistic scenarios conceived of by climate models, including humpback whales (Dalton, 2008), gray whales (Reeves *et al.*, 2002), northern fur seals (Reeves *et al.*, 2002), Atlantic cod (Bigg *et al.*, 2008), and sea otters (Doroff *et al.*, 2003; Estes, 1990), among others. Contrary to common biological assumption, small populations often retain sufficient genetic variation for significant recovery (e.g. Aguilar *et al.*, 2004; Kaeuffer *et al.*, 2007).”

Dyck *et al.* (2008) also point out that the climate models used by the forecasters predict a complete disappearance of sea ice over the central Arctic only for the late summer (September), and sea ice at Hudson Bay during the late winter or early spring is not predicted to completely disappear by the end of this century, even under extreme scenarios. They cite Gagnon and Gough (2005b, p. 291) who concluded that “Hudson Bay is expected to remain completely ice covered in those five models by the end of this century for at least part of the year.”

Taylor and Dowsley (2008) report “the majority (60%) of the IPCC models project ice cover in all seasons for the next 40-50 years throughout much of the North American continental shelf where most polar bears reside (Alley *et al.*, 2007; Serreze *et al.*, 2007). The IPCC climate model forecasts for ice reductions in fall, winter, and spring are substantially less than for the summer open water season (Serreze *et al.*, 2007).” This is significant because, as we previously reported, polar bears can fast for four months during the summer when the lack of ice reduces their access to seals (Watts and Hansen, 1987; Ramsay and Stirling, 1988; Ramsay and Hobson, 1991). So even the computer models that predict melting ice, which we’ve criticized as inherently unreliable and unsuited to forecasting, do not forecast a condition that would make it impossible for polar bears to survive.

Taylor and Dowsley also point out that most forecasts of declining polar bear populations assume a simple linear function between population and habitat availability, an argument similar to the discredited “survival envelopes” theory discussed earlier in this chapter. But the fact that polar bears in most subpopulations are being harvested (hunted) in significant numbers means their populations are not at

ecological carrying capacity, which means habitat availability is not the constraining factor affecting population. Populations in some areas (e.g., Viscount Melville Sound, M'Clintock Channel, and Kane Basin) are currently depleted due to over-hunting, so it should be obvious that polar bears there are not constrained by lack of habitat. "There is no evidence that polar bears are at carrying capacity for any population," write Taylor and Dowsley, "and there is no evidence to support any mechanism/s of density dependent population regulation for polar bears."

In conclusion, forecasts of dwindling polar bear populations assume trends in sea ice and temperature that are counterfactual, rely on computer climate models that are known to be unreliable, and violate most of the principles of scientific forecasting. In light of other evidence presented in this section showing no long-term trends toward less sea ice or rising temperatures in the Arctic, plus evidence of rising polar bear populations and their adaptability to climate change and other environmental stresses, we find there is no basis for concern that climate change will ever cause the extinction of polar bears.

## Human Health Effects

---

### 9. Human Health Effects

- 9.1. Diseases
- 9.2. Nutrition
- 9.3. Human Longevity
- 9.4. Food vs. Nature
- 9.5. Biofuels

The idea that CO<sub>2</sub>-induced global warming is harmful to people's health has become entrenched in popular culture, with the reports of the Intergovernmental Panel on Climate Change (IPCC) being the source of much of this concern. In the Working Group II contribution to the Fourth Assessment Report, the authors claim to have "very high confidence" that "climate change currently contributes to the global burden of disease and premature deaths" (IPCC, 2007-II, p. 393). They also claim climate change will "increase malnutrition and consequent disorders ... increase the number of people suffering from death, disease and injury from heatwaves, floods, storms, fires and droughts ... continue to change the range of some infectious disease vectors ... increase the burden of diarrhoeal diseases ... increase cardio-respiratory morbidity and mortality associated with ground-level ozone ... [and] increase the number of people at risk of dengue." The IPCC admits that warming weather would "bring some benefits to health, including fewer deaths from cold," but says those benefits "will be outweighed by the negative effects of rising temperatures worldwide, especially in developing countries" (Ibid.).

Some of these claims have been shown in previous chapters to be counterfactual. For example, research cited in Chapter 6 showed the global warming that occurred in the twentieth century did not cause more "heatwaves, floods, storms, fires and droughts," and that a warmer world is likely to see fewer episodes of these extreme weather events than a cooler world. We will not repeat that analysis in this chapter.

This chapter reviews data on the relationships between temperature and CO<sub>2</sub> and diseases, heat-related mortality, nutrition, and human longevity. We find in each case that global warming is likely to improve human health. Section 9.4 explains how rising CO<sub>2</sub> concentrations in the air will play a positive role in solving the conflict between the need to raise food for a growing population and the need to protect natural ecosystems. Section 9.5 describes the negative role played by increased use of biofuels, which the IPCC advocates in the Working Group III contribution to the Fourth Assessment Report (IPCC, 2007-III), in this same conflict.

## 9.1. Diseases

Which is more deadly: heat or cold? Rising temperatures or falling temperatures? The IPCC claims warming is the primary danger to be avoided at all costs. Real-world data, however, indicate the opposite.

Systematic research on the relationship between heat and human health dates back to the 1930s (Gover, 1938; Kutschenreuter, 1950; Kutschenreuter, 1960; Oechsli and Buechley, 1970). Early studies by Bull (1973) and Bull and Morton (1975a,b) in England and Wales, for example, demonstrated that normal changes in temperature typically are inversely associated with death rates, especially in older subjects. That is, when temperatures rise, death rates fall; when temperatures fall, death rates rise. Bull and Morton (1978) concluded “there is a close association between temperature and death rates from most diseases at all temperatures,” and it is “very likely that changes in external temperature cause changes in death rates.”

Since this early research was published, a large number of studies have confirmed the original findings. Contrary to the IPCC’s highly selective reading of the literature, the overwhelming majority of researchers in the field have found that warmer weather reduces rather than increases the spread and severity of many diseases and weather-related mortality rates. We review this literature in the following order: cardiovascular diseases, respiratory diseases, malaria, tick-borne diseases, and finally cold- and heat-related mortality from all diseases.

Additional information on this topic, including reviews on the health effects of CO<sub>2</sub> not discussed here, can be found at [http://www.co2\\_science.org/subject/h/subject\\_h.php](http://www.co2_science.org/subject/h/subject_h.php) under the heading Health Effects.

### 9.1.1. Cardiovascular Diseases

A good place to begin a review of temperature-related mortality is a cold location ... like Siberia. Feigin *et al.* (2000) examined the relationship between stroke occurrence and weather parameters in the Russian city of Novosibirsk, which has one of the highest incidence rates of stroke in the world. Analyzing the health records of 2,208 patients with a sex and age distribution similar to that of the whole of Russia over the period 1982-93, they found a statistically significant association between stroke occurrence and low ambient temperature. For ischemic stroke (IS), which accounted for 87 percent of all strokes recorded, they report that the risk of IS occurrence on days with low ambient temperature is 32 percent higher than on days with high ambient temperature. They recommend implementing “preventive measures ... such as avoiding low temperature.”

Hong *et al.* (2003) studied weather-related death rates in Incheon, Korea over the period January 1998 to December 2000, reporting that “decreased ambient temperature was associated with risk of acute ischemic stroke,” with the strongest effect being seen on the day after exposure to cold weather. They found that “even a moderate decrease in temperature can increase the risk of ischemic stroke.” In addition, “risk estimates associated with decreased temperature were greater in winter than in the summer,” suggesting that “low temperatures as well as temperature changes are associated with the onset of ischemic stroke.”

Nafstad *et al.* (2001) studied weather-related death rates in Oslo, Norway. Thanks to a Norwegian

law requiring all deaths to be examined by a physician who diagnoses cause and reports it on the death certificate, they were able to examine the effects of temperature on mortality due to all forms of cardiovascular disease for citizens of the country's capital over the period 1990 to 1995. They found that the average daily number of cardiovascular-related deaths was 15 percent higher in the winter months (October-March) than in the summer months (April-September), leading them to conclude that "a milder climate would lead to a substantial reduction in average daily number of deaths."

Hajat and Haines (2002) set out to determine if cardiovascular-related doctor visits by the elderly bore a similar relationship to cold temperatures. Based on data obtained for registered patients aged 65 and older from several London, England practices between January 1992 and September 1995, they found the mean number of general practitioner consultations was higher in the cool-season months (October-March) than in the warm-season months (April-September) for all cardiovascular diseases.

Of course, one might say, such findings are only to be expected in cold climates. What about warm climates, where summer maximum temperatures are often extreme, but summer minimum temperatures are typically mild? Research conducted by Green *et al.* (1994) in Israel revealed that between 1976 and 1985, mortality from cardiovascular disease was 50 percent higher in mid-winter than in mid-summer, both in men and women and in different age groups, in spite of the fact that summer temperatures in the Negev, where much of the work was conducted, often exceed 30°C, while winter temperatures typically do not drop below 10°C. These findings were substantiated by other Israeli studies reviewed by Behar (2000), who states that "most of the recent papers on this topic have concluded that a peak of sudden cardiac death, acute myocardial infarction and other cardiovascular conditions is usually observed in low temperature weather during winter."

Evidence of a seasonal variation in cardiac-related mortality has been found in the mild climate of southern California in the United States. In a study of all 222,265 death certificates issued by Los Angeles County for deaths caused by coronary artery disease from 1985 through 1996, Kloner *et al.* (1999) found that death rates in December and January were 33 percent higher than those observed in the period June through September.

Likewise, based on a study of the Hunter region of New South Wales, Australia that covered the

period 1 July 1985 to 30 June 1990, Enquselassie *et al.* (1993) determined that "fatal coronary events and non-fatal definite myocardial infarction were 20-40 percent more common in winter and spring than at other times of year." Regarding daily temperature effects, they found that "rate ratios for deaths were significantly higher for low temperatures," noting that "on cold days coronary deaths were up to 40 percent more likely to occur than at moderate temperatures."

In a study of "hot" and "cold" cities in the United States—where Atlanta, Georgia; Birmingham, Alabama; and Houston, Texas comprised the "hot" group, and Canton, Ohio; Chicago, Illinois; Colorado Springs, Colorado; Detroit, Michigan; Minneapolis-St. Paul, Minnesota; New Haven, Connecticut; Pittsburgh, Pennsylvania; and Seattle and Spokane, Washington comprised the "cold" group—Braga *et al.* (2002) determined the acute effects and lagged influence of temperature on cardiovascular-related deaths. They found that in the hot cities, neither hot nor cold temperatures had much impact on mortality related to cardiovascular disease (CVD). In the cold cities, on the other hand, they report that both high and low temperatures were associated with increased CVD deaths, with the effect of cold temperatures persisting for days but the effect of high temperatures restricted to the day of the death or the day before. Of particular interest was the finding that for all CVD deaths the hot-day effect was *five times smaller* than the cold-day effect. In addition, the hot-day effect included some "harvesting," where the authors observed a deficit of deaths a few days later, which they did not observe for the cold-day effect.

Gouveia *et al.* (2003), in a study conducted in Sao Paulo, Brazil using data from 1991-1994, found that the number of cardiovascular-related deaths in adults (15-64 years of age) increased by 2.6 percent for each 1°C decrease in temperature below 20°C, while there was no evidence for any heat-induced deaths due to temperatures rising above 20°C. In the elderly (65 years of age and above), however, a 1°C warming above 20°C led to a 2 percent increase in deaths; but a 1°C cooling below 20°C led to a 6.3 percent increase in deaths, or more than three times as many cardiovascular-related deaths due to cooling than to warming in the elderly.

Similar results have been found in Australia (Enquselassie *et al.*, 1993), Brazil (Sharovsky *et al.*, 2004), England (McGregor, 2005; Carder *et al.*, 2005; McGregor *et al.*, 2004; and Kovats *et al.*, 2004), Greece (Bartzokas *et al.*, 2004), Japan (Nakaji *et al.*, 2004), the United States (Cagle and Hubbard, 2005),

and parts of Africa, Asia, Europe, Latin America and the Caribbean (Chang *et al.*, 2004).

These studies demonstrate that global warming *reduces* the incidence of cardiovascular disease related to low temperatures and wintry weather by a much greater degree than it increases the incidence associated with high temperatures and summer heat waves.

### 9.1.2. Respiratory Diseases

As was true of cardiovascular-related mortality, deaths due to respiratory diseases are more likely to be associated with cold conditions in cold countries. In Oslo, where Nafstad *et al.* (2001) found winter deaths due to cardiovascular problems to be 15 percent more numerous than similar summer deaths, they also determined that deaths due to respiratory diseases were fully 47 percent more numerous in winter than in summer. Likewise, the London study of Hajat and Haines (2002) revealed that the number of doctor visits by the elderly was higher in cool-season than warm-season months for all respiratory diseases. At mean temperatures below 5°C, in fact, the relationship between respiratory disease consultations and temperature was linear, and stronger at a time lag of six to 15 days, such that a 1°C decrease in mean temperature below 5°C was associated with a 10.5 percent increase in all respiratory disease consultations.

Gouveia *et al.* (2003) found that death rates in Sao Paulo, Brazil due to a 1°C cooling were twice as great as death rates due to a 1°C warming in adults, and 2.8 times greater in the elderly. Donaldson (2006) studied the effect of annual mean daily air temperature on the length of the yearly respiratory syncytial virus (RSV) season in England and Wales for 1981-2004 and found “emergency department admissions (for 1990-2004) ended 3.1 and 2.5 weeks earlier, respectively, per 1°C increase in annual central England temperature (P = 0.002 and 0.043, respectively).” He concludes that “the RSV season has become shorter” and “these findings imply a health benefit of global warming in England and Wales associated with a reduction in the duration of the RSV season and its consequent impact on the health service.”

The study of hot and cold cities in the United States by Braga *et al.* (2002) found that increased temperature variability is the most significant aspect of climate change with respect to respiratory-related deaths in the U.S. Why is this finding important? Because Robeson (2002) has clearly demonstrated, from a 50-year study of daily temperatures at more than 1,000 U.S. weather stations, that temperature variability *declines* with warming, and at a very substantial rate. The reduced temperature variability in a warmer world would lead to reductions in temperature-related deaths at both the high and low ends of the daily temperature spectrum at all times of the year.

These studies show that a warming world would improve people’s health by reducing deaths related to respiratory disease.

Additional information on this topic, including reviews of newer publications as they become available, can be found at <http://www.co2science.org/subject/h/healtheffectresp.php>.

### 9.1.3. Malaria

Rogers and Randolph (2000) note that “predictions of global climate change have stimulated forecasts that vector-borne diseases will spread into regions that are at present too cool for their persistence.” Such predictions are a standard part of the narrative of those who believe global warming would have catastrophic effects. However, even the IPCC states “there is still much uncertainty about the potential impact of climate change on malaria in local and global scales” and “further research is warranted” (IPCC, 2007-II, p. 404).

According to Reiter (2000), claims that malaria resurgence is the product of CO<sub>2</sub>-induced global warming ignore the disease’s history and an extensive literature showing factors other than climate are

known to play more important roles in the disease's spread. For example, historical analysis reveals that malaria was an important cause of illness and death in England during the Little Ice Age. Its transmission began to decline only in the nineteenth century, during a warming phase when, according to Reiter, "temperatures were already much higher than in the Little Ice Age."

Why was malaria prevalent in Europe during some of the coldest centuries of the past millennium? And why have we only recently witnessed malaria's widespread decline at a time when temperatures are warming? Other factors are at work, such as the quality of public health services, irrigation and agricultural activities, land use practices, civil strife, natural disasters, ecological change, population change, use of insecticides, and the movement of people (Reiter, 2000; Reiter, 2001; Hay *et al.*, 2002). Models employed by the IPCC predict widespread future increases in malaria because nearly all of the analyses they cite used only one, or at most two, climate variables to make predictions of the future distribution of the disease over the earth, and they generally do not include any non-climatic factors.

In one modeling study that used more than just one or two variables, Rogers and Randolph (2000) employed five climate variables and obtained very different results. Briefly, they used the present-day distribution of malaria to determine the specific climatic constraints that best define that distribution, after which the multivariate relationship they derived from this exercise was applied to future climate scenarios derived from state-of-the-art climate models, in order to map potential future geographical distributions of the disease. They found only a 0.84 percent increase in potential malaria exposure under the "medium-high" scenario of global warming and a 0.92 percent decrease under the "high" scenario. They state that their quantitative model "contradicts prevailing forecasts of global malaria expansion" and "highlights the use [we would say superiority] of multivariate rather than univariate constraints in such applications." This study undercuts the claim that any future warming of the globe will allow malaria to spread into currently malaria-free regions.

Hay *et al.* (2002) investigated long-term trends in meteorological data at four East African highland sites that experienced significant increases in malaria cases over the past couple decades, reporting that "temperature, rainfall, vapour pressure and the number of months suitable for *P. falciparum*

transmission have not changed significantly during the past century or during the period of reported malaria resurgence." Therefore, these factors could not be responsible for the observed increases in malaria cases. Likewise, Shanks *et al.* (2000) examined trends in temperature, precipitation, and malaria rates in western Kenya over the period 1965-1997, finding no linkages among the variables.

Also working in Africa, Small *et al.* (2003) examined trends in a climate-driven model of malaria transmission between 1911 and 1995, using a spatially and temporally extensive gridded climate data set to identify locations where the malaria transmission climate suitability index had changed significantly over this time interval. Then, after determining areas of change, they more closely examined the underlying climate forcing of malaria transmission suitability for those localities. This protocol revealed that malaria transmission suitability did increase because of climate change in specific locations of limited extent, but in Southern Mozambique, which was the only region for which climatic suitability consistently increased, the cause of the increase was increased precipitation, not temperature.

In fact, Small *et al.* say that "climate warming, expressed as a systematic temperature increase over the 85-year period, does *not* appear to be responsible for an increase in malaria suitability over any region in Africa." They concluded that "research on the links between climate change and the recent resurgence of malaria across Africa would be best served through refinements in maps and models of precipitation patterns and through closer examination of the role of nonclimatic influences." The great significance of this has recently been demonstrated by Reiter *et al.* (2003) for dengue fever, another important mosquito-borne disease.

Examining the reemergence of malaria in the East African highlands, Zhou *et al.* (2004) conducted a nonlinear mixed-regression model study that focused on the numbers of monthly malaria outpatients of the past 10-20 years in seven East African highland sites and their relationships to the numbers of malaria outpatients during the previous time period, seasonality and climate variability. They say that "for all seven study sites, we found highly significant nonlinear, synergistic effects of the interaction between rainfall and temperature on malaria incidence, indicating that the use of either temperature or rainfall alone is not sensitive enough

for the detection of anomalies that are associated with malaria epidemics.” This has also been found by Githeko and Ndegwa (2001), Shanks *et al.* (2002) and Hay *et al.* (2002). Climate variability—not just temperature or warming—contributed less than 20 percent of the temporal variance in the number of malaria outpatients, and at only two of the seven sites studied.

In light of their findings, Zhou *et al.* concluded that “malaria dynamics are largely driven by autoregression and/or seasonality in these sites” and that “the observed large among-site variation in the sensitivity to climate fluctuations may be governed by complex interactions between climate and biological and social factors.” This includes “land use, topography, *P. falciparum* genotypes, malaria vector species composition, availability of vector control and healthcare programs, drug resistance, and other socioeconomic factors.” Among these are “failure to seek treatment or delayed treatment of malaria patients, and HIV infections in the human population,” which they say have “become increasingly prevalent.”

Kuhn *et al.* (2003) say “there has been much recent speculation that global warming may allow the reestablishment of malaria transmission in previously endemic areas such as Europe and the United States.” To investigate the robustness of this hypothesis, they analyzed the determinants of temporal trends in malaria deaths within England and Wales from 1840-1910. Their analysis found that “a 1°C increase or decrease was responsible for an increase in malaria deaths of 8.3 percent or a decrease of 6.5 percent, respectively,” which explains “the malaria epidemics in the ‘unusually hot summers’ of 1848 and 1859.” Nevertheless, the long-term near-linear temporal decline in malaria deaths over the period of study, in the words of the researchers, “was probably driven by nonclimatic factors.” Among these they list increasing livestock populations (which tend to divert mosquito biting from humans), decreasing acreages of marsh wetlands (where mosquitoes breed), as well as “improved housing, better access to health care and medication, and improved nutrition, sanitation, and hygiene.” They additionally note that the number of secondary cases arising from each primary imported case “is currently minuscule,” as demonstrated by the absence of any secondary malaria cases in the UK since 1953.

Although simplistic model simulations may suggest that the increase in temperature predicted for Britain by 2050 is likely to cause an 8-14 percent

increase in the potential for malaria transmission, Kuhn *et al.* say “the projected increase in proportional risk is clearly insufficient to lead to the reestablishment of endemicity.” Expanding on this statement, they note that “the national health system ensures that imported malaria infections are detected and effectively treated and that gametocytes are cleared from the blood in less than a week.” For Britain, they conclude that “a 15 percent rise in risk might have been important in the 19th century, but such a rise is now highly unlikely to lead to the reestablishment of indigenous malaria,” since “socioeconomic and agricultural changes” have greatly altered the cause-and-effect relationships of the past.

Zell (2004) states that many people “assume a correlation between increasing disease incidence and global warming.” However, “the factors responsible for the emergence/reemergence of vector-borne diseases are complex and mutually influence each other.” He cites as an example the fact that “the incidence and spread of parasites and arboviruses are affected by insecticide and drug resistance, deforestation, irrigation systems and dams, changes in public health policy (decreased resources of surveillance, prevention, and vector control), demographic changes (population growth, migration, urbanization), and societal changes (inadequate housing conditions, water deterioration, sewage, waste management).” Therefore, as he continues, “it may be over-simplistic to attribute emergent/re-emergent diseases to climate change and sketch the menace of devastating epidemics in a warmer world.” Indeed, Zell states that “variations in public health practices and lifestyle can easily outweigh changes in disease biology,” especially those that might be caused by global warming.

Rogers and Randolph (2006) ask if climate change could be responsible for recent upsurges of malaria in Africa. They demonstrate that “evidence for increasing malaria in many parts of Africa is overwhelming, but the more likely causes for most of these changes to date include land-cover and land-use changes and, most importantly, drug resistance rather than any effect of climate,” noting that “the recrudescence of malaria in the tea estates near Kericho, Kenya, in East Africa, where temperature has not changed significantly, shows all the signs of a disease that has escaped drug control following the evolution of chloroquine resistance by the malarial parasite.” They then go on to explain that “malaria waxes and wanes to the beat of two rhythms: an

annual one dominated by local, seasonal weather conditions and a *ca.* 3-yearly one dominated by herd immunity,” noting that “effective drugs suppress both cycles before they can be expressed,” but that “this produces a population which is mainly or entirely dependent on drug effectiveness, and which suffers the consequence of eventual drug failure, during which the rhythms reestablish themselves, as they appear to have done in Kericho.”

Childs *et al.* (2006) present a detailed analysis of malaria incidence in northern Thailand from January 1977 through January 2002 in the country’s 13 northern provinces. Over this time period, when the IPCC claims the world warmed at a rate and to a level that were unprecedented over the prior two millennia, Childs *et al.* report a decline in total malaria incidence (from a mean monthly incidence of 41.5 to 6.72 cases per hundred thousand people. Noting “there has been a steady reduction through time of total malaria incidence in northern Thailand, with an average decline of 6.45 percent per year,” they say this result “reflects changing agronomic practices and patterns of immigration, as well as the success of interventions such as vector control programs, improved availability of treatment and changing drug policies.”

Finally, some researchers have studied the effect of rising CO<sub>2</sub> concentrations on the mosquitos that transmit malaria. Tuchman *et al.* (2003) took leaf litter from *Populus tremuloides* (Michaux) trees that had been grown out-of-doors in open-bottom root boxes located within open-top above-ground chambers maintained at atmospheric CO<sub>2</sub> concentrations of either 360 or 720 ppm for an entire growing season, incubated the leaf litter for 14 days in a nearby stream, and fed the incubated litter to four species of detritivorous mosquito larvae to assess its effect on their development rates and survivorship. This work revealed that larval mortality was 2.2 times higher for *Aedes albopictus* (Skuse) mosquitos that were fed leaf litter that had been produced in the high-CO<sub>2</sub> chambers than it was for those fed litter that had been produced in the ambient-air chambers.

In addition, Tuchman *et al.* found that larval development rates of *Aedes triseriatus* (Say), *Aedes aegypti* (L.), and *Armigeres subalbatus* (Coquillett) were slowed by 78 percent, 25 percent, and 27 percent, respectively, when fed litter produced in the high-CO<sub>2</sub> as opposed to the ambient-CO<sub>2</sub> chambers, so that mosquitos of these species spent 20, 11, and nine days longer in their respective larval stages when feeding on litter produced in the CO<sub>2</sub>-enriched as

compared to the ambient-CO<sub>2</sub> chambers. As for the reason behind these observations, the researchers suggest that “increases in lignin coupled with decreases in leaf nitrogen induced by elevated CO<sub>2</sub> and subsequent lower bacterial productivity [on the leaf litter in the water] were probably responsible for [the] decreases in survivorship and/or development rate of the four species of mosquitos.”

What is the significance of these findings? In the words of Tuchman *et al.*, “the indirect impacts of an elevated CO<sub>2</sub> atmosphere on mosquito larval survivorship and development time could potentially be great,” because longer larval development times could result in fewer cohorts of mosquitos surviving to adulthood; and with fewer mosquitos around, there should be lower levels of mosquito-borne diseases.

In conclusion, research that takes into account more than one or two variables typically shows little or no relationship between the incidence of malaria and temperature. Many factors are more important than temperature, and those that are subject to human control are being used to steadily reduce the incidence of deaths from this disease. In the words of Dye and Reiter (2000), “given adequate funding, technology, and, above all, commitment, the campaign to ‘Roll Back Malaria,’ spearheaded by the World Health Organization, will have halved deaths related to [malaria] by 2010” - independent of whatever tack earth’s climate might take in the interim.

#### 9.1.4. Tick-Borne Diseases

The IPCC claims that one of the likely consequences of the increase in temperature would be expanded geographic ranges of tick-borne diseases, although once again this prediction is highly qualified. "Climate change alone is unlikely to explain recent increases in the incidences of tick-borne disease in Europe or North America," the IPCC admits, and "other explanations cannot be ruled out" (IPCC 2007-II, p. 403).

Randolph and Rogers (2000) reported that tick-borne encephalitis (TBE) "is the most significant vector-borne disease in Europe and Eurasia," having "a case morbidity rate of 10-30 percent and a case mortality rate of typically 1-2 percent but as high as 24 percent in the Far East." The disease is caused by a flavivirus (TBEV), which is maintained in natural rodent-tick cycles; humans may be infected with it if bitten by an infected tick or by drinking untreated milk from infected sheep or goats.

Early writings on the relationship of TBE to global warming predicted it would expand its range and become more of a threat to humans in a warmer world. However, Randolph and Rogers indicate that "like many vector-borne pathogen cycles that depend on the interaction of so many biotic agents with each other and with their abiotic environment, enzootic cycles of TBEV have an inherent fragility," so that "their continuing survival or expansion cannot be predicted from simple univariate correlations." The two researchers decided to explore the subject in greater detail than had ever been done before.

Confining their analysis to Europe, Randolph and Rogers first correlated the present-day distribution of TBEV to the present-day distributions of five climatic variables: monthly mean, maximum, and minimum temperatures, rainfall and saturation vapor pressure, "to provide a multivariate description of present-day areas of disease risk." Then, they applied this understanding to outputs of a general circulation model of the atmosphere that predicted how these five climatic variables may change in the future. The results of these operations indicated that the

distribution of TBEV might expand both north and west of Stockholm, Sweden in a warming world. For most other parts of Europe, however, the two researchers say “fears for increased extent of risk from TBEV caused by global climate change appear to be unfounded.” They found that “the precise conditions required for enzootic cycles of TBEV are predicted to be disrupted” in response to global warming, and that the new climatic state “appears to be lethal for TBEV.” This finding, in their words, “gives the lie to the common perception that a warmer world will necessarily be a world under greater threat from vector-borne diseases.” In the case of TBEV, in fact, they report that the predicted change “appears to be to our advantage.”

Similarly, Estrada-Peña (2003) evaluated the effects of various abiotic factors on the habitat suitability of four tick species that are major vectors of livestock pathogens in South Africa. This work revealed “year-to-year variations in the forecasted habitat suitability over the period 1983-2000 show a clear decrease in habitat availability, which is attributed primarily to increasing temperature in the region over this period.” In addition, when climate variables were projected to the year 2015, Estrada-Peña found that “the simulations show a trend toward the destruction of the habitats of the four tick species.” This is the opposite of what is predicted by those who warn of catastrophic consequences from global warming.

Zell (2004) determined that “the factors responsible for the emergence/reemergence of vector-borne diseases are complex and mutually influence each other,” citing as an example that “the incidence and spread of parasites and arboviruses are affected by insecticide and drug resistance, deforestation, irrigation systems and dams, changes in public health policy (decreased resources of surveillance, prevention, and vector control), demographic changes (population growth, migration, urbanization), and societal changes (inadequate housing conditions, water deterioration, sewage, waste management).”

In light of these many complicating factors, Zell says “it may be over-simplistic to attribute emergent/re-emergent diseases to climate change and sketch the menace of devastating epidemics in a warmer world.” Indeed, he concludes that “variations in public health practices and lifestyle can easily outweigh changes in disease biology,” especially those that might be caused by global warming.

### 9.1.5. Heat-related Mortality

Keatinge and Donaldson (2001) analyzed the effects of temperature, wind, rain, humidity, and sunshine during high pollution days in the greater London area over the period 1976-1995 to determine what weather and/or pollution factors have the biggest influence on human mortality. Their most prominent finding was that simple plots of mortality rate versus daily air temperature revealed a linear increase in deaths as temperatures fell from 15°C to near 0°C. Mortality rates at temperatures above 15°C were, in the words of the researchers, “grossly ailinear,” showing no trend. Days with high pollutant concentrations were colder than average, but a multiple regression analysis revealed that no pollutant was associated with a significant increase in mortality among people over 50 years of age. Indeed, only low temperatures were shown to have a significant effect on both immediate (one day after the temperature perturbation) and long-term (up to 24 days after the temperature perturbation) mortality rates.

Keatinge *et al.* (2000) examined heat- and cold-related mortality in north Finland, south Finland, southwest Germany, the Netherlands, Greater London, north Italy, and Athens, Greece in people aged 65-74. For each of these regions, they determined the 3°C temperature interval of lowest mortality and then evaluated mortality deviations

from that base level as temperatures rose and fell by 0.1°C increments. The result, according to the researchers, was that “all regions showed more annual cold related mortality than heat related mortality.” Over the seven regions studied, annual cold-related deaths were nearly 10 times greater than annual-heat related deaths. The scientists also note that the very successful adjustment of the different populations they studied to widely different summer temperatures “gives grounds for confidence that they would adjust successfully, with little increase in heat related mortality, to the global warming of around 2°C predicted to occur in the next half century.” Indeed, they say their data suggest “any increases in mortality due to increased temperatures would be outweighed by much larger short term declines in cold related mortalities.” For the population of Europe, therefore, an increase in temperature would appear to be a climate change for the better.

Gouveia *et al.* (2003) conducted a similar study in Sao Paulo, Brazil, where they tabulated the numbers of daily deaths from all causes (excepting violent deaths and deaths of infants up to one month of age), which they obtained from the city’s mortality information system for the period 1991-1994. They then analyzed these data for children (less than 15 years of age), adults (ages 15-64), and the elderly (age 65 and above) with respect to the impacts of warming and cooling. For each 1°C increase above the minimum-death temperature of 20°C for a given and prior day’s mean temperature, there was a 2.6 percent increase in deaths from all causes in children, a 1.5 percent increase in deaths from all causes in adults, and a 2.5 percent increase in deaths from all causes in the elderly. For each 1°C decrease below the 20°C minimum-death temperature, however, the cold effect was greater, with increases in deaths from all causes in children, adults, and the elderly registering 4.0 percent, 2.6 percent, and 5.5 percent, respectively. These cooling-induced death rates are 54 percent, 73 percent, and 120 percent greater than those attributable to warming.

Kan *et al.* (2003), in a study conducted in Shanghai, China from June 1, 2000 to December 31, 2001, found a V-like relationship between total mortality and temperature that had a minimum mortality risk at 26.7°C. Above this temperature, they note that “total mortality increased by 0.73 percent for each degree Celsius increase; while for temperatures below the optimum value, total mortality decreased by 1.21 percent for each degree Celsius increase.” The net effect of a warming of the climate of

Shanghai, therefore, would likely be reduced mortality on the order of 0.5 percent per degree Celsius increase in temperature, or perhaps even more, in light of the fact that the warming of the past few decades has been primarily due to increases in daily minimum temperatures.

Goklany and Straja (2000) studied deaths in the United States due to all causes over the period 1979-97. They found deaths due to extreme cold exceeded those due to extreme heat by 80 percent to 125 percent. No trends were found due to either extreme heat or cold in the entire population or, remarkably, in the older, more susceptible, age groups, i.e., those aged 65 and over, 75 and over, and 85 and over. Goklany and Straja say the absence of any trend “suggests that adaptation and technological change may be just as important determinants of such trends as more obvious meteorological and demographic factors.”

Davis *et al.* (2003) examined daily mortality rates for 28 major U.S. cities over 29 years between 1964 and 1998. In order to control for changes in the age structure of each city’s population that might bias temporal comparisons, they standardized each day’s mortality count relative to a hypothetical standard city with a population of one million people, with the demographics of that city based on the age distribution of the entire U.S. population in the year 2000. They found “heat-related mortality rates declined significantly over time in 19 of the 28 cities. For the 28-city average, there were 41.0+/- 4.8 (mean +/- SE) excess heat-related deaths per year (per standard million) in the 1960s and 1970s, 17.3 +/- 2.7 in the 1980s, and 10.5 +/- 2.0 in the 1990s.” This 74 percent drop in heat-related deaths occurred despite an average increase in temperature of 1.0°C during the same period. They interpret this to mean that “the U.S. populace has become systematically less affected by hot and humid weather conditions,” and they say this “calls into question the utility of efforts linking climate change forecasts to future mortality responses in the United States,” something the IPCC explicitly does. The four scientists conclude that “there is no simple association between increased heat wave duration or intensity and higher mortality rates in the United States.”

Donaldson *et al.* (2003) determined the mean daily May-August 3°C temperature bands in which deaths of people aged 55 and above were at a minimum for three areas of the world—North Carolina, USA; South Finland; and Southeast England. They then compared heat- and cold-related

deaths that occurred at temperatures above and below this optimum temperature interval for each region, after which they determined how heat-related deaths in the three areas changed between 1971 and 1997 in response to: (1) the 1.0°C temperature rise that was experienced in North Carolina over this period (from an initial temperature of 23.5°C), (2) the 2.1°C temperature rise experienced in Southeast England (from an initial temperature of 14.9°C), and (3) the unchanging 13.5°C temperature of South Finland.

First, it was determined that the 3°C temperature band at which mortality was at its local minimum was lowest for the coolest region (South Finland), highest for the warmest region (North Carolina), and intermediate for the region of intermediate temperature (Southeast England). This suggests these three populations were somewhat acclimated to their respective thermal regimes. Second, in each region, cold-related mortality (expressed as excess mortality at temperatures below the region's optimum 3°C temperature band) was greater than heat-related mortality (expressed as excess mortality at temperatures above the region's optimum 3°C temperature band).

Third, the researchers found that in the coldest of the three regions (South Finland, where there was no change in temperature over the study period), heat-related deaths per million inhabitants in the 55-and-above age group declined from 382 to 99. In somewhat warmer Southeast England, where it warmed by 2.1°C over the study period, heat-related deaths declined but much less, from 111 to 108. In the warmest of the three regions (North Carolina, USA, where mean daily May-August temperature rose by 1.0°C over the study period), heat-related deaths fell most dramatically, from 228 to a mere 16 per million.

From these observations we learn that most people can adapt to both warmer and cooler climates and that cooling tends to produce many more deaths than warming, irrespective of the initial temperature regime. As for the reason behind the third observation—the dramatic decline in heat-related deaths in response to warming in the hottest region of the study (North Carolina)—Donaldson *et al.* attribute it to the increase in the availability of air conditioning in the South Atlantic region of the United States, where they note that the percentage of households with some form of air conditioning rose from 57 percent in 1978 to 72 percent in 1997. With respect to the declining heat-related deaths in the other two areas, they say “the explanation is likely to lie in the

fact that both regions shared with North Carolina an increase in prosperity, which could be expected to increase opportunities for avoiding heat stress.”

Huynen *et al.* (2001) analyzed mortality rates in the entire population of Holland. For the 19-year period from January 1979 through December 1997, the group of five scientists compared the numbers of deaths in people of all ages that occurred during well-defined heat waves and cold spells. They found a total excess mortality of 39.8 deaths per day during heat waves and 46.6 deaths per day during cold spells. These numbers indicate that a typical cold-spell day kills at a rate that is 17 percent greater than a typical heat-wave day in the Netherlands.

The researchers note that the heat waves they studied ranged from 6 to 13 days in length, while the cold spells lasted 9 to 17 days, making the average cold spell approximately 37 percent longer than the average heat wave. Adjusting for this duration differential makes the number of deaths per cold spell in the Netherlands fully 60 percent greater than the number of deaths per heat wave. What is more, excess mortality continued during the whole month *after* the cold spells, leading to even more deaths, while there appeared to be mortality deficits in the month following heat waves, suggesting, in the words of the authors, “that some of the heat-induced increase in mortality can be attributed to those whose health was already compromised” or “who would have died in the short term anyway.” This same conclusion has been reached in a number of other studies (Kunst *et al.*, 1993; Alberdi *et al.*, 1998; Eng and Mercer, 1998; Rooney *et al.*, 1998). It is highly likely, therefore, that the 60 percent greater death toll we have calculated for cold spells in the Netherlands as compared to heat waves is an underestimate of the true differential killing power of these two extreme weather phenomena.

The Dutch could well ask themselves, therefore, “Will global climate change reduce climate-related mortalities in the Netherlands?” ... which is exactly what the senior and second authors of the Huynen *et al.* paper did in a letter to the editor of *Epidemiology* (Martens and Huynen, 2001). Based on the predictions of nine different GCMs for an atmospheric CO<sub>2</sub> concentration of 550 ppm in the year 2050—which implied a 50 percent increase in Dutch heat waves and a 67 percent drop in Dutch cold spells—they calculated a total mortality *decrease* for Holland of approximately 1,100 people per year at that point in time.

Data from Germany tell much the same story. Laschewski and Jendritzky (2002) analyzed daily mortality rates of the population of Baden-Württemberg, Germany (10.5 million inhabitants) over the 30-year period 1958-1997 to determine the sensitivity of the people living in this moderate climatic zone of southwest Germany to long- and short-term episodes of heat and cold. They found the mortality data “show a marked seasonal pattern with a minimum in summer and a maximum in winter” and “cold spells lead to excess mortality to a relatively small degree, which lasts for weeks,” and that “the mortality increase during heat waves is more pronounced, but is followed by lower than average values in subsequent weeks.” The authors’ data demonstrate that the mean duration of above-normal mortality for the 51 heat episodes that occurred from 1968 to 1997 was 10 days, with a mean increase in mortality of 3.9 percent, after which there was a mean *decrease* in mortality of 2.3 percent for 19 days. Hence, the net effect of the heat waves was a calculated overall decrease in mortality of 0.2 percent over the full 29-day period.

We end with the work of Thomas Gale Moore, an economist at Stanford University USA. In his first publication reviewed here (Moore, 1998), Moore reported the results of two regression analyses he conducted to estimate the effect on the U.S. death rate of a 4.5°F increase in average temperature, the IPCC’s “best estimate” at the time (1992) of likely warming over the course of the next century. For the first analysis, Moore “regressed various measures of warmth on deaths in Washington, DC, from January 1987 through December 1989,” a period of 36 months, and then extrapolated the results for the entire country. He used Washington, DC because temperatures are recorded for major urban areas, not states, while monthly data on deaths is available from the National Center for Health Statistics only for states, but the center treats the nation’s capital as a state. This analysis found a 4.5°F rise “would cut deaths for the country as a whole by about 37,000 annually.”

For his second analysis, Moore regressed the death rates in 89 large U.S. counties with various weather variables, including actual average temperatures in 1979, highest summer temperature, lowest winter temperature, number of heating degree days, and number of cooling degree days, and several other variables known to affect death rates (percent of the population over age 65, percent black, percent with 16 years or more of schooling, median

household income, per-capita income, air pollution, and health care inputs such as number of hospital beds and physicians per 100,000 population.) He found “the coefficient for average temperature implies that if the United States were enjoying temperatures 4.5 degrees warmer than today, mortality would be 41,000 less. This savings in lives is quite close to the number estimated based on the Washington, DC data, for the period 1987 through 1989.” Moore notes that “a warmer climate would reduce mortality by about the magnitude of highway deaths.”

Two years later, in a report published by the Hoover Institution, Moore estimated the number of deaths that would be caused by the costs associated with reducing U.S. greenhouse gas emissions (Moore, 2000). “Economists studying the relationship of income and earnings to mortality have found that the loss of \$5 million to \$10 million in the U.S. GDP [gross domestic product] leads to one extra death,” Moore writes. Since the Energy Information Administration (EIA) estimated that meeting the Kyoto Protocol’s goal of reducing greenhouse gas emissions to 7 percent below 1990 levels by 2010-2012 would cost \$338 billion annually (without emissions trading), “the EIA estimates imply that somewhere between 33,800 and 67,000 more Americans will die annually between 2008 and 2012.”

These studies of the effects of temperature on human mortality show that cooling, not warming, kills the largest number of people each year. The number of lives saved by warmer weather, if the IPCC’s forecasts of future warming are correct (and we doubt that they are), would far exceed the number of lives lost. The margin in the United States is enormous, with the number of prevented deaths exceeding the number of deaths that occur on the nation’s highways each year. Conversely, attempting to stop global warming by reducing emissions would cost lives—between 33,800 and 67,000 a year in the U.S. alone, according to Moore (2000). These staggering numbers leave little doubt that global warming does not pose a threat to human health.

## 9.2. Nutrition

Rising concentrations of CO<sub>2</sub> in the atmosphere affect human health indirectly by enhancing plant productivity, a topic examined at length in Chapter 7. In this section we review the scientific literature on CO<sub>2</sub>-induced changes to the quantity and quality of food crops—in particular the protein and antioxidants present in grains and fruits—and on the medicinal properties of some plants. We find the overwhelming weight of evidence indicates a positive effect of global warming on human health.

### 9.2.1. Food Quantity

The concentration of CO<sub>2</sub> in the earth's atmosphere has risen approximately 100 ppm since the inception of the Industrial Revolution. To measure the effect this increase had on wheat, Mayeux *et al.* (1997) grew two cultivars of commercial wheat in a 38-meter-long soil container topped with a transparent tunnel-like polyethylene cover within which a CO<sub>2</sub> gradient was created that varied from approximately 350 ppm at one end of the tunnel to about 200 ppm at the other end. Both wheat cultivars were irrigated weekly over the first half of the 100-day growing season, to maintain soil water contents near optimum conditions. Over the last half of the season, this regimen was maintained on only half of the wheat of each cultivar, in order to create both water-stressed and well-watered treatments.

At the conclusion of the experiment, the scientists determined that the growth response of the wheat was a linear function of atmospheric CO<sub>2</sub> concentration in both cultivars under both adequate and less-than-adequate soil water regimes. Based on the linear regression equations they developed for grain yield in these situations, we calculate that the 100-ppm increase in atmospheric CO<sub>2</sub> concentration experienced over the past century-and-a-half probably

increased the mean grain yield of the two wheat cultivars by about 72 percent under well-watered conditions and 48 percent under water-stressed conditions, for a mean yield increase on the order of 60 percent under the full range of moisture conditions likely to have existed in the real world. In other words, the historical rise in CO<sub>2</sub> concentrations may have increased wheat yields by 60 percent, clearly a benefit to a growing population.

This CO<sub>2</sub>-induced yield enhancement to wheat production also has been documented by Alexandrov and Hoogenboom, 2000a; Brown and Rosenberg, 1999; Cuculeanu *et al.*, 1999; Dijkstra *et al.*, 1999; Eitzinger *et al.*, 2001; Harrison and Butterfield, 1996; Masle, 2000; Southworth *et al.*, 2002; and van Ittersum *et al.*, 2003. Nor is wheat the only food crop that benefits from CO<sub>2</sub>-fertilization. Research reviewed in Chapter 7 showing increased production by other crops exposed to enhanced CO<sub>2</sub>, includes the following:

- Alfalfa (De Luis *et al.*, 1999; Luscher *et al.*, 2000; Morgan *et al.*, 2001; Sgherri *et al.*, 1998)
- Cotton (Booker, 2000; Booker *et al.*, 2000; Leavitt *et al.*, 1994; Reddy *et al.*, 1999; Reddy *et al.*, 1998. Tischler *et al.*, 2000)
- Corn (maize) (Baczek-Kwinta and Koscielniak, 2003; Bootsma *et al.*, 2005; Conway and Toenniessen, 2003; Leakey *et al.*, 2004; Magrin *et al.*, 2005; Maroco *et al.*, 1999; Shen *et al.*, 2005; Watling and Press, 1997; Watling and Press, 2000)
- Peanuts (Alexandrov and Hoogenboom, 2000b; Prasad *et al.*, 2003; Stanciel *et al.*, 2000; Vu, 2005)
- Potatoes (Bunce, 2003; Chen and Setter, 2003; Fangmeier and Bender, 2002; Kauder *et al.*, 2000; Lawson *et al.*, 2001; Louche-Tessandier *et al.*, 1999; Ludewig *et al.*, 1998; Magliulo *et al.*, 2003; Miglietta *et al.*, 1998; Olivo *et al.*, 2002; Pruski *et al.*, 2002; Schapendonk, *et al.*, 2000; Sicher and Bunce, 1999; Wolf and van Oijen, 2002; Wolf and van Oijen, 2003)
- Rice (Baker *et al.*, 2000; De Costa *et al.*, 2003a; De Costa *et al.*, 2003b; Gesch *et al.*, 2002; Kim *et al.*, 2003; Kim *et al.*, 2001; Kobayashi *et al.*, 2001; Tako, *et al.*, 2001; Watling and Press, 2000; Weerakoon *et al.*, 2000; Widodo *et al.*, 2003; Ziska *et al.*, 1997)

- Strawberries (Bunce, 2001; Bushway and Pritts, 2002; Deng and Woodward, 1998)

Based on this voluminous data and much more, Idso and Idso (2000) calculated that the increase in atmospheric CO<sub>2</sub> concentration during the past 150 years probably caused mean yield increases on the order of 70 percent for wheat and other C<sub>3</sub> cereals, 28 percent for C<sub>4</sub> cereals, 33 percent for fruits and melons, 62 percent for legumes, 67 percent for root and tuber crops, and 51 percent for vegetables.

Such major increases in production by important food plants due to the historical increase in the air's CO<sub>2</sub> content have undoubtedly benefitted human health. In fact, it is safe to say that some of the people reading these words would not be alive today were it not for the CO<sub>2</sub> enrichment caused by human industry since the beginning of the Industrial Revolution.

What does the IPCC say about this extraordinary benefit to human health made possible by rising CO<sub>2</sub> levels? Incredibly, it is not mentioned anywhere in the contribution of Working Group I to the Fourth Assessment Report of the IPCC (IPCC 2007-I) or in the chapter on the impact of global warming on human health in the contribution of Working Group II (IPCC 2007-II). It is treated dismissively in the chapter on agriculture in the contribution of Working Group III (IPCC 2007-III), even though the proposals justified in the first two volumes and advanced in the third would *reduce* CO<sub>2</sub> emissions and therefore have a negative impact on crop yields. To call this a gross oversight is to be kind to the authors of these reports.

In view of these observations, it is indisputable that the ongoing rise in the air's CO<sub>2</sub> content has bestowed a huge benefit to human health by expanding the yields of food crops.

Additional information on this topic, including reviews of newer publications as they become available, can be found at <http://www.co2science.org/subject/a/agriculture.php>.

### 9.2.2. Food Quality

The quantity of food is mankind's primary concern when it comes to survival. But after survival is assured, the *quality* of food rises to the fore. What role does the ongoing rise in the air's CO<sub>2</sub> content play here? In this section we survey the literature on the effects of higher CO<sub>2</sub> air concentration on plant protein and antioxidant content.

#### 9.2.2.1. Protein Content

Idso and Idso (2001) and Idso *et al.* (2001) cited studies where elevated levels of atmospheric CO<sub>2</sub> either increased, decreased, or had no effect on the protein concentrations of various agricultural crops.

The relationship, as we will see, is complex, though in the end it appears that enhanced atmospheric CO<sub>2</sub> has a positive effect on the protein content of most crops.

Pleijel *et al.* (1999) analyzed the results of 16 open-top chamber experiments that had been conducted on spring wheat in Denmark, Finland, Sweden, and Switzerland between 1986 and 1996. In addition to CO<sub>2</sub> enrichment of the air, these experiments included increases and decreases in atmospheric ozone (O<sub>3</sub>). The scientists found that while increasing O<sub>3</sub> pollution reduced wheat grain yield it simultaneously increased the protein concentration of the grain. Removing O<sub>3</sub> from the air led to higher grain yield but lower protein concentration. The opposite relationship was found for atmospheric CO<sub>2</sub> enrichment, which increased grain yield but lowered protein concentration. Water stress, which was also a variable in one of the experiments, reduced yield and increased grain protein concentrations.

In an earlier study of CO<sub>2</sub> and O<sub>3</sub> effects on wheat grain yield and quality, Rudorff *et al.* (1996) found that “flour protein contents were increased by enhanced O<sub>3</sub> exposure and reduced by elevated CO<sub>2</sub>” but that “the combined effect of these gases was minor.” They conclude that “the concomitant increase of CO<sub>2</sub> and O<sub>3</sub> in the troposphere will have no significant impact on wheat grain quality.”

Earlier, Evans (1993) had found several other crops to be greatly affected by soil nitrogen availability. Rogers *et al.* (1996) observed CO<sub>2</sub>-induced reductions in the protein concentration of flour derived from wheat plants growing at low soil nitrogen concentrations, but no such reductions were evident when the soil nitrogen supply was increased. Pleijel *et al.* concluded that the oft-observed negative impact of atmospheric CO<sub>2</sub> enrichment on grain protein concentration would probably be alleviated by higher applications of nitrogen fertilizers.

The study of Kimball *et al.* (2001) confirmed their hypothesis. Kimball *et al.* studied the effects of a 50 percent increase in atmospheric CO<sub>2</sub> concentration on wheat grain nitrogen concentration and the baking properties of the flour derived from that grain throughout four years of free-air CO<sub>2</sub> enrichment experiments. In the first two years of their study, soil water content was an additional variable; in the last two years, soil nitrogen content was a variable. The most influential factor in reducing grain nitrogen concentration was determined to be low soil nitrogen.

Under this condition, atmospheric CO<sub>2</sub> enrichment further reduced grain nitrogen and protein concentrations, although the change was much less than that caused by low soil nitrogen. When soil nitrogen was not limiting, however, increases in the air’s CO<sub>2</sub> concentration did not affect grain nitrogen and protein concentrations; neither did they reduce the baking properties of the flour derived from the grain. Hence, it would appear that given sufficient water and nitrogen, atmospheric CO<sub>2</sub> enrichment can significantly increase wheat grain yield without sacrificing grain protein concentration in the process.

There are some situations where atmospheric CO<sub>2</sub> enrichment has been found to *increase* the protein concentration of wheat. Agrawal and Deepak (2003), for example, grew two cultivars of wheat (*Triticum aestivum* L. cv. Malviya 234 and HP1209) in open-top chambers maintained at atmospheric CO<sub>2</sub> concentrations of 350 and 600 ppm alone and in combination with 60 ppb SO<sub>2</sub> to study the interactive effects of elevated CO<sub>2</sub> and this major air pollutant on crop growth. They found that exposure to the elevated SO<sub>2</sub> caused a 13 percent decrease in foliar protein concentrations in both cultivars; but when the plants were concomitantly exposed to an atmospheric CO<sub>2</sub> concentration of 600 ppm, leaf protein levels decreased only by 3 percent in HP1209, while they actually increased by 4 percent in Malviya 234.

In the case of rice—which according to Wittwer (1995) is “the basic food for more than half the world’s population,” supplying “more dietary energy than any other single food”—Jablonski *et al.* (2002) conducted a wide-ranging review of the scientific literature, finding that it too appeared to suffer no reduction in grain nitrogen (protein) concentration in response to atmospheric CO<sub>2</sub> enrichment. Likewise, they found no CO<sub>2</sub>-induced decrease in seed nitrogen concentration in the studies of legumes they reviewed. This finding is also encouraging, since according to Wittwer (1995) legumes “are a direct food resource providing 20 percent of the world’s protein for human consumption,” as well as “about two thirds of the world’s protein concentrate for livestock feeding.” What is more, the biomass of the CO<sub>2</sub>-enriched wheat, rice, and legumes was found by Jablonski *et al.* to be significantly increased above that of the same crops grown in normal air. Hence, there will likely be a large increase in the total amount of protein made available to humanity in a future CO<sub>2</sub>-enriched world, both directly via food crops and indirectly via livestock.

With respect to the leguminous soybean, Thomas *et al.* (2003) additionally note that “oil and protein comprise ~20 and 40 percent, respectively, of the dry weight of soybean seed,” which “unique chemical composition,” in their words, “has made it one of the most valuable agronomic crops worldwide.” In addition, they say “the intrinsic value of soybean seed is in its supply of essential fatty acids and amino acids in the oil and protein, respectively,” and they report that Heagle *et al.* (1998) “observed a positive significant effect of CO<sub>2</sub> enrichment on soybean seed oil and oleic acid concentration.”

Legumes and their responses to atmospheric CO<sub>2</sub> enrichment also figure prominently in a number of studies of mixed forage crops. In a study of nitrogen cycling in grazed pastures on the North Island of New Zealand, for example, Allard *et al.* (2003) report that under elevated CO<sub>2</sub>, leaves of the individual species exhibited lower nitrogen concentrations but higher water-soluble carbohydrate (WSC) concentrations. They also say “there was a significantly greater proportion of legume in the diet at elevated CO<sub>2</sub>,” and that this “shift in the botanical composition towards a higher proportion of legumes counterbalanced the nitrogen decrease observed at the single species scale, resulting in a nitrogen concentration of the overall diet that was unaffected by elevated CO<sub>2</sub>.” They further report that “changes at the species level and at the sward level appeared to combine additively in relation to WSC,” and “as there was a significant correlation between WSC and digestibility (as previously observed by Dent and Aldrich, 1963 and Humphreys, 1989), there was also an increase in digestibility of the high CO<sub>2</sub> forage,” which result, in their words, “matches that found in a Mini-FACE experiment under cutting (Teyssonneyre, 2002; Picon-Cochard *et al.*, 2004),” where “digestibility also increased in response to CO<sub>2</sub> despite reduced crude protein concentration.” These data, plus the strong relationship between soluble sugars (rather than nitrogen) and digestibility, led them to suggest that “the widespread response to CO<sub>2</sub> of increased soluble sugars might lead to an increase in forage digestibility.”

Luscher *et al.* (2004) found much the same thing in their review of the subject, which was based primarily on studies conducted at the Swiss FACE facility that hosts what has become the world’s longest continuous atmospheric CO<sub>2</sub> enrichment study of a naturally occurring grassland. In response to an approximate two-thirds increase in the air’s CO<sub>2</sub> concentration, leaf nitrogen (N) concentrations of

white clover (*Trifolium repens* L.) and perennial ryegrass (*Lolium perenne* L.) were reduced by 7 percent and 18 percent, respectively, when they were grown separately in pure stands. However, as Luscher *et al.* report, “the considerably lower concentration of N under elevated CO<sub>2</sub>, observed for *L. perenne* leaves in pure stands, was found to a much lesser extent for *L. perenne* leaves in the bi-species mixture with *T. repens* (Zanetti *et al.*, 1997; Hartwig *et al.*, 2000).” Furthermore, as they continue, “under elevated CO<sub>2</sub> the proportion of N-rich *T. repens* (40 mg N g<sup>-1</sup> dry matter) increased in the mixture at the expense of the N-poor *L. perenne* (24 mg N g<sup>-1</sup> dry matter when grown in monoculture),” the end result being that “the concentration of N in the harvested biomass of the mixture showed no significant reduction.”

Campbell *et al.* (2000) analyzed research conducted between 1994 and 1999 by a worldwide network of 83 scientists associated with the Global Change and Terrestrial Ecosystems (GCTE) Pastures and Rangelands Core Research Project 1 (CRP1) that resulted in the publication of more than 165 peer-reviewed scientific journal articles. Campbell *et al.* determined from this massive collection of data that the legume content of grass-legume swards was typically increased by approximately 10 percent in response to a doubling of the air’s CO<sub>2</sub> content.

Luscher *et al.* (2004) state that “the nutritive value of herbage from intensively managed grassland dominated by *L. perenne* and *T. repens* ... is well above the minimum range of the concentration of crude protein necessary for efficient digestion by ruminants (Barney *et al.*, 1981).” They conclude that “a small decrease in the concentration of crude protein in intensively managed forage production systems [which may never occur, as noted above] is not likely to have a negative effect on the nutritive value or on the intake of forage.”

One final forage study is Newman *et al.* (2003), who investigated the effects of two levels of nitrogen fertilization and an approximate doubling of the air’s CO<sub>2</sub> content on the growth and chemical composition of tall fescue (*Festuca arundinacea* Schreber cv. KY-31), both when infected and uninfected with a mutualistic fungal endophyte (*Neotyphodium coenophialum* Morgan-Jones and Gams). They found that the elevated CO<sub>2</sub> reduced the crude protein content of the forage by an average of 21 percent in three of the four situations studied: non-endophyte-infected plants in both the low and high nitrogen treatments, and endophyte-infected plants in the high nitrogen treatment. However, there was no protein

reduction for endophyte-infected plants in the low nitrogen treatment.

As noted by Newman *et al.*, “the endophyte is present in many native and naturalized populations and the most widely sown cultivars of *F. arundinacea*,” so the first two situations in which the CO<sub>2</sub>-induced protein reduction occurred (those involving non-endophyte-infected plants) are not typical of the real world. In addition, since the dry-weight biomass yield of the forage was increased by fully 53 percent under the low nitrogen regime, and since the 10-times-greater high nitrogen regime boosted yields only by an additional 8 percent, there would appear to be no need to apply any extra nitrogen to *F. arundinacea* in a CO<sub>2</sub>-enriched environment. Consequently, under best management practices in a doubled-CO<sub>2</sub> world of the future, little to no nitrogen would be added to the soil and there would be little to no reduction in the crude protein content of *F. arundinacea*, but there would be more than 50 percent more of it produced on the same amount of land.

With respect to the final plant quality studied by Newman *et al.*—i.e., forage digestibility—increasing soil nitrogen lowered *in vitro* neutral detergent fiber digestibility in both ambient and CO<sub>2</sub>-enriched air; this phenomenon was most pronounced in the elevated CO<sub>2</sub> treatment. Again, however, under low nitrogen conditions there was no decline in plant digestibility. Hence, there is a second good reason not to apply extra nitrogen to *F. arundinacea* in a high CO<sub>2</sub> world of the future and, of course, little to no need to do so. Under best management practices in a future CO<sub>2</sub>-enriched atmosphere, therefore, the results of this study suggest much greater quantities of good-quality forage could be produced without the addition of any, or very little, extra nitrogen to the soil.

But what about the unmanaged world of nature? Increases in the air’s CO<sub>2</sub> content often—but not always (Goverde *et al.*, 1999)—lead to greater decreases in the concentrations of nitrogen and protein in the foliage of C<sub>3</sub> as compared to C<sub>4</sub> grasses (Wand *et al.*, 1999); as a result, in the words of Barbehenn *et al.* (2004a), “it has been predicted that insect herbivores will increase their feeding damage on C<sub>3</sub> plants to a greater extent than on C<sub>4</sub> plants” (Lincoln *et al.*, 1984, 1986; Lambers, 1993).

To test this hypothesis, Barbehenn *et al.* (2004a) grew *Lolium multiflorum* Lam. (Italian ryegrass, a common C<sub>3</sub> pasture grass) and *Bouteloua curtipendula* (Michx.) Torr. (sideoats gramma, a

native C<sub>4</sub> rangeland grass) in chambers maintained at either the ambient atmospheric CO<sub>2</sub> concentration of 370 ppm or the doubled CO<sub>2</sub> concentration of 740 ppm for two months, after which newly molted sixth-instar larvae of *Pseudaletia unipuncta* (a grass-specialist noctuid) and *Spodoptera frugiperda* (a generalist noctuid) were allowed to feed upon the grasses. As expected, foliage protein concentration decreased by 20 percent in the C<sub>3</sub> grass, but by only 1 percent in the C<sub>4</sub> grass, when grown in the CO<sub>2</sub>-enriched air. However, and “contrary to our expectations,” according to Barbehenn *et al.*, “neither caterpillar species significantly increased its consumption rate to compensate for the lower concentration of protein in [the] C<sub>3</sub> grass,” noting that “this result does not support the hypothesis that C<sub>3</sub> plants will be subject to greater rates of herbivory relative to C<sub>4</sub> plants in future [high-CO<sub>2</sub>] atmospheric conditions (Lincoln *et al.*, 1984).” In addition, and “despite significant changes in the nutritional quality of *L. multiflorum* under elevated CO<sub>2</sub>,” they report that “no effect on the relative growth rate of either caterpillar species on either grass species resulted” and there were “no significant differences in insect performance between CO<sub>2</sub> levels.”

In a similar study with the same two plants, Barbehenn *et al.* (2004b) allowed grasshopper (*Melanoplus sanguinipes*) nymphs that had been reared to the fourth instar stage to feed upon the grasses; once again, “contrary to the hypothesis that insect herbivores will increase their feeding rates disproportionately in C<sub>3</sub> plants under elevated atmospheric CO<sub>2</sub>,” they found that “*M. sanguinipes* did not significantly increase its consumption rate when feeding on the C<sub>3</sub> grass grown under elevated CO<sub>2</sub>,” suggesting this observation implies that “post-ingestive mechanisms enable these grasshoppers to compensate for variable nutritional quality in their host plants,” and noting that some of these post-ingestive responses may include “changes in gut size, food residence time, digestive enzyme levels, and nutrient metabolism (Simpson and Simpson, 1990; Bernays and Simpson, 1990; Hinks *et al.*, 1991; Zanutto *et al.*, 1993; Yang and Joern, 1994a,b).” In fact, their data indicated that *M. sanguinipes* growth rates may have actually *increased*, perhaps by as much as 12 percent, when feeding upon the C<sub>3</sub> foliage that had been produced in the CO<sub>2</sub>-enriched air.

In conclusion, the ongoing rise of the air’s CO<sub>2</sub> concentration is not reducing the protein concentration in, or digestibility of, most important

plant crops. In cases where protein concentration might be reduced, the addition of nitrogen fertilizer appears to offset the effect.

#### 9.2.2.2. Antioxidant Content

Antioxidants are chemical compounds that inhibit oxidation. Some antioxidants found in the human diet, such as vitamin E, vitamin C, and beta carotene, are thought to protect body cells from the damaging effects of oxidation. Scurvy—a condition characterized by general weakness, anemia, gum disease (gingivitis), and skin hemorrhages—is induced by low intake of vitamin C. There is some evidence that the condition may be resurgent in industrial countries, especially among children (Dickinson *et al.*, 1994; Ramar *et al.*, 1993; Gomez-Carrasco *et al.*, 1994). Hampl *et al.* (1999) found that 12-20 percent of 12- to 18-year-old school children in the United States “drastically under-consume” foods that supply vitamin C. Johnston *et al.* (1998) determined that 12-16 percent of U.S. college students have marginal plasma concentrations of vitamin C.

Since vitamin C intake correlates strongly with the consumption of citrus juice (Dennison *et al.*, 1998), and since the only high-vitamin-C juice consumed in any quantity by children is orange juice (Hampl *et al.*, 1999), even a modest role played by the ongoing rise in the air's CO<sub>2</sub> content in increasing the vitamin C concentration of orange juice could prove to be of considerable significance for public health in the United States and elsewhere. Thus, determining if rising CO<sub>2</sub> concentrations increase or

hinder the production of antioxidants in human food is relevant to the issue of what effect the historical rise in CO<sub>2</sub> concentrations is having on human health.

Antioxidant concentrations in plants are generally observed to be high when environmental stresses are present, such as exposure to pollutants, drought, intense solar radiation, and high air or water temperatures. Stress generates highly reactive oxygenated compounds that damage plants, and ameliorating these stresses typically involves the production of antioxidant enzymes that scavenge and detoxify the highly reactive oxygenated compounds. In a study of two soybean genotypes, Pritchard *et al.* (2000) reported that three months' exposure to twice-ambient CO<sub>2</sub> concentrations reduced the activities of superoxide dismutase and catalase by an average of 23 and 39 percent, respectively. Likewise, Polle *et al.* (1997) showed that two years of atmospheric CO<sub>2</sub> enrichment reduced the activities of several key antioxidative enzymes, including catalase and superoxide dismutase, in beech seedlings. Moreover, Schwanz and Polle (1998) demonstrated this phenomenon can persist indefinitely, as they discovered similar reductions in these same enzymes in mature oak trees that had been growing near natural CO<sub>2</sub>-emitting springs for 30 to 50 years.

The standard interpretation of these results is that the observed reductions in the activities of antioxidative enzymes under CO<sub>2</sub>-enriched conditions imply that plants exposed to higher-than-current atmospheric CO<sub>2</sub> concentrations experience less oxidative stress and thus have a reduced need for antioxidant protection. This conclusion further suggests that "CO<sub>2</sub>-advantaged" plants will be able to funnel more of their limited resources into the production of other plant tissues or processes essential to their continued growth and development.

On the other hand, when oxidative stresses do occur under high CO<sub>2</sub> conditions, the enhanced rates of photosynthesis and carbohydrate production resulting from atmospheric CO<sub>2</sub> enrichment generally enable plants to better deal with such stresses by providing more of the raw materials needed for antioxidant enzyme synthesis. Thus, when CO<sub>2</sub>-enriched sugar maple seedlings were subjected to an additional 200 ppb of ozone, Niewiadomska *et al.* (1999) reported that ascorbate peroxidase, which is the first line of enzymatic defense against ozone, significantly increased. Likewise, Schwanz and Polle (2001) noted that poplar clones grown at 700 ppm CO<sub>2</sub> exhibited a much greater increase in superoxide dismutase activity upon chilling induction than clones

grown in ambient air. In addition, Lin and Wang (2002) observed that activities of superoxide dismutase and catalase were much higher in CO<sub>2</sub>-enriched wheat than in ambiently grown wheat following the induction of water stress.

In some cases, the additional carbon fixed during CO<sub>2</sub>-enrichment is invested in antioxidative compounds, rather than enzymes. One of the most prominent of these plant products is *ascorbate* or vitamin C. In the early studies of Barbale (1970) and Madsen (1971, 1975), a tripling of the atmospheric CO<sub>2</sub> concentration produced a modest (7 percent) increase in this antioxidant in the fruit of tomato plants. Kimball and Mitchell (1981), however, could find no effect of a similar CO<sub>2</sub> increase on the same species, although the extra CO<sub>2</sub> of their study stimulated the production of vitamin A. In bean sprouts, on the other hand, a mere one-hour-per-day doubling of the atmospheric CO<sub>2</sub> concentration actually *doubled* plant vitamin C contents over a seven-day period (Tajiri, 1985).

Probably the most comprehensive investigation of CO<sub>2</sub> effects on vitamin C production in an agricultural plant—a tree crop (sour orange)—was conducted by Idso *et al.* (2002). In an atmospheric CO<sub>2</sub> enrichment experiment begun in 1987 and still ongoing, a 75 percent increase in the air's CO<sub>2</sub> content was observed to increase sour orange juice vitamin C concentration by approximately 5 percent in run-of-the-mill years when total fruit production was typically enhanced by about 80 percent. In aberrant years when the CO<sub>2</sub>-induced increase in fruit production was much greater, however, the increase in fruit vitamin C concentration also was greater, rising to a CO<sub>2</sub>-induced enhancement of 15 percent when fruit production on the CO<sub>2</sub>-enriched trees was 3.6 times greater than it was on the ambient-treatment trees.

Wang *et al.* (2003) evaluated the effects of elevated CO<sub>2</sub> on the antioxidant activity and flavonoid content of strawberry fruit in field plots at the U.S. Department of Agriculture's Beltsville Agricultural Research Center in Beltsville, Maryland, where they grew strawberry plants (*Fragaria x ananassa* Duchesne cv. Honeoye) in six clear-acrylic open-top chambers, two of which were maintained at the ambient atmospheric CO<sub>2</sub> concentration, two of which were maintained at ambient + 300 ppm CO<sub>2</sub>, and two of which were maintained at ambient + 600 ppm CO<sub>2</sub> for a period of 28 months (from early spring of 1998 through June 2000). The scientists harvested the strawberry fruit, in their words, "at the

commercially ripe stage” in both 1999 and 2000, after which they analyzed them for a number of different antioxidant properties and flavonol contents.

Before reporting what they found, Wang *et al.* provide some background by noting that “strawberries are good sources of natural antioxidants (Wang *et al.*, 1996; Heinonen *et al.*, 1998).” They further report that “in addition to the usual nutrients, such as vitamins and minerals, strawberries are also rich in anthocyanins, flavonoids, and phenolic acids,” and that “strawberries have shown a remarkably high scavenging activity toward chemically generated radicals, thus making them effective in inhibiting oxidation of human low-density lipoproteins (Heinonen *et al.*, 1998).” In this regard, they note that previous studies (Wang and Jiao, 2000; Wang and Lin, 2000) “have shown that strawberries have high oxygen radical absorbance activity against peroxyl radicals, superoxide radicals, hydrogen peroxide, hydroxyl radicals, and singlet oxygen.”

They determined, first, that strawberries had higher concentrations of ascorbic acid (AsA) and glutathione (GSH) “when grown under enriched CO<sub>2</sub> environments.” In going from ambient to ambient + 300 ppm CO<sub>2</sub> and ambient + 600 ppm CO<sub>2</sub>, for example, AsA concentrations increased by 10 and 13 percent, respectively, while GSH concentrations increased by 3 and 171 percent, respectively. They also learned that “an enriched CO<sub>2</sub> environment resulted in an increase in phenolic acid, flavonol, and anthocyanin contents of fruit.” For nine different flavonoids, for example, there was a mean concentration increase of  $55 \pm 23$  percent in going from the ambient atmospheric CO<sub>2</sub> concentration to ambient + 300 ppm CO<sub>2</sub>, and a mean concentration increase of  $112 \pm 35$  percent in going from ambient to ambient + 600 ppm CO<sub>2</sub>. In addition, they report that the “high flavonol content was associated with high antioxidant activity.” As for the significance of these findings, Wang *et al.* note that “anthocyanins have been reported to help reduce damage caused by free radical activity, such as low-density lipoprotein oxidation, platelet aggregation, and endothelium-dependent vasodilation of arteries (Heinonen *et al.*, 1998; Rice-Evans and Miller, 1996).”

In summarizing their findings, Wang *et al.* say “strawberry fruit contain flavonoids with potent antioxidant properties, and under CO<sub>2</sub> enrichment conditions, increased the[ir] AsA, GSH, phenolic acid, flavonol, and anthocyanin concentrations,” further noting that “plants grown under CO<sub>2</sub>

enrichment conditions also had higher oxygen radical absorbance activity against [many types of oxygen] radicals in the fruit.”

Deng and Woodward (1998) reported that after growing strawberry plants in air containing an additional 170 ppm of CO<sub>2</sub>, total fresh fruit weights were 42 and 17 percent greater than weights displayed by control plants grown at high and low soil nitrogen contents, respectively. Bushway and Pritts (2002) reported that a two- to three-fold increase in the air’s CO<sub>2</sub> content boosted strawberry fruit yield by an average of 62 percent. In addition, Campbell and Young (1986), Keutgen *et al.* (1997), and Bunce (2001) reported positive strawberry photosynthetic responses to an extra 300 ppm of CO<sub>2</sub> ranging from 9 percent to 197 percent (mean of 76 percent  $\pm$  15 percent); and Desjardins *et al.* (1987) reported a 118 percent increase in photosynthesis in response to a 600 ppm increase in the air’s CO<sub>2</sub> concentration.

Other researchers have found similar enhancements of antioxidative compounds under enriched levels of atmospheric CO<sub>2</sub>. Estiarte *et al.* (1999), for example, reported that a 180-ppm increase in the air’s CO<sub>2</sub> content increased the foliar concentrations of flavonoids, which protect against UV-B radiation damage, in field-grown spring wheat by 11 to 14 percent. Caldwell *et al.* (2005) found that an ~75 percent increase in the air’s CO<sub>2</sub> content increased the total isoflavone content of soybean seeds by 8 percent when the air temperature during seed fill was 18°C, by 104 percent when the air temperature during seed fill was 23°C, by 101 percent when the air temperature was 28°C, and by 186 percent and 38 percent, respectively, when a drought-stress treatment was added to the latter two temperature treatments.

Lastly, in an experiment conducted under very high atmospheric CO<sub>2</sub> concentrations, Ali *et al.* (2005) found that CO<sub>2</sub> levels of 10,000 ppm, 25,000 ppm, and 50,000 ppm increased total flavonoid concentrations of ginseng roots by 228 percent, 383 percent, and 232 percent, respectively, total phenolic concentrations by 58 percent, 153 percent, and 105 percent, cysteine contents by 27 percent, 65 percent, and 100 percent, and non-protein thiol contents by 12 percent, 43 percent, and 62 percent, all of which substances are potent antioxidants.

In summary, as the CO<sub>2</sub> content of the air rises, plants typically experience less oxidative stress, and since they thus need fewer antioxidants for protection, antioxidant levels in their leaves decline, which

enables them to use more of their valuable resources for other purposes. However, elevated CO<sub>2</sub> also provides more of the raw materials needed for oxidant enzyme synthesis, leading to higher levels of antioxidative compounds—such as *ascorbate*, or vitamin C. Research shows this happens with enough frequency that higher CO<sub>2</sub> levels will lead to higher concentrations of antioxidants, leading to better health.

### 9.2.3. Medicinal Constituents

Primitive medical records indicate that extracts from many species of plants have been used for treating a variety of human health problems for perhaps the past 3,500 years (Machlin, 1992; Pettit *et al.*, 1993, 1995). In modern times the practice has continued, with numerous chemotherapeutic agents being isolated (Gabrielsen *et al.*, 1992a). Until recently, however, no studies had investigated the effects of atmospheric CO<sub>2</sub> enrichment on specific plant compounds of direct medicinal value.

Stuhlfauth *et al.* (1987) studied the individual and combined effects of atmospheric CO<sub>2</sub> enrichment and water stress on the production of secondary metabolites in the woolly foxglove (*Digitalis lanata* EHRH), which produces the cardiac glycoside *digoxin* that is used in the treatment of cardiac insufficiency. Under controlled well-watered conditions in a phytotron, a near-tripling of the air's CO<sub>2</sub> content increased plant dry weight production in this medicinal plant by 63 percent, while under water-stressed conditions the CO<sub>2</sub>-induced dry weight increase was 83 percent. In addition, the concentration of digoxin within the plant dry mass was enhanced by 11 percent under well-watered conditions and by 14 percent under conditions of water stress.

In a subsequent whole-season field experiment, Stuhlfauth and Fock (1990) obtained similar results. A near-tripling of the air's CO<sub>2</sub> concentration led to a 75 percent increase in plant dry weight production per unit land area and a 15 percent increase in digoxin yield per unit dry weight of plant, which combined to produce a doubling of total digoxin yield per hectare of cultivated land.

Idso *et al.* (2000) evaluated the response of the tropical spider lily (*Hymenocallis littoralis* Jacq. Salisb.) to elevated levels of atmospheric CO<sub>2</sub> over four growing seasons. This plant has been known since ancient times to possess anti-tumor activity; in modern times it has been shown to contain constituents that are effective against lymphocytic leukemia and ovary sarcoma (Pettit *et al.*, 1986). These same plant constituents also have been proven to be effective against the U.S. National Cancer Institute's panel of 60 human cancer cell lines, demonstrating greatest effectiveness against melanoma, brain, colon, lung, and renal cancers (Pettit *et al.*, 1993). In addition, it exhibits strong anti-viral activity against Japanese encephalitis and

yellow, dengue, Punta Tora, and Rift Valley fevers (Gabrielsen *et al.*, 1992a,b).

Idso *et al.* determined that a 75 percent increase in the air's CO<sub>2</sub> concentration produced a 56 percent increase in the spider lily's below-ground bulb biomass, where the disease-fighting substances are found. In addition, for these specific substances, they observed a 6 percent increase in the concentration of a two-constituent (1:1) mixture of 7-deoxynarciclasine and 7-deoxy-trans-dihydronarciclasine, an 8 percent increase in pancratistatin, an 8 percent increase in trans-dihydronarciclasine, and a 28 percent increase in narciclasine. Averaged together and combined with the 56 percent increase in bulb biomass, these percentage concentration increases resulted in a total mean active-ingredient increase of 75 percent for the plants grown in air containing 75 percent more CO<sub>2</sub>.

Other plant constituents that perform important functions in maintaining human health include sugars, lipids, oils, fatty acids, and macro- and micro-nutrients. Although concerns have been raised about the availability of certain of the latter elements in plants growing in a CO<sub>2</sub>-enriched world (Loladze, 2002), the jury is still out with respect to this subject as a consequence of the paucity of pertinent data.

Literally thousands of studies have assessed the impact of elevated levels of atmospheric CO<sub>2</sub> on the quantity of biomass produced by agricultural crops, but only a tiny fraction of that number have looked at any aspect of food quality. From what has been learned about plant protein, antioxidants, and the few medicinal substances that have been investigated in this regard, there is no reason to believe these other plant constituents would be present in lower concentrations in a CO<sub>2</sub>-enriched world and ample evidence that they may be present in significantly higher concentrations and greater absolute amounts.

Additional information on this topic, including reviews of newer publications as they become available, can be found at <http://www.co2science.org/subject/h/co2healthpromoting.php>.

## 9.3. Human Longevity

The past two centuries have witnessed a significant degree of global warming as the earth recovered from the Little Ice Age and entered the Current Warm Period. Simultaneously, the planet has seen an increase in its atmospheric CO<sub>2</sub> concentration. What effect have these trends had on human longevity? Although no one can give a precise quantitative answer to this question, it is possible to assess their relative importance by considering the history of human longevity.

Tuljapurkar *et al.* (2000) examined mortality over the period 1950-1994 in Canada, France, Germany (excluding the former East Germany), Italy, Japan, the United Kingdom, and the United States, finding that “in every country over this period, mortality at each age has declined exponentially at a roughly constant rate.” In discussing these findings, Horiuchi (2000) notes that the average lifespan of early humans was about 20 years, but that in the major industrialized countries it is now about 80 years, with the bulk of this increase having come in the past 150 years. He then notes that “it was widely expected that as life expectancy became very high and approached the ‘biological limit of human longevity,’ the rapid ‘mortality decline’ would slow down and eventually level off,” but “such a deceleration has not occurred.” “These findings give rise to two interrelated questions,” says Horiuchi: (1) “Why has mortality decline not started to slow down?” and (2) “Will it continue into the future?”

Some points to note in attempting to answer these questions are the following. First, in Horiuchi’s words, “in the second half of the nineteenth century and the first half of the twentieth century, there were large decreases in the number of deaths from infectious and parasitic diseases, and from poor nutrition and disorders associated with pregnancy and childbirth,” which led to large reductions in the deaths of infants, children, and young adults. In the second half of the twentieth century, however, Horiuchi notes that “mortality from degenerative diseases, most notably heart diseases and stroke, started to fall,” and the reduction was most pronounced among the elderly. Some suspected this latter drop in mortality might have been achieved “through postponing the deaths of seriously ill people,” but data from the United States demonstrate, in his words, that “the health of the elderly greatly improved in the 1980s and 1990s, suggesting that the extended length of life in old age is mainly due to better health rather than prolonged survival in sickness.”

Additional support for this conclusion comes from the study of Manton and Gu (2001). With the completion of the latest of the five National Long-Term Care Surveys of disability in U.S. citizens over 65 years of age—which began in 1982 and extended to 1999 at the time of the writing of their paper—these researchers were able to discern two trends: (1) disabilities in this age group decreased over the entire period studied, and (2) disabilities decreased at a rate that grew ever larger with the passing of time. Over

the 17-year period of record, the percentage of the group that was disabled dropped 25 percent, from 26.2 percent in 1982 to 19.7 percent in 1999. The percentage disability decline rate per year for the periods 1982-1989, 1989-1994, and 1994-1999 was 0.26, 0.38, and 0.56 percent per year, respectively. Commenting on the accelerating rate of this disability decline, the authors say “it is surprising, given the low level of disability in 1994, that the rate of improvement accelerated” over the most recent five-year interval.

Looking outside the United States, Oeppen and Vaupel (2002) reported that “world life expectancy more than doubled over the past two centuries, from roughly 25 years to about 65 for men and 70 for women.” They noted that “for 160 years, best-performance life expectancy has steadily increased by a quarter of a year per year,” and they emphasized that this phenomenal trend “is so extraordinarily linear that it may be the most remarkable regularity of mass endeavor ever observed.”

These observations demonstrate that if the increases in air temperature and CO<sub>2</sub> concentration of the past two centuries were bad for our health, their combined negative influence was minuscule compared to whatever else was at work in promoting this vast increase in worldwide human longevity. It is that “whatever else” to which we now turn our attention.

It is evident that in developed countries, the elderly are living longer with the passing of time. This phenomenon is likely due to ever-improving health in older people, which in turn is likely the result of continuing improvements in the abilities of their bodies to repair cellular damage caused by degenerative processes associated with old age, i.e., stresses caused by the reactive oxygen species that are generated by normal metabolism (Finkel and Holbrook, 2000).

Wentworth *et al.* (2003) report they found “evidence for the production of ozone in human disease,” specifically noting that “signature products unique to cholesterol ozonolysis are present within atherosclerotic tissue at the time of carotid endarterectomy, suggesting that ozone production occurred during lesion development.” According to Marx (2003), “researchers think that inflammation of blood vessels is a major instigator of plaque formation,” that “ozone contributes to plaque formation by oxidizing cholesterol,” and that the new findings “suggest new strategies for preventing

atherosclerosis.” Also according to Marx, Daniel Steinberg of the University of California, San Diego, says that although it’s still too early to definitively state whether ozone production in plaques is a major contributor to atherosclerosis, he expresses his confidence that once we know for sure, we’ll know which antioxidants will work in suppressing plaque formation.

Reactive oxygen species (ROS) generated during cellular metabolism or peroxidation of lipids and proteins also play a causative role in the pathogenesis of cancer, along with coronary heart disease (CHD), as demonstrated by Slaga *et al.* (1987), Frenkel (1992), Marnett (2000), Zhao *et al.* (2000) and Wilcox *et al.* (2004). However, as noted by Yu *et al.* (2004), “antioxidant treatments may terminate ROS attacks and reduce the risks of CHD and cancer, as well as other ROS-related diseases such as Parkinson’s disease (Neff, 1997; Chung *et al.*, 1999; Wong *et al.*, 1999; Espin *et al.*, 2000; Merken and Beecher, 2000).” As a result, they say that “developing functional foods rich in natural antioxidants may improve human nutrition and reduce the risks of ROS-associated health problems.”

Consider, in this regard, the common strawberry. Wang *et al.* (2003) report that strawberries are especially good sources of natural antioxidants. They say that “in addition to the usual nutrients, such as vitamins and minerals, strawberries are also rich in anthocyanins, flavonoids, and phenolic acids,” and that “strawberries have shown a remarkably high scavenging activity toward chemically generated radicals, thus making them effective in inhibiting oxidation of human low-density lipoproteins (Heinonen *et al.*, 1998).” They also note that Wang and Jiao (2000) and Wang and Lin (2000) “have shown that strawberries have high oxygen radical absorbance activity against peroxyl radicals, superoxide radicals, hydrogen peroxide, hydroxyl radicals, and singlet oxygen.” And they say that “anthocyanins have been reported to help reduce damage caused by free radical activity, such as low-density lipoprotein oxidation, platelet aggregation, and endothelium-dependent vasodilation of arteries (Heinonen *et al.*, 1998; Rice-Evans and Miller, 1996).”

Our reason for citing all of this information is that Wang *et al.* (2003) have recently demonstrated that enriching the air with carbon dioxide increases both the concentrations and activities of many of these helpful substances. They determined, for example, that strawberries had higher concentrations of

ascorbic acid and glutathione when grown in CO<sub>2</sub>-enriched environments. They also learned that “an enriched CO<sub>2</sub> environment resulted in an increase in phenolic acid, flavonol, and anthocyanin contents of fruit.” For nine different flavonoids there was a mean concentration increase of 55 percent in going from the ambient atmospheric CO<sub>2</sub> concentration to ambient + 300 ppm CO<sub>2</sub>, and a mean concentration increase of 112 percent in going from ambient to ambient + 600 ppm CO<sub>2</sub>. Also, they report that “high flavonol content was associated with high antioxidant activity.”

There is little reason to doubt that similar concentration and activity increases in the same and additional important phytochemicals in other food crops would occur in response to the same increases in the air’s CO<sub>2</sub> concentration. Indeed, the aerial fertilization effect of atmospheric CO<sub>2</sub> enrichment is a near-universal phenomenon that operates among plants of all types, and it is very powerful (e.g., Mayeux *et al.*, 1997; Idso and Idso, 2000). There must have been significant concomitant increases in the concentrations and activities of the various phytochemicals in these foods that act as described by Wang *et al.* (2003).

Could some part of the rapid lengthening of human longevity reported by Oeppen and Vaupel (2002) be due to enhanced CO<sub>2</sub> in the air putting more antioxidants in our diets? Two recent experiments showing the positive effects of antioxidants on animal lifespan provide some additional evidence that this may be the case.

Melov *et al.* (2000) examined the effects of two superoxide dismutase-/catalase-like mimetics (EUK-8 and EUK-134) on the lifespan of normal and mutant *Caenorhabditis elegans* worms that ingested various concentrations of the mimetics. In all of their experiments, treatment of normal worms with the antioxidant mimetics significantly increased both mean and maximum lifespan. Treatment of normal worms with only 0.05 mM EUK-134, for example, increased their mean lifespan by fully 54 percent. In mutant worms whose lifespan had been genetically shortened by 37 percent, treatment with 0.5 mM EUK-134 restored their lifespan to normal by increasing their mutation-reduced lifespan by 67 percent. It also was determined that these effects were not due to a reduction in worm metabolism, which could have reduced the production of oxygen radicals, but “by augmenting natural antioxidant defenses without having any overt effects on other traits.” In the words of the authors, “these results suggest that

endogenous oxidative stress is a major determinant of the rate of aging,” the significance of which statement resides in the fact that antioxidants tend to reduce such stresses in animals, including man.

Another study addressing the subject was conducted by Larsen and Clarke (2002), who fed diets with and without coenzyme Q to wild-type *Caenorhabditis elegans* and several mutants during the adult phases of their lives, while they recorded the lengths of time they survived. This work revealed that “withdrawal of coenzyme Q from the diet of wild-type nematodes extends adult life-span by ~60 percent.” In addition, they found that the lifespans of the four different mutants they studied were extended by a Q-less diet. More detailed experiments led them to conclude that the life-span extensions were due to reduced generation and/or increased scavenging of reactive oxygen species, leading them to conclude in the final sentence of their paper that “the combination of reduced generation and increased scavenging mechanisms are predicted to result in a substantial decrease in the total cellular ROS and thereby allow for an extended life-span.”

In light of these many diverse observations of both plants and animals, there is some reason to believe that the historical increase of CO<sub>2</sub> in the air has helped lengthen human lifespans since the advent of the Industrial Revolution, and that its continued upward trend will provide more of the same benefit.

Additional information on this topic, including reviews of newer publications as they become available, can be found at <http://www.co2science.org/subject/h/humanlifespan.php>.

#### 9.4. Food vs. Nature

Norman Borlaug, the father of the Green Revolution, recently expressed in a *Science* editorial his concern over the challenge of “feeding a hungry world” by noting that “some 800 million people still experience chronic and transitory hunger each year,” and that “over the next 50 years, we face the daunting job of

feeding 3.5 billion additional people, most of whom will begin life in poverty” (Borlaug, 2007). He described how the scientific and technological innovations he played a major role in discovering and implementing helped reduce the proportion of hungry people in the world “from about 60% in 1960 to 17% in 2000.” Had that movement failed, he says, environmentally fragile land would have been brought into agricultural production and the resulting “soil erosion, loss of forests and grasslands, reduction in biodiversity, and extinction of wildlife species would have been disastrous.”

Rising CO<sub>2</sub> concentrations in the air helped make it possible to feed a growing global population in the past without devastating nature, but what of the future? The world’s population in 2008 was estimated to be 6.7 billion and is projected to reach between 9.1 and 9.7 billion by 2050 (United Nations, 2009; U.S. Census Bureau, 2008). There is real concern about our ability to feed the world’s population a mere 50 years hence.

Tilman *et al.* (2001) analyzed the global environmental impacts likely to occur if agriculture is to keep pace with population growth. They report that “humans currently appropriate more than a third of the production of terrestrial ecosystems and about half of usable freshwaters.” They estimate that the amount of land devoted to agriculture by the year 2050 will have to increase 18 percent to meet the rising demand for food. Because developed countries are expected to withdraw large areas of land from farming over the next 50 years for recreation, open space, and reforestation, the net loss of natural ecosystems to cropland and pasture in developing countries will amount to about half of all potentially suitable remaining land, which would “represent the worldwide loss of natural ecosystems larger than the United States.” Similar warnings of a coming food vs. nature conflict have been expressed by other scientists, for example, Wallace (2000) and Raven (2002).

What, if anything, can be done to address this conflict between the need to produce food and the wish to preserve nature? And what role, if any, will climate change play in averting the crisis or making it even worse?

We begin by observing that the fear that there isn’t enough land to support a growing population’s food needs is a very old one, dating at least to Thomas Malthus (1798) and expressed in our day by popular writers such as Paul Ehrlich (2008) and Al Gore (1992). Predictions of widespread famine have

been wrong before, as trends in food production and daily intake of calories per capita, while not linear in the short term, show long-term positive trends that are driven primarily by gains in yields per acre, not expansion of the area under cultivation (Alexandratos, 1995; Goklany, 1999; Waggoner and Ausubel, 2001). Malthusian concerns are misplaced because, as Max Singer once explained, “multiplying food production by five times over the next one hundred or two hundred years will be easier than multiplying it by over seven times as we did in the last two hundred years. No miracles, no scientific breakthroughs, no unknown lands or unexpected new resources, and no reforms of human character or government are required. All that is required is a continuing use of current evolutionary processes in technology and in economic development, and as much peace as we have had in the last century” (Singer, 1987).

We also agree with the sensible assessment of science writer Gregg Easterbrook that “the whole notion that there is a proper level of population for *Homo sapiens*, or for any species, would be nonsensical to nature” and “there is no reason in principle that the Earth cannot support vastly more human beings than live upon it today, with other species preserved and wild habitats remaining intact” (Easterbrook, 1995). Similar sentiments have been expressed by Waggoner (1995, 1996), Waggoner *et al.* (1996), and Meyer and Ausubel (1999).

Regardless of whether the goal of feeding a growing population while protecting nature is attainable, the question remains about global warming’s role in this very real conflict. Tilman and a second set of collaborators, writing a year after their previously cited analysis, said “raising yields on existing farmland is essential for ‘saving land for nature’” (Tilman *et al.* (2002). They proposed a three-part strategy: (1) increasing crop yield per unit of land area, (2) increasing crop yield per unit of nutrients applied, and (3) increasing crop yield per unit of water used.

With respect to the first of these efforts—increasing crop yield per unit of land area—the researchers note that in many parts of the world the historical rate-of-increase in crop yield is declining as the genetic ceiling for maximal yield potential is being approached. This “highlights the need for efforts to steadily increase the yield potential ceiling.” With respect to the second effort—increasing crop yield per unit of nutrients applied—they note that “without the use of synthetic fertilizers, world food

production could not have increased at the rate [that it did in the past] and more natural ecosystems would have been converted to agriculture.” Hence, they say the solution “will require significant increases in nutrient use efficiency, that is, in cereal production per unit of added nitrogen.” With respect to the third effort—increasing crop yield per unit of water used—Tilman *et al.* note that “water is regionally scarce,” and that “many countries in a band from China through India and Pakistan, and the Middle East to North Africa either currently or will soon fail to have adequate water to maintain per capita food production from irrigated land.”

The ongoing rise in the atmosphere’s CO<sub>2</sub> concentration will help the world’s farmers achieve all three parts of the Tilman strategy. First, since atmospheric CO<sub>2</sub> is the basic “food” of nearly all plants, the more of it there is in the air, the better they function and the more productive they become. As discussed in Section 9.2, a 300 ppm increase in the atmosphere’s CO<sub>2</sub> concentration would increase the productivity of earth’s herbaceous plants by 30 to 50 percent (Kimball, 1983; Idso and Idso, 1994) and the productivity of its woody plants by 50 to 80 percent (Saxe *et al.*, 1998; Idso and Kimball, 2001). These increases will be in addition to whatever yield gains are made possible by advances in plant genetics, pest control, and other agricultural practices. Consequently, as the air’s CO<sub>2</sub> content continues to rise, so too will the land-use efficiency and productive capacity of the planet improve.

Regarding the second strategy, of increasing crop yield per unit of nutrients applied, many studies have investigated the effects of an increase in the air’s CO<sub>2</sub> content on plants growing in soils with different nitrogen concentrations. (See Chapter 7, Section 7.3.7, for a thorough review of these studies.) These studies found that many plants increase their photosynthetic nitrogen-use efficiency when atmospheric CO<sub>2</sub> concentration is raised. For example, Smart *et al.* (1998) found wheat grown in controlled-environment chambers maintained at an atmospheric CO<sub>2</sub> concentration of 1,000 ppm increased average plant biomass by approximately 15 percent, irrespective of soil nitrogen content.

Zerihun *et al.* (2000) studied the effects of CO<sub>2</sub> enrichment on sunflowers using three different soil nitrogen concentrations and found whole plant biomass values that were 44, 13 and 115 percent greater than those of the plants growing in ambient air at low, medium and high levels of soil nitrogen,

respectively. Deng and Woodward (1998) found that strawberries grown in high CO<sub>2</sub> environments produced 17 percent greater fresh fruit weight even when receiving the lowest levels of nitrogen fertilization. Newman *et al.* (2003) investigated the effects of two levels of nitrogen fertilization and an approximate doubling of the air's CO<sub>2</sub> concentration on the growth of tall fescue, an important forage crop. They found the plants grown in the high-CO<sub>2</sub> air and under low N conditions photosynthesized 15 percent more and produced 53 percent more dry matter (DM).

Demmers-Derks *et al.* (1998) grew sugar beets at atmospheric CO<sub>2</sub> concentrations of 360 and 700 ppm and high and low nitrogen treatment levels, and found the extra CO<sub>2</sub> enhanced total plant biomass by 13 percent even in plants receiving the low nitrogen treatments. Also working with sugar beets, Romanova *et al.* (2002) doubled atmospheric CO<sub>2</sub> concentrations while fertilizing plants with three different levels of nitrate-nitrogen. The plants exhibited rates of net photosynthesis that were approximately 50 percent greater than those displayed by the plants grown in ambient air, regardless of soil nitrate availability.

Fangmeier *et al.* (2000) grew barley plants in containers at atmospheric CO<sub>2</sub> concentrations of either 360 or 650 ppm and either a high or low nitrogen fertilization regime. The elevated CO<sub>2</sub> had the greatest relative impact on yield when the plants were grown under the less-than-optimum low-nitrogen regime, i.e., a 48 percent increase vs. 31 percent under high-nitrogen conditions.

Finally, the review and analysis of Kimball *et al.* (2002) of most FACE studies conducted on agricultural crops since the introduction of that technology back in the late 1980s found that in response to a 300-ppm increase in the air's CO<sub>2</sub> concentration, rates of net photosynthesis in several C<sub>3</sub> grasses were enhanced by an average of 46 percent under conditions of ample soil nitrogen supply and by 44 percent when nitrogen was limiting to growth. Clover experienced a 38 percent increase in belowground biomass production at ample soil nitrogen, and a 32 percent increase at low soil nitrogen. Wheat and ryegrass experienced an average increase of 18 percent at ample nitrogen, while wheat experienced only a 10 percent increase at low nitrogen.

Other studies have found that many species of plants respond to increases in the air's CO<sub>2</sub> content by increasing fine-root numbers and surface area, which tends to increase total nutrient uptake under CO<sub>2</sub>-enriched conditions (Staddon *et al.*, 1999; Rouhier

and Read, 1998; BassiriRad *et al.*, 1998; and Barrett *et al.*, 1998). This once again advances the Tilman strategy of increasing crop yield per unit of available nutrient. (See Chapter 7, Section 7.8.2, for a thorough review of those studies.)

Tilman's third strategy—increasing crop yield per unit of water used—is also advanced by rising levels of CO<sub>2</sub> in the atmosphere. Plants exposed to elevated levels of atmospheric CO<sub>2</sub> generally do not open their leaf stomatal pores—through which they take in carbon dioxide and give off water vapor—as wide as they do at lower CO<sub>2</sub> concentrations and tend to produce fewer of these pores per unit area of leaf surface. Both changes tend to reduce most plants' rates of water loss by transpiration. The amount of carbon they gain per unit of water lost—or water-use efficiency—therefore typically rises, increasing their ability to withstand drought.

In the study of Serraj *et al.* (1999), soybeans grown at 700 ppm CO<sub>2</sub> displayed 10 to 25 percent reductions in total water loss while simultaneously exhibiting increases in dry weight of as much as 33 percent. Likewise, Garcia *et al.* (1998) determined that spring wheat grown at 550 ppm CO<sub>2</sub> exhibited a water-use efficiency that was about one-third greater than that exhibited by plants grown at 370 ppm CO<sub>2</sub>. Hakala *et al.* (1999) reported that twice-ambient CO<sub>2</sub> concentrations increased the water-use efficiency of spring wheat by 70 to 100 percent, depending on experimental air temperature.

Hunsaker *et al.* (2000) reported CO<sub>2</sub>-induced increases in water-use efficiency for field-grown wheat that were 20 and 10 percent higher than those displayed by ambiently grown wheat subjected to high and low soil nitrogen regimes, respectively. Also, pea plants grown for two months in growth chambers receiving atmospheric CO<sub>2</sub> concentrations of 700 ppm displayed an average water-use efficiency that was 27 percent greater than that exhibited by ambiently grown control plants (Gavito *et al.*, 2000). (See Chapter 7, Section 7.2, for a thorough review of those studies.)

An issue related to water-use efficiency that could become more important in the future is the buildup of soil salinity from repeated irrigations, which can sometimes reduce crop yields. Similarly, in natural ecosystems where exposure to brackish or salty water is commonplace, saline soils can induce growth stress in plants not normally adapted to coping with this problem. The studies reported below show that rising atmospheric CO<sub>2</sub> concentrations also can help to alleviate this problem.

Mavrogianopoulos *et al.* (1999) reported that atmospheric CO<sub>2</sub> concentrations of 800 and 1200 ppm stimulated photosynthesis in parron melons by 75 and 120 percent, respectively, regardless of soil salinity, which ranged from 0 to 50 mM NaCl. Atmospheric CO<sub>2</sub> enrichment also partially alleviated the negative effects of salinity on melon yield, which increased with elevated CO<sub>2</sub> at all salinity levels.

Maggio *et al.* (2002) grew tomatoes at 400 and 900 ppm in combination with varying degrees of soil salinity and noted that plants grown in elevated CO<sub>2</sub> tolerated an average root-zone salinity threshold value that was about 60 percent greater than that exhibited by plants grown at 400 ppm CO<sub>2</sub> (51 vs. 32 mmol dm<sup>-3</sup> Cl). The review of Poorter and Perez-Soba (2001) found no changes in the effect of elevated CO<sub>2</sub> on the growth responses of most plants over a wide range of soil salinities, in harmony with the earlier findings of Idso and Idso (1994).

These various studies suggest that elevated CO<sub>2</sub> concentrations will help farmers achieve all three of the strategies Tilman *et al.* say are essential to addressing the conflict between feeding a growing human population and preserving space for nature. The actual degree of crop yield enhancement likely to be provided by the increase in atmospheric CO<sub>2</sub> concentration expected to occur between 2000 and 2050 has been calculated by Idso and Idso (2000) to be sufficient—but just barely—to close the gap between the supply and demand for food some four decades from now. Consequently, letting the evolution of technology take its course—which includes continued emissions of CO<sub>2</sub> into the atmosphere by industry—appears to be the only way we can grow enough food to support ourselves in the year 2050 without taking unconscionable amounts of land and freshwater resources from nature.

In spite of the dilemma described above and the fact that enhanced levels of CO<sub>2</sub>, in the air are a necessary part of the solution, the IPCC calls for strict measures to reduce anthropogenic CO<sub>2</sub> emissions—a strategy that, if it has any effect at all on plant and animal life, would lead to lower land-use efficiency, lower nitrogen-use efficiency, and lower plant water-use efficiency, just the opposite of what Tilman *et al.* called for.

One might ask whose predictions are more reliable, the IPCC's computer-model-generated forecasts of catastrophic consequences due to rising temperatures a century or longer from now, or our projections of human population growth and

agricultural productivity just four decades into the future? In addition to the obvious time differential between the two sets of predictions, human population growth and agricultural productivity are much better-understood processes than is global climate change, which involves a host of complex phenomena that span a spatial scale of fully 14 orders of magnitude, ranging from the planetary scale of 10<sup>7</sup> meters to the cloud microphysical scale of 10<sup>-6</sup> meter.

Many of the component processes that comprise today's state-of-the-art climate models are so far from adequately understood (see Chapters 1 and 2) that even the *signs* of their impacts on global temperature change (whether positive or negative) are not yet known. Consequently, in light of the much greater confidence that can realistically be vested in demographic and agricultural production models, it would seem that much greater credence can be placed in our predictions than in the predictions of climate doom.

In conclusion, the aerial fertilization effect of the increase in the air's CO<sub>2</sub> content that is expected to occur by the year 2050 would boost crop yields by the amounts required to prevent mass starvation in many parts of the globe, without a large-scale encroachment on the natural world. Acting prematurely to reduce human CO<sub>2</sub> emissions, as urged by the IPCC, could interrupt this response, resulting in the death by starvation of millions of people, loss of irreplaceable natural ecosystems, or both.

## 9.5. Biofuels

Biofuels are liquid and gaseous fuels made from organic matter. They include ethanol, biodiesel, and methanol. Biofuels may have some advantages over gasoline and diesel fuels, but they are more expensive to produce and can supply only a small part of the world's total transportation energy needs. Because they compete with food crops and nature for land and nutrients, expanding the use of biofuels could negatively affect human health and natural ecosystems.

The IPCC does not discuss biofuels in the contributions of Group I (Science) or Group II (Impacts, Adaptation and Vulnerability) to the Fourth Assessment Report. When it finally does discuss them, in two sections of the contribution of Group III (Mitigation), it fails to address the likely adverse consequences of increased use of biofuels on human health and the natural environment. We discuss those consequences in this section.

### 9.5.1. About Biofuels

Biofuels are not new—Henry Ford's first vehicle was fueled by ethanol—and conversion technologies exist or are in development for converting biomass into a wide range of biofuels suitable for heating, electric production, and transportation. For example, residues from agriculture and forestry long have been used by the lumber and papermaking industries to generate heat and power. Methane from animal waste and composting is captured and used locally or sold in commercial markets.

Of particular interest, and the focus of this section, is the biochemical conversion using enzymes of corn, soybeans, sugarcane, and other food crops into ethanol, biodiesel, and other biofuels used mainly for transportation. The country with the most aggressive biofuels program in the world is Brazil. After the country launched its National Alcohol Program in 1975, ethanol production in Brazil rose dramatically and now accounts for approximately 40 percent of total fuel consumption in the country's passenger vehicles (EIA, 2008).

Ethanol became popular as a gasoline supplement in the U.S. during the 1990s, when Congress mandated that oil refiners add oxygenates to their product to reduce some emissions. Congress did not provide liability protection for the makers of methyl tertiary butyl ether (MTBE), ethanol's main

competitor in the oxygenate business, so most companies quickly switched from MTBE to ethanol (Lehr, 2006). Some states also began to mandate ethanol use for reasons discussed below.

Most ethanol made in the U.S. comes from corn. Its production consumed 13 percent of the U.S. corn crop (1.43 billion bushels of corn grain) in 2005 and an estimated 20 percent of the 2006 crop. E10 (a blend of 10 percent ethanol and 90 percent gasoline) is widely available. E85 is an alternative fuel (85 percent ethanol and 15 percent gasoline) available mainly in corn-producing states; vehicles must be modified to use this fuel.

The Energy Policy Act of 2005 mandated the use of 4 billion gallons of ethanol in 2006. The 2007 Energy Independence and Security Act (EISA) subsequently mandated the use of 36 billion gallons of renewable fuels by 2022—16 billion gallons of cellulosic ethanol, 15 billion gallons of corn ethanol, and 5 billion gallons of biodiesel and other advanced biofuels (U.S. Congress, 2007).

Federal subsidies to ethanol producers in the U.S. cost taxpayers about \$2 billion a year (Dirksen, 2006). Congress protects domestic ethanol producers by imposing a 2.5 percent tariff and 54 cents per gallon duty on imports. Ethanol producers with plants of up to 60 million gallons annual production capacity are eligible to receive a production incentive of 10 cents per gallon on the first 15 million gallons of ethanol produced each year. Ethanol is also subsidized by scores of other countries and by at least 19 U.S. states (Doornbosch and Steenblich, 2007, Annex 1, pp. 45-47).

U.S. ethanol output rose from 3.4 billion gallons from 81 facilities in 2004 to 9 billion gallons from 170 facilities in 2008 (RFA, 2009). According to a forecast by the Energy Information Administration (EIA), "total U.S. biofuel consumption rises from 0.3 quadrillion Btu (3.7 billion gallons) in 2005 to 2.8 quadrillion Btu (29.7 billion gallons) in 2030, when it represents about 11.3 percent of total U.S. motor vehicle fuel on a Btu basis" (EIA, 2008). In 2005 ethanol represented about 2 percent of total gasoline consumption, and biodiesel less than 0.2 percent of diesel consumption, in the U.S.

Doornbosch and Steenblich (2007), in a report produced for the Organization for Economic Cooperation and Development (OECD), reported that "global production of biofuels amounted to 0.8 EJ [exajoule] in 2005, or roughly 1% of total road transport fuel consumption. Technically, up to 20 EJ from conventional ethanol and biodiesel, or 11% of

total demand for liquid fuels in the transport sector, has been judged possible by 2050.” Also for the world as a whole, EIA predicts “alternative fuels [will] account for only 9 percent of total world liquids use in 2030, despite an average annual increase of 5.6 percent per year, from 2.5 million barrels per day in 2005 to 9.7 million barrels per day in 2030” (EIA, 2008).

### 9.5.2. Costs and Benefits

Proponents of biofuels say their increased production will increase the supply of transportation fuels and therefore lead to lower prices. Critics of biofuels point out that ethanol often costs more, not less, than gasoline, either because of production costs or supplies that can’t keep pace with government mandates, and therefore leads to higher prices at least in the short run.

Ethanol has only two-thirds the energy content of gasoline, which makes it a poor value for most consumers. The production cost of ethanol (which is only one component in determining its price) has fallen as a result of technological innovation and economies of scale, but some properties of ethanol continue to make it expensive compared to gasoline. Transportation costs for ethanol, for example, are high because it picks up water if it travels through

existing pipelines, diluting the ethanol and corroding the pipelines. Therefore, it is being trucked to the Northeast and along the Gulf Coast. Ethanol must be kept in a different container at the terminal and is blended into the gasoline in the truck on its way to the retailer from the terminal. This has caused regional shortages, further increasing the retail prices in these areas (Dirksen, 2006).

Ethanol also has been promoted as a fuel additive to reduce emissions. It reduces carbon monoxide in older vehicles and dilutes the concentration of aromatics in gasoline, reducing emissions of toxins such as benzene. Because ethanol has only two-thirds the energy content per volume as gasoline, it increases volumetric fuel use (with small increases in energy efficiency.) Ethanol increases air emissions such as aldehydes. In some areas, the use of 10 percent ethanol blends may increase ozone due to local atmospheric conditions (Niven, 2004).

Ethanol also is promoted as a “homegrown” and renewable energy source, so using more of it could help reduce a country’s dependency on foreign oil, which in turn might benefit national security and international relations. But ethanol used in the U.S. mostly supplants oil from domestic suppliers, which is more expensive than foreign oil, and leaves the country’s dependency on foreign oil the same or even makes it higher (Yacobucci, 2006). Rural communities benefit from the economic boost that comes from higher prices for corn and the jobs created by ethanol plants, but those economic benefits come at a high price in terms of higher food prices and tax breaks financed by government debt or higher taxes on other goods and services.

Finally, biofuels are renewable resources, which advocates say makes them environmentally friendlier than fossil fuels. But the energy consumed to make biofuels—to plant, fertilize, irrigate, and harvest corn and other feedstocks as well as to generate the heat used during the fermentation process and to transport biofuels to markets by train or trucks—is considerable. Fossil fuels (natural gas or coal) are typically the source of that energy. This environmental impact is the focus of the rest of this section.

### 9.5.3. Net Emissions

The US 2007 Energy Independence and Security Act (EISA) mandates that life-cycle greenhouse gas emissions of corn ethanol, cellulosic ethanol, and advanced biofuels achieve 20 percent, 60 percent, and 50 percent greenhouse gas (GHG) emission reductions relative to gasoline, respectively. But there is considerable controversy over whether these fuels do in fact reduce GHG emissions.

Numerous studies of GHG emissions produced during the life-cycle of ethanol (from the planting of crops to consumption as a fuel) have found them to be less than those of gasoline, with most estimates around 20 percent (Hill *et al.*, 2006; Wang *et al.*, 2007; CBO, 2009). Emissions vary considerably based on the choice of feedstock, production process, type of fossil fuels used, location, and other factors (ICSU, 2009). Liska *et al.* (2009), in their study of life-cycle emissions of corn ethanol systems, found the direct-effect GHG emissions of ethanol (without any offset due to changes in land use) to be “equivalent to a 48% to 59% reduction compared to gasoline, a twofold to threefold greater reduction than reported in previous studies,” largely because they incorporate a credit for the commercial use of dry distilled grain (DDG). They report that “in response to the large increase in availability of distillers grains coproduct from ethanol production and the rise in soybean prices, cattle diets now largely exclude soybean meal and include a larger proportion of distillers grains coproduct (Klopfenstein *et al.*, 2008). Thus, the energy and GHG credits attributable to feeding distillers grains must be based on current practices for formulating cattle diets.” They give corn ethanol systems DDG credits ranging from 19% to 38% depending on region and type of fossil fuels used.

None of these estimates, however, takes into account the emission increases likely to come about from land-use changes. Righelato and Spracklen (2007) wrote that using ethanol derived from crops as a substitute for gasoline, and vegetable oils in place of diesel fuel, “would require very large areas of land in

order to make a significant contribution to mitigation of fossil fuel emissions and would, directly or indirectly, put further pressure on natural forests and grasslands.” The two British scientists calculated that a 10 percent substitution of biofuels for gasoline and diesel fuel would require “43% and 38% of current cropland area in the United States and Europe, respectively,” and that “even this low substitution level cannot be met from existing arable land.”

Righelato and Spracklen add that “forests and grasslands would need to be cleared to enable production of the energy crops,” resulting in “the rapid oxidation of carbon stores in the vegetation and soil, creating a large up-front emissions cost that would, in all cases examined, out-weigh the avoided emissions.” They report further that individual life-cycle analyses of the conversion of sugar cane, sugar beet, wheat, and corn to ethanol, as well as the conversion of rapeseed and woody biomass to diesel, indicate that “forestation of an equivalent area of land would sequester two to nine times more carbon over a 30-year period than the emissions avoided by the use of the biofuel.” They conclude that “the emissions cost of liquid biofuels exceeds that of fossil fuels.”

Fargione *et al.* (2008), writing in *Science*, said “increasing energy use, climate change, and carbon dioxide (CO<sub>2</sub>) emissions from fossil fuels make switching to low-carbon fuels a high priority. Biofuels are a potential low-carbon energy source, but whether biofuels offer carbon savings depends on how they are produced.” They explain that “converting native habitats to cropland releases CO<sub>2</sub> as a result of burning or microbial decomposition of organic carbon stored in plant biomass and soils. After a rapid release from fire used to clear land or from the decomposition of leaves and fine roots, there is a prolonged period of GHG release as coarse roots and branches decay and as wood products decay or burn. We call the amount of CO<sub>2</sub> released during the first 50 years of this process the ‘carbon debt’ of land conversion. Over time, biofuels from converted land can repay this carbon debt if their production and combustion have net GHG emissions that are less than the life-cycle emissions of the fossil fuels they displace. Until the carbon debt is repaid, biofuels from converted lands have greater GHG impacts than those of the fossil fuels they displace.”

Fargione *et al.* calculate the number of years required to repay carbon debts for six areas: Brazilian Amazon (319 years), Brazilian Cerrado wooded (17 years), Brazilian Cerrado grassland (37 years), Indonesian or Malaysian lowland tropical rainforest

(86 years), Indonesian or Malaysian peatland tropical rainforest (423 years), and U.S. central grassland (93 years). They observe that no carbon debt is incurred when abandoned cropland or marginal prairie in the U.S. is used without irrigation to produce ethanol. They conclude that “the net effect of biofuels production via clearing of carbon-rich habitats is to increase CO<sub>2</sub> emissions for decades or centuries relative to the emissions caused by fossil fuel use,” and “at least for current or developing biofuels technologies, any strategy to reduce GHG emissions that causes land conversion from native ecosystems to cropland is likely to be counterproductive.”

In a companion essay in the same issue of *Science*, Searchinger *et al.* (2008) also describe the carbon debt due to land-use conversion, but measure it as the difference between biofuels and gasoline in GHG emissions measured in grams per MJ (megajoule) of energy. They begin by explaining that “to produce biofuels, farmers can directly plow up more forest or grassland, which releases to the atmosphere much of the carbon previously stored in plants and soils through decomposition or fire. ... Alternatively, farmers can divert existing crops or croplands into biofuels, which causes similar emissions indirectly. The diversion triggers higher crop prices, and farmers around the world respond by clearing more forest and grassland to replace crops for feed and food.”

Searchinger *et al.* used the Greenhouse gases Regulated Emissions and Energy use in Transportation (GREET) computer program created by the Center for Transportation Research at Argonne National Laboratory to calculate the GHGs in grams of CO<sub>2</sub> equivalent emissions per MJ of energy consumed over the production and use life-cycles of gasoline, corn ethanol, and biomass ethanol fuels. They observe that “emissions from corn and cellulosic ethanol emissions exceed or match those from fossil fuels, and therefore produce no greenhouse benefits,” unless biofuels are given a “carbon uptake credit” for the amount of carbon dioxide removed from the air by the growing biofuels feedstocks. When that adjustment is made, they estimate that gasoline (which gets no carbon uptake credit) produces 92g/MJ; corn ethanol, 74g/MJ; and biomass ethanol, 27g/MJ.

Searchinger *et al.* then calculate the amount of land that would be converted from forest and grassland into cropland to support the biofuels and, like Fargione *et al.* (2008), apply the GHG emissions

due to land-use change to each type of fuel. The result is that total net GHG emissions from both kinds of biofuel *exceed* those from gasoline, 177g vs. 92g in the case of corn ethanol and 138g vs. 92g in the case of biomass ethanol. They conclude that “corn-based ethanol, instead of producing a 20% savings, nearly doubles greenhouse emissions over 30 years and increases greenhouse gases for 167 years. Biofuels from switchgrass, if grown on U.S. corn lands, increase emissions by 50%. This result raises concerns about large biofuels mandates and highlights the value of using waste products.”

Coming to much the same conclusion, Laurance (2007) observed that “tropical forests, in particular, are crucial for combating global warming, because of their high capacity to store carbon and their ability to promote sunlight-reflecting clouds via large-scale evapotranspiration,” which led him to conclude that “such features are key reasons why preserving and restoring tropical forests could be a better strategy for mitigating the effects of carbon dioxide than dramatically expanding global biofuel production.”

Doornbosch and Steenblik (2007), while reporting that biofuels could provide up to 11 percent of the total world demand for road transport fuel by 2050, say “an expansion on this scale could not be achieved, however, without significant impacts on the wider global economy. In theory there might be enough land available around the globe to feed an ever increasing world population and produce sufficient biomass feedstock simultaneously, but it is more likely that land-use constraints will limit the amount of new land that can be brought into production leading to a ‘food-versus-fuel’ debate.”

Looking at a different environmental impact of expanded biofuel production, Crutzen and three collaborators calculated the amount of nitrous oxide (N<sub>2</sub>O) that would be released to the atmosphere as a result of using nitrogen fertilizer to produce the crops used for biofuels (Crutzen *et al.*, 2007). Their work revealed that “all past studies have severely underestimated the release rates of N<sub>2</sub>O to the atmosphere, with great potential impact on climate warming” because, as they report, N<sub>2</sub>O “is a ‘greenhouse gas’ with a 100-year average global warming potential 296 times larger than an equal mass of CO<sub>2</sub>.” The consequence is that “when the extra N<sub>2</sub>O emission from biofuel production is calculated in ‘CO<sub>2</sub>-equivalent’ global warming terms, and compared with the quasi-cooling effect of ‘saving’ emissions of CO<sub>2</sub> derived from fossil fuel,

the outcome is that the production of commonly used biofuels, such as biodiesel from rapeseed and bioethanol from corn, can contribute as much or more to global warming by N<sub>2</sub>O emissions than cooling by fossil fuel savings.”

Crutzen *et al.* concluded that “on a globally averaged basis the use of agricultural crops for energy production ... can readily be detrimental for climate due to the accompanying N<sub>2</sub>O emissions.” Their concerns were confirmed by a 2009 report from the International Council for Science (ICSU), which found “the increased N<sub>2</sub>O flux associated with producing ethanol from corn is likely to more than offset any positive advantage from reduced carbon dioxide fluxes (compared to burning fossil fuels). Even for ethanol from sugar cane or biodiesel from rapeseed, emissions of nitrous oxide probably make these fuels less effective as an approach for reducing global warming than has been previously believed” (ICSU, 2009).

Producing ethanol from crop residues, or stover, is often proposed as a way to avoid carbon emissions arising from land conversion. But as Lal (2007) points out, crop residues perform many vital functions. He reports that “there are severe adverse impacts of residue removal on soil and environmental degradation, and negative carbon sequestration as is documented by the dwindling soil organic carbon reserves.” He notes that “the severe and widespread problem of soil degradation, and the attendant agrarian stagnation/deceleration, are caused by indiscriminate removal of crop residues.” Lal concludes that “short-term economic gains from using crop residues for biofuel must be objectively assessed in relation to adverse changes in soil quality, negative nutrients and carbon budget, accelerated erosion, increase in non-point source pollution, reduction in agronomic production, and decline in biodiversity.”

Finally, while using abandoned or degraded lands to produce biomass, rather than converting existing cropland or forests, is often alleged to reduce carbon emissions (e.g., Fargione *et al.*, 2008), the ICSU report notes that “of course, if the lands have the potential to revert to forests, conversion to biofuels represents a lost opportunity for carbon storage. The environmental consequences of inputs (irrigation water, fertilizer) required to make degraded and marginal lands productive must also be considered” (ICSU, 2009).

In conclusion, the production and use of biofuels frequently does not reduce net GHG emissions relative to gasoline, the fossil fuel they are intended to

replace. Therefore, there is no basis from an environmental perspective for preferring them to fossil fuels.

#### 9.5.4. Impact on Food Prices

Biofuel refineries compete with livestock growers and food processors for corn, soybeans, and other feedstocks usually used to produce biofuels in the United States, leading to higher animal feed and ingredient costs for farmers, ranchers, and food manufacturers. Some of that cost is eventually passed on to consumers. A study by the Congressional Budget Office (CBO) found “the demand for corn for ethanol production, along with other factors, exerted upward pressure on corn prices, which rose by more than 50 percent between April 2007 and April 2008. Rising demand for corn also increased the demand for cropland and the price of animal feed” (CBO, 2009). The CBO estimated that increased use of ethanol “contributed between 0.5 and 0.8 percentage points of the 5.1 percent increase in food prices measured by the consumer price index (CPI).”

Johansson and Azar (2007) analyzed what they called the “food-fuel competition for bio-productive land,” developing in the process “a long-term economic optimization model of the U.S. agricultural and energy system,” wherein they found that the competition for land to grow crops for both food and fuel production leads to a situation where “prices for all crops as well as animal products increase substantially.” Similarly, Doornbosch and Steenblich (2007) say “any diversion of land from food or feed production to production of energy biomass will influence food prices from the start, as both compete for the same inputs. The effects on farm commodity prices can already be seen today. The rapid growth of the biofuels industry is likely to keep these prices high and rising throughout at least the next decade (OECD/FAO, 2007).”

Runge and Senauer (2007), writing in *Foreign Affairs*, reported that the production of corn-based ethanol in the United States “takes so much supply to keep ethanol production going that the price of corn—and those of other food staples—is shooting up around the world.” The rising prices caused food riots to break out in Haiti, Bangladesh, Egypt, and Mozambique in April 2008, prompting Jean Ziegler, the United Nations’ “special rapporteur on the right to food,” to call using food crops to create ethanol “a crime against humanity” (CNN, 2008). Jeffrey Sachs, director of Columbia University’s Earth Institute, said

at the time, “We’ve been putting our food into the gas tank—this corn-to-ethanol subsidy which our government is doing really makes little sense” (Ibid.). Former U.S. President Bill Clinton was quoted by the press as saying “corn is the single most inefficient way to produce ethanol because it uses a lot of energy and because it drives up the price of food” (Ibid.). Unfortunately, as the CBO report concluded a year later, corn is likely to remain the main source of ethanol for quite some time as “current technologies for producing cellulosic ethanol are not commercially viable” (CBO, 2009).

### 9.5.5. Use of Water

The third strategy proposed by Tilman *et al.* (2002) to address the conflict between growing food and preserving natural ecosystems is finding ways to conserve water. Biofuels, as the following studies demonstrate, fail to advance this objective.

Elcock (2008) projects that 12.9 billion gallons per day of water will be consumed in the manufacture of ethanol by 2030. This “increase accounts for roughly 60% of the total projected nationwide increase in water consumption over the 2005-2030 period, and it is more than double the amount of water projected to be consumed for industrial and commercial use in 2030 by the entire United States.”

A 2009 study by Argonne National Laboratory estimated life-cycle water consumption for one gallon of four types of fuel: ethanol, gasoline from domestic conventional crude oil, gasoline from Saudi conventional crude oil, and gasoline from Canadian oil sands (Wu *et al.*, 2009). For ethanol, they estimated an average consumption of 3.0 gallon of water/gallon of corn ethanol during the production process in a corn dry mill, a yield of 2.7 gallons of ethanol per bushel of corn, and the average consumptive use of irrigation water for corn farming in three U.S. Department of Agriculture Regions (5, 6, and 7) representing the vast majority of corn production in the United States. They found “total groundwater and surface water use for corn growing vary significantly across the three regions, producing 1 gallon of corn-based ethanol consumes a net of 10 to 17 gallon of freshwater when the corn is grown in Regions 5 and 6, as compared with 324 gallon when the corn is grown in Region 7.” When these figures are adjusted to reflect the lower Btu/gallon of ethanol compared to gasoline (75,700 / 115,000, or .66), the amount of water consumed per gallon of gasoline equivalent ranges from 15.2 to 25.8 gallons in Regions 5 and 6 and 492 gallons in Region 7.

Wu *et al.* (2009) found the amount of water required to create a gallon of gasoline was dramatically less: 3.4-6.6 gallons of water to make one gallon of gasoline from U.S. conventional crude oil, 2.8-5.8 gallons to make one gallon of gasoline from Saudi conventional crude, and 2.6-6.2 gallons to make one gallon of gasoline from Canadian oil sands.

An even more recent review of the literature conducted by the International Council for Science (ICSU) found “the water requirements of biofuel-derived energy are 70 to 400 times larger than other energy sources such as fossil fuels, wind or solar.

Roughly 45 billion cubic meters of irrigation water were used for biofuel production in the [sic] 2007, or some 6 times more water than people drink globally” (ICSU, 2009). The authors also point out that “severe water pollution can result from runoff from agricultural fields and from waste produced during the production of biofuels,” and that “the increase in corn [production] to support ethanol goals in the United States is predicted to increase nitrogen inputs to the Mississippi River by 37%.”

In light of this evidence, there can be little doubt that biofuels are a much less efficient use of scarce water resources than are fossil fuels. This means increased reliance on fossil fuels would make it more difficult to increase food production per unit of water in the future, one of Tilman *et al.*'s three strategies to solve the food vs. nature conflict.

### 9.5.6. Conclusion

The production and use of biofuels has increased dramatically in recent years, due largely to government mandates and taxpayer subsidies. But the alleged environmental benefits of these “renewable fuels” disappear upon close inspection. As Doornbosch and Steenblich (2007) say in their OECD report, “when such impacts as soil acidification,

fertilizer use, biodiversity loss and toxicity of agricultural pesticides are taken into account, the overall environmental impacts of ethanol and biodiesel can very easily exceed those of petrol and mineral diesel. The conclusion must be that the potential of the current technologies of choice—ethanol and biodiesel—to deliver a major contribution to the energy demands of the transport sector without compromising food prices and the environment is very limited.”

The decision by the IPCC and many environmental groups to embrace ethanol pits energy production against food production, making even worse the conflict between the two that this section has addressed. There can be little doubt that ethanol mandates and subsidies have made both food *and* energy more, not less, expensive, and therefore less

available to a growing population. The extensive damage to natural ecosystems already caused by this poor policy decision, and the much greater destruction yet to come, are a high price to pay for refusing to understand and utilize the true science of climate change.

Additional information on this topic, including reviews of newer publications as they become available, can be found at <http://www.co2science.org/subject/b/biofuels.php>

# Appendix 2

## Table 7.1.1 – Plant Dry Weight (Biomass) Responses to Atmospheric CO<sub>2</sub> Enrichment

Table 7.1.1 reports the results of peer-reviewed scientific studies indicating the biomass growth response of plants to a 300-ppm increase in atmospheric CO<sub>2</sub> concentration. Plants are listed by both common and/or scientific names, followed by the number of experimental studies conducted on each plant, the mean biomass response to a 300-ppm increase in the air's CO<sub>2</sub> content, and the standard error of that mean. Whenever the CO<sub>2</sub> increase was not exactly 300 ppm, a linear adjustment was computed. For example, if the CO<sub>2</sub> increase was 350 ppm and the growth response was a 60 percent enhancement, the adjusted 300-ppm CO<sub>2</sub> growth response was calculated as  $(300/350) \times 60\% = 51\%$ .

The data in this table are printed by permission of the Center for the Study of Carbon Dioxide and Global Change and were taken from its Plant Growth database as it existed on 23 March 2009. Additional data are added to the database at approximately weekly intervals and can be accessed free of charge at the Center's website at [http://www.co2science.org/data/plant\\_growth/dry/dry\\_subject.php](http://www.co2science.org/data/plant_growth/dry/dry_subject.php). This online database also archives information pertaining to the experimental conditions under which each plant growth experiment was conducted, as well as the complete reference to the journal article from which the experimental results were obtained. The Center's online database also lists percent increases in plant biomass for 600- and/or 900-ppm increases in the air's CO<sub>2</sub> concentration.

## Table 7.1.2 – Plant Photosynthesis (Net CO<sub>2</sub> Exchange Rate) Responses to Atmospheric CO<sub>2</sub> Enrichment

Table 7.1.2 reports the results of peer-reviewed scientific studies measuring the photosynthetic growth response of plants to a 300-ppm increase in atmospheric CO<sub>2</sub> concentration. Plants are listed by both common and/or scientific names, followed by the number of experimental studies conducted on each plant, the mean photosynthetic response to a 300-ppm increase in the air's CO<sub>2</sub> content, and the standard error of that mean. Whenever the CO<sub>2</sub> increase was not exactly 300 ppm, a linear adjustment was computed. For example, if the CO<sub>2</sub> increase was 350 ppm and the growth response was a 60 percent enhancement, the adjusted 300-ppm CO<sub>2</sub> growth response was calculated as  $(300/350) \times 60\% = 51\%$ .

The data in this table appear by permission of the Center for the Study of Carbon Dioxide and Global Change and were taken from its Plant Growth database as it existed on 23 March 2009. Additional data are added to the database at approximately weekly intervals and can be accessed free of charge at the Center's website at [http://www.co2science.org/data/plant\\_growth/dry/dry\\_subject.php](http://www.co2science.org/data/plant_growth/dry/dry_subject.php). This online database also archives information pertaining to the experimental conditions under which each plant growth experiment was conducted, as well as the complete reference to the journal article from which the experimental results were obtained. The Center's online database also lists percent increases in plant photosynthetic rate for 600- and/or 900-ppm increases in the air's CO<sub>2</sub> concentration.

## The Petition Project

### Appendix 4. The Petition Project

- 1.1. About the Petition
- 1.2. Qualifications of Signers
- 1.3. Frequently Asked Questions
- 1.4. Directory of Signers
- 1.5. Summary of Peer-Reviewed Research

### 1.1. About the Petition

The petition pictured above has been signed by 31,478 Americans with university degrees in science, including 9,029 with Ph.D.s. The petition reads in part: “There is no convincing scientific evidence that human release of carbon dioxide, methane, or other greenhouse gases is causing or will, in the foreseeable future, cause catastrophic heating of the Earth’s atmosphere and disruption of of the Earth’s climate. Moreover, there is substantial scientific evidence that

increases in atmospheric carbon dioxide produce many beneficial effects upon the natural plant and animal environments of the Earth.” A copy of one actual signed petition appears on this page. The majority of the current listed signatories signed or re-signed the petition after October 2007.

The purpose of the Petition Project is to demonstrate that the claim of “settled science” and an overwhelming “consensus” in favor of the hypothesis of human-caused global warming and consequent climatological damage is wrong. No such consensus

or settled science exists. As indicated by the petition text and signatory list, a very large number of American scientists reject this hypothesis.

From the clear and strong petition statement that they have signed, it is evident that these 31,478 American scientists are not “skeptics.” These scientists are instead convinced that the human-caused global warming hypothesis is without scientific validity and that government action on the basis of this hypothesis would unnecessarily and counterproductively damage both human prosperity and the natural environment of the Earth.

This petition is primarily circulated by U.S. Postal Service mailings to scientists. Included in the mailings are the petition card, a letter from Frederick Seitz (reproduced on the following page), a scientific review article (reproduced on the pages following the directory of petition signers), and a return envelope. If a scientist wishes to sign, he or she completes the petition and mails it to the project by first-class mail. Additionally, many petition signers obtain petition cards from their colleagues, who request these cards from the project. A scientist can also obtain a copy of the petition from [www.PetitionProject.org](http://www.PetitionProject.org), sign, and mail it. Fewer than 5 percent of the current signatories obtained their petition in this way.

The letter on the following page, from Professor Frederick Seitz, is circulated with the petition. Dr. Seitz, a physicist, was president of the U.S. National Academy of Sciences and of Rockefeller University. He received the National Medal of Science, the Compton Award, the Franklin Medal, and numerous other awards, including honorary doctorates from 32 universities around the world. In August 2007, Dr. Seitz reviewed and approved the article by Dr. Arthur B. Robinson, Dr. Noah E. Robinson, and Dr. Willie Soon that is circulated with the petition and gave his enthusiastic approval to the continuation of the Petition Project. A vigorous supporter of the Petition Project since its inception in 1998, Professor Seitz died on March 2, 2008.

## 1.2. Qualifications of Signers

Petition project volunteers evaluate each signer’s credentials, verify signer identities, and, if appropriate, add the signer’s name to the petition list. Signatories are approved for inclusion in the Petition Project list if they have obtained formal educational degrees at the level of Bachelor of Science or higher

in appropriate scientific fields. The petition has been circulated only in the United States.

The current list of petition signers includes 9,029 persons who hold Ph.D.s, 7,153 who hold an MS, 2,585 who hold MDs or DVMs, and 12,711 who hold a BS or equivalent academic degrees. Most of the MD and DVM signers also have underlying degrees in basic science.

All of the listed signers have formal educations in fields of specialization that suitably qualify them to evaluate the research data related to the petition statement. Many of the signers currently work in climatological, meteorological, atmospheric, environmental, geophysical, astronomical, and biological fields directly involved in the climate change controversy. The Petition Project classifies petition signers on the basis of their formal academic training, as summarized below. Scientists often pursue specialized fields of endeavor that are different from their formal education, but their underlying training can be applied to any scientific field in which they become interested.

Outlined below are the numbers of Petition Project signatories, subdivided by educational specialties. These have been combined, as indicated, into seven categories.

1. Atmospheric, environmental, and Earth sciences includes 3,803 scientists trained in specialties directly related to the physical environment of the Earth and the past and current phenomena that affect that environment.

2. Computer and mathematical sciences includes 935 scientists trained in computer and mathematical methods. Since the human-caused global warming hypothesis rests entirely upon mathematical computer projections and not upon experimental observations, these sciences are especially important in evaluating this hypothesis.

3. Physics and aerospace sciences include 5,810 scientists trained in the fundamental physical and molecular properties of gases, liquids, and solids, which are essential to understanding the physical properties of the atmosphere and Earth.

4. Chemistry includes 4,818 scientists trained in the molecular interactions and behaviors of the substances of which the atmosphere and Earth are composed.

5. Biology and agriculture includes 2,964 scientists trained in the functional and environmental requirements of living things on the Earth.

Enclosed is a twelve-page review of information on the subject of “global warming,” a petition in the form of a reply card, and a return envelope. Please consider these materials carefully.

The United States is very close to adopting an international agreement that would ration the use of energy and of technologies that depend upon coal, oil, and natural gas and some other organic compounds.

This treaty is, in our opinion, based upon flawed ideas. Research data on climate change do not show that human use of hydrocarbons is harmful. To the contrary, there is good evidence that increased atmospheric carbon dioxide is environmentally helpful.

The proposed agreement would have very negative effects upon the technology of nations throughout the world, especially those that are currently attempting to lift from poverty and provide opportunities to the over 4 billion people in technologically underdeveloped countries.

It is especially important for America to hear from its citizens who have the training necessary to evaluate the relevant data and offer sound advice.

We urge you to sign and return the enclosed petition card. If you would like more cards for use by your colleagues, these will be sent.

Frederick Seitz  
Past President, National Academy of Sciences, U.S.A.  
President Emeritus, Rockefeller University

6. Medicine includes 3,046 scientists trained in the functional and environmental requirements of human beings on the Earth.

7. Engineering and general science includes 10,102 scientists trained primarily in the many engineering specialties required to maintain modern

civilization and the prosperity required for all human actions, including environmental programs.

The outline below gives a more detailed analysis of the signers' educations.

## Qualifications of Petition Signers

### Atmosphere, Earth, and Environment (3,803)

1. Atmosphere (578)
  - a) Atmospheric Science (113)
  - b) Climatology (39)
  - c) Meteorology (341)
  - d) Astronomy (59)
  - e) Astrophysics (26)
2. Earth (2,240)
  - a) Earth Science (94)
  - b) Geochemistry (63)
  - c) Geology (1,684)
  - d) Geophysics (341)
  - e) Geoscience (36)
  - f) Hydrology (22)
3. Environment (985)
  - a) Environmental Engineering (486)
  - b) Environmental Science (253)
  - c) Forestry (163)
  - d) Oceanography (83)

### Computers and Math (935)

1. Computer Science (242)
2. Math (693)
  - a) Mathematics (581)
  - b) Statistics (112)

### Physics and Aerospace (5,810)

1. Physics (5,223)
  - a) Physics (2,365)
  - b) Nuclear Engineering (223)
  - c) Mechanical Engineering (2,635)
2. Aerospace Engineering (587)

### Chemistry (4,818)

1. Chemistry (3,126)
2. Chemical Engineering (1,692)

### Biochemistry, Biology, and Agriculture (2,964)

1. Biochemistry (744)
  - a) Biochemistry (676)
  - b) Biophysics (68)
2. Biology (1,437)
  - a) Biology (1,048)
  - b) Ecology (76)
  - c) Entomology (59)
  - d) Zoology (149)
  - e) Animal Science (105)
3. Agriculture (783)
  - a) Agricultural Science (296)
  - b) Agricultural Engineering (114)
  - c) Plant Science (292)
  - d) Food Science (81)

### Medicine (3,046)

1. Medical Science (719)
2. Medicine (2,327)

### General Engineering and General Science (10,102)

1. General Engineering (9,833)
  - a) Engineering (7,280)
  - b) Electrical Engineering (2,169)
  - c) Metallurgy (384)
2. General Science (269)

### 1.3. Frequently Asked Questions

#### 1. Is the Petition Project fulfilling the expectations of its organizers?

Yes. In Ph.D. scientist signers alone, the project already includes 15 times more scientists than are seriously involved in the United Nations' IPCC process. The very large number of petition signers demonstrates that, if there is a consensus among American scientists, it is in opposition to the human-caused global warming hypothesis rather than in favor of it. Moreover, the current totals of 31,478 signers, including 9,029 PhDs, are limited only by Petition Project resources. With more funds for printing and postage, those numbers would be much higher.

#### 2. Has the petition project helped to diminish the threat of energy and technology rationing?

The accomplishments of science and engineering have transformed the world. They have markedly increased the quality, quantity, and length of human life and have enabled human beings to make many improvements in the natural environment of the Earth.

Today, scientists are seeing the accomplishments of science demonized and one of the three most important molecular substances that make life possible—atmospheric carbon dioxide (the other two being oxygen and water)—denigrated as an atmospheric “pollutant” in a widely circulated movie. Scientists who have carefully examined the facts know this movie contains numerous falsehoods. This and many other similar misguided propaganda efforts in the media naturally repel men and women who know the truth. The search for truth is the essence of science. When science is misrepresented, scientists are naturally incensed.

There is, therefore, a rapidly growing backlash of opposition among American scientists to this egregious misuse of the reputation and procedures of science. The Petition Project is helping to demonstrate this opposition and, therefore, to reduce the chances of misguided political reductions in science-based technology.

#### 3. Who organized the Petition Project?

The Petition Project was organized by a group of physicists and physical chemists who conduct scientific research at several American scientific institutions. The petition statement and the signatures of its 31,478 signers, however, speak for themselves. The primary relevant role of the organizers is that they are among the 9,029 PhD signers of the petition.

#### 4. Who pays for the Petition Project?

The Petition Project is financed by non-tax deductible donations to the Petition Project from private individuals, many of whom are signers of the petition. The project has no financing whatever from industrial sources. No funds or resources of the Oregon Institute of Science and Medicine are used for the Petition Project. The Oregon Institute of Science and Medicine has never received funds or resources from energy industries, and none of the scientists at the Institute have any funding whatever from corporations or institutions involved in hydrocarbon technology or energy production. Donations to the project are primarily used for printing and postage. Most of the labor for the project has been provided by scientist volunteers.

#### 5. Does the petition list contain names other than those of scientist signers?

Opponents of the Petition Project sometimes submit forged signatures in efforts to discredit the project. Usually, these efforts are eliminated by our verification procedures. On one occasion, a forged signature appeared briefly on the signatory list. It was removed as soon as discovered.

In a group of more than 30,000 people, there are many individuals with names similar or identical to other signatories, or to non-signatories—real or fictional. Opponents of the petition project sometimes use this statistical fact in efforts to discredit the project. For example, Perry Mason and Michael Fox are real scientists who have signed the petition and happen also to have names identical to fictional or real non-scientists.

#### 6. Does the petition project list contain duplicate names?

Thousands of scientists have signed the petition more than once. These duplicates have been carefully removed from the petition list. The list contains many instances of scientists with closely similar and sometimes identical names, as is statistically expected in a list of this size, but these signers are different people, who live at different addresses, and usually have different fields of specialization. Primarily as a result of name and address variants, occasional duplicate names are found in the list. These are immediately removed.

#### 7. Are any of the listed signers dead?

In a group of more than 30,000 people, deaths are a frequent occurrence. The Petition Project has no comprehensive method by which it is notified about

deaths of signatories. When we do learn of a death, an “\*” is placed beside the name of the signatory. For examples, Edward Teller, Arnold Beckman, Philip Abelson, William Nierenberg, and Martin Kamen are American scientists who signed the Petition and are now deceased.

#### **8. Why is this effort called “Petition Project?”**

Signatories to the petition have signed just the petition—which speaks for itself. The organizers—themselves scientists located at several scientific institutions—have designed the project to emphasize this single fact. The use of a post office box mailing address, a generic name— Petition Project—and other institutionally neutral aspects of the project are intended to avoid the impression that the signatories have endorsed the agenda or actions of any institution, group, or other activity. They are simply signers of this petition to the government of the United States.

#### **9. Why was the review article published in the *Journal of American Physicians and Surgeons*?**

The authors chose to submit this article for peer-review and publication to the *Journal of American Physicians and Surgeons* because that journal was willing to waive its copyright and permit extensive reproduction and distribution of the article by the Petition Project.

#### **10. Why is the Petition Project necessary?**

In December 1997, then U.S. Vice-President Al Gore participated in a meeting in Kyoto, Japan during which he signed a treaty to ration world energy production based upon fear of human-caused global warming. This treaty was not, however, presented to the United States Senate for ratification.

Since before that Kyoto meeting and continuing to the present day, Mr. Gore and his supporters at the United Nations and elsewhere have claimed that the “science is settled” – that an overwhelming “consensus” of scientists agrees with the hypothesis of human-caused global warming, with only a handful of skeptical scientists in disagreement. These

proponents of world energy rationing have consistently argued that, in view of this claimed scientific “consensus,” no further discussion of the science involved in this issue is warranted before legislative action is taken to heavily tax, regulate, and ration hydrocarbon energy.

Realizing, from discussions with their scientific colleagues, that this claimed “consensus” does not exist, a group of scientists initiated the Petition Project in early 1998. Thousands of signatures were gathered in a campaign during 1998-1999. Between 1999 and 2007, the list of petition signatories grew gradually, without a special campaign. Between October 2007 and March 2008, a new campaign for signatures was initiated. The majority of the current listed signatories signed or re-signed the petition after October 2007. The original review article that accompanied the petition effort in 1998-1999 was replaced in October 2007 with a new review incorporating the research literature up to that date.

The renewed petition campaign in 2007 was prompted by an escalation of the claims of “consensus,” release of the movie *An Inconvenient Truth* by Al Gore, and related events. The campaign to severely ration hydrocarbon energy technology has been markedly expanded, and many scientifically invalid claims about impending climate emergencies are being made. Simultaneously, proposed political actions to sharply reduce hydrocarbon use now threaten the prosperity of Americans and the very existence of hundreds of millions of people in poorer countries.

As Professor Seitz states in his Petition Project letter, which speaks of this impending threat to all humanity, “It is especially important for America to hear from its citizens who have the training necessary to evaluate the relevant data and offer sound advice.”

The Petition Project is a means by which those citizens are offering that advice.
