## Preface

---

Before facing major surgery, wouldn't you want a second opinion?

When a nation faces an important decision that risks its economic future, or perhaps the fate of the ecology, it should do the same. It is a time-honored tradition in science to set up a "Team B," which examines the same original evidence but may reach a different conclusion. The Nongovernmental International Panel on Climate Change (NIPCC) was set up to examine the same climate data used by the United Nations-sponsored Intergovernmental Panel on Climate Change (IPCC).

In 2007, the IPCC released to the public its three-volume Fourth Assessment Report titled *Climate Change 2007* (IPCC-AR4, 2007). Its constituent documents were said by the IPCC to comprise "the most comprehensive and up-to-date reports available on the subject," and to constitute "the standard reference for all concerned with climate change in academia, government and industry worldwide." But are these characterizations correct?

On the most important issue, the IPCC's claim that "most of the observed increase in global average temperatures since the mid-twentieth century is *very likely* due to the observed increase in anthropogenic greenhouse gas concentrations [emphasis in the original]," NIPCC reaches the opposite conclusion—namely, that natural causes are very likely to be the dominant cause. Note: We do not say anthropogenic greenhouse gases (GHG) cannot produce some warming or has not in the past. Our conclusion is that the evidence shows they are not playing a *substantial* role.

Almost as importantly, on the question of what effects the present and future warming might have on human health and the natural environment, the IPCC says global warming will "increase the number of people suffering from death, disease and injury from heatwaves, floods, storms, fires and droughts." The NIPCC again reaches the opposite conclusion: A warmer world will be a safer and healthier world for humans and wildlife alike. Once again, we do not say global warming won't occur or have any effects (positive or negative) on human health and wildlife.

Rather, our conclusion is that the evidence shows the *net* effect of continued warming and rising carbon dioxide concentrations in the atmosphere will be beneficial to humans, plants, and wildlife.

We have reviewed the materials presented in the first two volumes of the Fourth Assessment—*The Physical Science Basis* and *Impacts, Adaptation and Vulnerability*—and we find them to be highly selective and controversial with regard to making future projections of climate change and discerning a significant human-induced influence on current and past climatic trends. Although the IPCC claims to be unbiased and to have based AR4 on the best available science, such is not the case. In many instances conclusions have been seriously exaggerated, relevant facts have been distorted, and key scientific studies have been omitted or ignored.

We present support for this thesis in the body of this volume, where we describe and reference thousands of peer-reviewed scientific journal articles that document scientific or historical facts that contradict the IPCC's central claims, that global warming is man-made and that its effects will be catastrophic. Some of this research became available after the AR4's self-imposed deadline of May 2006, but much of it was in the scientific record that was available to, and should have been familiar to, the IPCC's editors.

Below, we first sketch the history of the IPCC and NIPCC, which helps explain why two scientific bodies could study the same data and come to very different conclusions. We then explain the list of 31,478 American scientists that appears in Appendix 4, and end by expressing what we hoped to achieve by producing this report.

### A Brief History of the IPCC

The rise in environmental consciousness since the 1970s has focused on a succession of 'calamities': cancer epidemics from chemicals, extinction of birds and other species by pesticides, the depletion of the

ozone layer by supersonic transports and later by freons, the death of forests ('Waldsterben') because of acid rain, and finally, global warming, the "mother of all environmental scares" (according to the late Aaron Wildavsky).

The IPCC can trace its roots to World Earth Day in 1970, the Stockholm Conference in 1971-72, and the Villach Conferences in 1980 and 1985. In July 1986, the United Nations Environment Program (UNEP) and the World Meteorological Organization (WMO) established the Intergovernmental Panel on Climate Change (IPCC) as an organ of the United Nations.

The IPCC's key personnel and lead authors were appointed by governments, and its Summaries for Policymakers (SPM) have been subject to approval by member governments of the UN. The scientists involved with the IPCC are almost all supported by government contracts, which pay not only for their research but for their IPCC activities. Most travel to and hotel accommodations at exotic locations for the drafting authors is paid with government funds.

The history of the IPCC has been described in several publications. What is not emphasized, however, is the fact that it was an activist enterprise from the very beginning. Its agenda was to justify control of the emission of greenhouse gases, especially carbon dioxide. Consequently, its scientific reports have focused solely on evidence that might point toward human-induced climate change. The role of the IPCC "is to assess on a comprehensive, objective, open and transparent basis the latest scientific, technical and socio-economic literature produced worldwide relevant to the understanding of *the risk of human-induced climate change*, its observed and projected impacts and options for adaptation and mitigation" [emphasis added] (IPCC 2008).

The IPCC's three chief ideologues have been (the late) Professor Bert Bolin, a meteorologist at Stockholm University; Dr. Robert Watson, an atmospheric chemist at NASA, later at the World Bank, and now chief scientist at the UK Department of Environment, Food and Rural Affairs; and Dr. John Houghton, an atmospheric radiation physicist at Oxford University, later head of the UK Met Office as Sir John Houghton.

Watson had chaired a self-appointed group to find evidence for a human effect on stratospheric ozone and was instrumental in pushing for the 1987 Montreal Protocol to control the emission of chlorofluorocarbons (CFCs). Using the blueprint of

the Montreal Protocol, environmental lawyer David Doniger of the Natural Resources Defense Council then laid out a plan to achieve the same kind of control mechanism for greenhouse gases, a plan that eventually was adopted as the Kyoto Protocol.

From the very beginning, the IPCC was a political rather than scientific entity, with its leading scientists reflecting the positions of their governments or seeking to induce their governments to adopt the IPCC position. In particular, a small group of activists wrote the all-important Summary for Policymakers (SPM) for each of the four IPCC reports (McKittrick *et al.*, 2007).

While we are often told about the thousands of scientists on whose work the Assessment reports are based, the vast majority of these scientists had no direct influence on the conclusions expressed by the IPCC. Those policy summaries were produced by an inner core of scientists, and the SPMs were revised and agreed to, line-by-line, by representatives of member governments. This obviously is not how real scientific research is reviewed and published.

These SPMs turn out, in all cases, to be highly selective summaries of the voluminous science reports—typically 800 or more pages, with no indexes (except, finally, the Fourth Assessment Report released in 2007), and essentially unreadable except by dedicated scientists.

The IPCC's First Assessment Report (IPCC-FAR, 1990) concluded that the observed temperature changes were "broadly consistent" with greenhouse models. Without much analysis, it gave the "climate sensitivity" of a 1.5 to 4.5° C rise for a doubling of greenhouse gases. The IPCC-FAR led to the adoption of the Global Climate Treaty at the 1992 Earth Summit in Rio de Janeiro.

The FAR drew a critical response (SEPP, 1992). FAR and the IPCC's style of work also were criticized in two editorials in *Nature* (Anonymous, 1994, Maddox, 1991).

The IPCC's Second Assessment Report (IPCC-SAR, 1995) was completed in 1995 and published in 1996. Its SPM contained the memorable conclusion, "the balance of evidence suggests a discernible human influence on global climate." The SAR was again heavily criticized, this time for having undergone significant changes in the body of the report to make it 'conform' to the SPM—*after* it was finally approved by the scientists involved in writing the report. Not only was the report altered, but a key graph was also doctored to suggest a human

influence. The evidence presented to support the SPM conclusion turned out to be completely spurious.

There is voluminous material available about these text changes, including a *Wall Street Journal* editorial article by Dr. Frederick Seitz (Seitz, 1996). This led to heated discussions between supporters of the IPCC and those who were aware of the altered text and graph, including an exchange of letters in the *Bulletin of the American Meteorological Society* (Singer *et al.*, 1997).

SAR also provoked the 1996 publication of the Leipzig Declaration by SEPP, which was signed by some 100 climate scientists. A booklet titled *The Scientific Case Against the Global Climate Treaty* followed in September 1997 and was translated into several languages. (SEPP, 1997. All these are available online at [www.sepp.org](http://www.sepp.org).) In spite of its obvious shortcomings, the IPCC report provided the underpinning for the Kyoto Protocol, which was adopted in December 1997. The background is described in detail in the booklet *Climate Policy—From Rio to Kyoto*, published by the Hoover Institution (Singer, 2000).

The Third Assessment Report of the IPCC (IPCC-TAR 2001) was noteworthy for its use of spurious scientific papers to back up its SPM claim of “new and stronger evidence” of anthropogenic global warming. One of these was the so-called “hockey-stick” paper, an analysis of proxy data, which claimed the twentieth century was the warmest in the past 1,000 years. The paper was later found to contain basic errors in its statistical analysis (McIntyre and McKittrick, 2003, 2005; Wegman *et al.*, 2006). The IPCC also supported a paper that claimed pre-1940 warming was of human origin and caused by greenhouse gases. This work, too, contained fundamental errors in its statistical analysis. The SEPP response to TAR was a 2002 booklet, *The Kyoto Protocol is Not Backed by Science* (SEPP, 2002).

The Fourth Assessment Report of the IPCC (IPCC-AR4 2007) was published in 2007; the SPM of Working Group I was released in February; and the full report from this Working Group was released in May—after it had been changed, once again, to “conform” to the Summary. It is significant that AR4 no longer makes use of the hockey-stick paper or the paper claiming pre-1940 human-caused warming. Once again controversy ensued, however, this time when the IPCC refused to publicly share comments submitted by peer-reviewers, then sent all the reviewers’ comments in hard copy to a library that

was closed for renovation, and then finally, but only under pressure, posted them online. Inspection of those comments revealed that the authors had rejected more than half of all the reviewers’ comments in the crucial chapter attributing recent warming to human activities.

AR4 concluded that “most of the observed increase in global average temperatures since the mid-20th century is *very likely* due to the observed increase in anthropogenic greenhouse gas concentrations” (emphasis in the original). However, as the present report will show, it ignored available evidence against a human contribution to current warming and the substantial research of the past few years on the effects of solar activity on climate change.

Why have IPCC reports been marred by controversy and so frequently contradicted by subsequent research? Certainly its agenda to find evidence of a human role in climate change is a major reason; its organization as a government entity beholden to political agendas is another major reason; and the large professional and financial rewards that go to scientists and bureaucrats who are willing to bend scientific facts to match those agendas is yet a third major reason.

Another reason for the IPCC’s unreliability is the naive acceptance by policymakers of “peer-reviewed” literature as necessarily authoritative. It has become the case that refereeing standards for many climate-change papers are inadequate, often because of the use of an “invisible college” of reviewers of like inclination to a paper’s authors (Wegman *et al.*, 2006). Policy should be set upon a background of demonstrable science, not upon simple (and often mistaken) assertions that, because a paper was refereed, its conclusions must be accepted.

### **Nongovernmental International Panel on Climate Change (NIPCC)**

When new errors and outright falsehoods were observed in the initial drafts of AR4, SEPP set up a “Team B” to produce an independent evaluation of the available scientific evidence. While the initial organization took place at a meeting in Milan in 2003, Team B was activated after the AR4 SPM appeared in February 2007. It changed its name to the Nongovernmental International Panel on Climate Change (NIPCC) and organized an international climate workshop in Vienna in April 2007.

The present report stems from the Vienna workshop and subsequent research and contributions by a larger group of international scholars. For a list of those contributors, see page ii. Craig Idso then made a major contribution to the report by tapping the extensive collection of reviews of scientific research he helped collect and write, which is available on the Web site of the Center for the Study of Carbon Dioxide and Global Change ([www.CO2science.org](http://www.CO2science.org)). A Summary for Policymakers, edited by S. Fred Singer, was published by The Heartland Institute in 2008 under the title *Nature, Not Human Activity, Rules the Planet* (Singer, 2008). Since the summary was completed prior to a major expansion and completion of the full NIPCC report, the two documents now stand on their own as independent scholarly works and substantially agree.

What was our motivation? It wasn't financial self-interest: Except for a foundation grant late in the process to enable Craig Idso to devote the many hours necessary to assemble and help edit the final product, no grants or contributions were provided or promised in return for producing this report. It wasn't political: No government agency commissioned or authorized our efforts, and we do not advise or support the candidacies of any politicians or candidates for public office.

We donated our time and best efforts to produce this report out of concern that the IPCC was provoking an irrational fear of anthropogenic global warming based on incomplete and faulty science. Global warming hype has led to demands for unrealistic efficiency standards for cars, the construction of uneconomic wind and solar energy stations, the establishment of large production facilities for uneconomic biofuels such as ethanol from corn, requirements that electric companies purchase expensive power from so-called "renewable" energy sources, and plans to sequester, at considerable expense, carbon dioxide emitted from power plants. While there is nothing wrong with initiatives to increase energy efficiency or diversify energy sources, they cannot be justified as a realistic means to control climate. Neither does science justify policies that try to hide the huge cost of greenhouse gas controls, such as cap and trade, a "clean development mechanism," carbon offsets, and similar schemes that enrich a few at the expense of the rest of us.

Seeing science clearly misused to shape public policies that have the potential to inflict severe economic harm, particularly on low-income groups,

we choose to speak up for science at a time when too few people outside the scientific community know what is happening, and too few scientists who know the truth have the will or the platforms to speak out against the IPCC.

NIPCC is what its name suggests: an international panel of *nongovernment* scientists and scholars who have come together to understand the causes and consequences of climate change. Because we are not predisposed to believe climate change is caused by human greenhouse gas emissions, we are able to look at evidence the IPCC ignores. Because we do not work for any governments, we are not biased toward the assumption that greater government activity is necessary.

### The Petition Project

Attached as Appendix 4 to this report is a description of "The Petition Project" and a directory of the 31,478 American scientists who have signed the following statement:

We urge the United States government to reject the global warming agreement that was written in Kyoto, Japan in December, 1997, and any other similar proposals. The proposed limits on greenhouse gases would harm the environment, hinder the advance of science and technology, and damage the health and welfare of mankind.

There is no convincing scientific evidence that human release of carbon dioxide, methane, or other greenhouse gases is causing or will, in the foreseeable future, cause catastrophic heating of the Earth's atmosphere and disruption of the Earth's climate. Moreover, there is substantial scientific evidence that increases in atmospheric carbon dioxide produce many beneficial effects upon the natural plant and animal environments of the Earth.

This is a remarkably strong statement of dissent from the perspective advanced by the IPCC, and it is similar to the perspective represented by the NIPCC and the current report. The fact that more than *ten times* as many scientists have signed it as are alleged to have "participated" in some way or another in the research, writing, and review of IPCC AR4 is very significant. These scientists, who include among their number 9,029 individuals with Ph.D.s, actually *endorse* the statement that appears above. By contrast, fewer than 100 of the scientists (and nonscientists) who are listed in the appendices to the IPCC AR4

actually participated in the writing of the all-important Summary for Policymakers or the editing of the final report to comply with the summary, and therefore could be said to endorse the main findings of that report. Consequently, we cannot say for sure whether more than 100 scientists in the entire world actually endorse the most important claims that appear in the IPCC AR4 report.

We will not make the same mistake as the IPCC. We do not claim the 31,478 scientists whose names appear at the end of this report endorse all of the findings and conclusions of this report. As the authors of the petition say (in an introduction to the directory of signers in Appendix 4), “signatories to the petition have signed just the petition—which speaks for itself.” We append the list of their names to this report with the permission of the persons who maintain the list to demonstrate unequivocally the broad support within the scientific community for the general perspective expressed in this report, and to highlight one of the most telling differences between the NIPCC and the IPCC.

For more information about The Petition Project, including the text of the letter endorsing it written by the late Dr. Frederick Seitz, past president of the National Academy of Sciences and president emeritus of Rockefeller University, please turn to Appendix 4 or visit the project’s Web site at [www.petitionproject.org](http://www.petitionproject.org).

## Looking Ahead

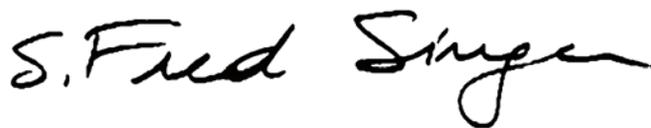

The public’s fear of anthropogenic global warming, despite almost hysterical coverage of the issue by the mainstream media, seems to have hit a ceiling and is falling. Only 34 percent of Americans polled (Rasmussen Reports, 2009) believe humans are causing global warming. A declining number even believe the Earth is experiencing a warming trend (Pew Research Center, 2008). A poll of 12,000 people in 11 countries, commissioned by the financial institution HSBC and environmental advocacy groups, found only one in five respondents—20 percent—said they would be willing to spend any extra money to reduce climate change, down from 28 percent a year earlier (O’Neil, 2008).

While the present report makes it clear that the scientific debate is tilting away from global warming alarmism, we are pleased to see the political debate also is not over. Global warming “skeptics” in the policy arena include Vaclav Klaus, president of the

Czech Republic and 2009 president of the Council of the European Union; Helmut Schmidt, former German chancellor; and Lord Nigel Lawson, former United Kingdom chancellor of the exchequer. There is some evidence that policymakers world-wide are reconsidering the wisdom of efforts to legislate reductions in greenhouse gas (GHG) emissions.

We regret that many advocates in the debate have chosen to give up debating the science and focus almost exclusively on questioning the motives of “skeptics,” name-calling, and *ad hominem* attacks. We view this as a sign of desperation on their part, and a sign that the debate has shifted toward climate realism.

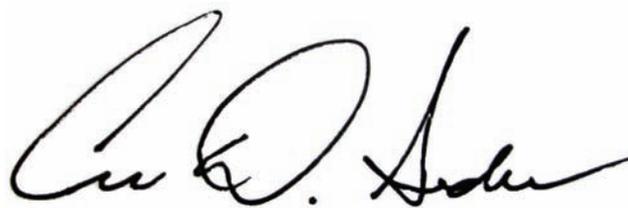

We hope the present study will help bring reason and balance back into the debate over climate change, and by doing so perhaps save the peoples of the world from the burden of paying for wasteful, unnecessary energy and environmental policies. We stand ready to defend the analysis and conclusion in the study that follows, and to give further advice to policymakers who are open-minded on this most important topic.

# Executive Summary

---

The Fourth Assessment Report of the Intergovernmental Panel on Climate Change's Working Group-1 (Science) (IPCC-AR4 2007), released in 2007, is a major research effort by a group of dedicated specialists in many topics related to climate change. It forms a valuable compendium of the current state of the science, enhanced by having an index which had been lacking in previous IPCC reports. AR4 also permits access to the numerous critical comments submitted by expert reviewers, another first for the IPCC.

While AR4 is an impressive document, it is far from being a reliable reference work on some of the most important aspects of climate change science and policy. It is marred by errors and misstatements, ignores scientific data that were available but were inconsistent with the authors' pre-conceived conclusions, and has already been contradicted in important parts by research published since May 2006, the IPCC's cut-off date.

In general, the IPCC fails to consider important scientific issues, several of which would upset its major conclusion—that “most of the observed increase in global average temperatures since the mid-20th century is *very likely* due to the observed increase in anthropogenic greenhouse gas concentrations [emphasis in the original].” The IPCC defines “very likely” as at least 90 percent certain. They do not explain how they derive this number. The IPCC also does not define the word “most,” nor do they provide any explanation.

The IPCC does not apply generally accepted methodologies to determine what fraction of current warming is natural, or how much is caused by the rise in greenhouse gases (GHG). A comparison of “fingerprints” from best available observations with the results of state-of-the-art GHG models leads to the conclusion that the (human-caused) GHG contribution is minor. This fingerprint evidence, though available, was ignored by the IPCC.

The IPCC continues to undervalue the overwhelming evidence that, on decadal and century-long time scales, the Sun and associated atmospheric

cloud effects are responsible for much of past climate change. It is therefore highly likely that the Sun is also a major cause of twentieth-century warming, with anthropogenic GHG making only a minor contribution. In addition, the IPCC ignores, or addresses imperfectly, other science issues that call for discussion and explanation.

These errors and omissions are documented in the present report by the Nongovernmental International Panel on Climate Change (NIPCC). The report is divided into nine chapters that are briefly summarized here, and then more fully described in the remainder of this summary.

Chapter 1 describes the limitations of the IPCC's attempt to forecast future climate conditions by using computer climate models. The IPCC violates many of the rules and procedures required for scientific forecasting, making its “projections” of little use to policymakers. As sophisticated as today's state-of-the-art models are, they suffer deficiencies and shortcomings that could alter even the very *sign* (plus or minus, warming or cooling) of earth's projected temperature response to rising atmospheric CO<sub>2</sub> concentrations. If the global climate models on which the IPCC relies are not validated or reliable, most of the rest of the AR4, while it makes for fascinating reading, is irrelevant to the public policy debate over what should be done to stop or slow the arrival of global warming.

Chapter 2 describes feedback factors that reduce the earth's temperature sensitivity to changes in atmospheric CO<sub>2</sub>. Scientific studies suggest the model-derived temperature sensitivity of the earth for a doubling of the pre-industrial CO<sub>2</sub> level is much lower than the IPCC's estimate. Corrected feedbacks in the climate system reduce climate sensitivity to values that are an order of magnitude smaller than what the IPCC employs.

Chapter 3 reviews empirical data on past temperatures. We find no support for the IPCC's claim that climate observations during the twentieth century are either unprecedented or provide evidence of an anthropogenic effect on climate. We reveal the

methodological errors of the “hockey stick” diagram of Mann *et al.*, evidence for the existence of a global Medieval Warm Period, flaws in the surface-based temperature record of more modern times, evidence from highly accurate satellite data that there has been no net warming over the past 29 years, and evidence that the distribution of modern warming does not bear the “fingerprint” of an anthropogenic effect.

Chapter 4 reviews observational data on glacier melting, sea ice area, variation in precipitation, and sea level rise. We find no evidence of trends that could be attributed to the supposedly anthropogenic global warming of the twentieth century.

Chapter 5 summarizes the research of a growing number of scientists who say variations in solar activity, not greenhouse gases, are the true driver of climate change. We describe the evidence of a solar-climate link and how these scientists have grappled with the problem of finding a specific mechanism that translates small changes in solar activity into larger climate effects. We summarize how they may have found the answer in the relationships between the sun, cosmic rays and reflecting clouds.

Chapter 6 investigates and debunks the widespread fears that global warming might cause more extreme weather. The IPCC claims global warming will cause (or already is causing) more droughts, floods, hurricanes, storms, storm surges, heat waves, and wildfires. We find little or no support in the peer-reviewed literature for these predictions and considerable evidence to support an opposite prediction: That weather would be *less* extreme in a warmer world.

Chapter 7 examines the biological effects of rising CO<sub>2</sub> concentrations and warmer temperatures. This is the largely unreported side of the global warming debate, perhaps because it is unequivocally good news. Rising CO<sub>2</sub> levels increase plant growth and make plants more resistant to drought and pests. It is a boon to the world’s forests and prairies, as well as to farmers and ranchers and the growing populations of the developing world.

Chapter 8 examines the IPCC’s claim that CO<sub>2</sub>-induced increases in air temperature will cause unprecedented plant and animal extinctions, both on land and in the world’s oceans. We find there little real-world evidence in support of such claims and an abundance of counter evidence that suggests ecosystem biodiversity will *increase* in a warmer and CO<sub>2</sub>-enriched world.

Chapter 9 challenges the IPCC’s claim that CO<sub>2</sub>-induced global warming is harmful to human health.

The IPCC blames high-temperature events for increasing the number of cardiovascular-related deaths, enhancing respiratory problems, and fueling a more rapid and widespread distribution of deadly infectious diseases, such as malaria, dengue and yellow fever. However, a thorough examination of the peer-reviewed scientific literature reveals that further global warming would likely do just the opposite and actually reduce the number of lives lost to extreme thermal conditions. We also explain how CO<sub>2</sub>-induced global warming would help feed a growing global population without major encroachment on natural ecosystems, and how increasing production of biofuels (a strategy recommended by the IPCC) damages the environment and raises the price of food.

The research summarized in this report is only a small portion of what is available in the peer-reviewed scientific literature. To assist readers who want to explore information not contained between the covers of this volume, we have included Internet hyperlinks to the large and continuously updated databases maintained by the Center for the Study of Carbon Dioxide and Global Change at [www.co2science.org](http://www.co2science.org).

## Key Findings by Chapter

### Chapter 1. Global Climate Models and Their Limitations

- The IPCC places great confidence in the ability of general circulation models (GCMs) to simulate future climate and attribute observed climate change to anthropogenic emissions of greenhouse gases.
- The forecasts in the Fourth Assessment Report were not the outcome of validated scientific procedures. In effect, they are the opinions of scientists transformed by mathematics and obscured by complex writing. The IPCC’s claim that it is making “projections” rather than “forecasts” is not a plausible defense.
- Today’s state-of-the-art climate models fail to accurately simulate the physics of earth’s radiative energy balance, resulting in uncertainties “as large as, or larger than, the doubled CO<sub>2</sub> forcing.”
- A long list of major model imperfections prevents models from properly modeling cloud formation and cloud-radiation interactions, resulting in large

## Executive Summary

differences between model predictions and observations.

- Computer models have failed to simulate even the correct sign of observed precipitation anomalies, such as the summer monsoon rainfall over the Indian region. Yet it is understood that precipitation plays a major role in climate change.

### Chapter 2. Feedback Factors and Radiative Forcing

- Scientific research suggests the model-derived temperature sensitivity of the earth accepted by the IPCC is too large. Corrected feedbacks in the climate system could reduce climate sensitivity to values that are an order of magnitude smaller.
- Scientists may have discovered a connection between cloud creation and sea surface temperature in the tropics that creates a “thermostat-like control” that automatically vents excess heat into space. If confirmed, this could totally compensate for the warming influence of all anthropogenic CO<sub>2</sub> emissions experienced to date, as well as all those that are anticipated to occur in the future.
- The IPCC dramatically underestimates the total cooling effect of aerosols. Studies have found their radiative effect is comparable to or larger than the temperature forcing caused by all the increase in greenhouse gas concentrations recorded since pre-industrial times.
- Higher temperatures are known to increase emissions of dimethyl sulfide (DMS) from the world’s oceans, which increases the albedo of marine stratus clouds, which has a cooling effect.
- Iodocompounds—created by marine algae—function as cloud condensation nuclei, which help create new clouds that reflect more incoming solar radiation back to space and thereby cool the planet.
- As the air’s CO<sub>2</sub> content—and possibly its temperature—continues to rise, plants emit greater amounts of carbonyl sulfide gas, which eventually makes it way into the stratosphere, where it is transformed into solar-radiation-reflecting sulfate aerosol particles, which have a cooling effect.
- As CO<sub>2</sub> enrichment enhances biological growth, atmospheric levels of biosols rise, many of which

function as cloud condensation nuclei. Increased cloudiness diffuses light, which stimulates plant growth and transfers more fixed carbon into plant and soil storage reservoirs.

- Since agriculture accounts for almost half of nitrous oxide (N<sub>2</sub>O) emissions in some countries, there is concern that enhanced plant growth due to CO<sub>2</sub> enrichment might increase the amount and warming effect of this greenhouse gas. But field research shows that N<sub>2</sub>O emissions fall as CO<sub>2</sub> concentrations and temperatures rise, indicating this is actually another negative climate feedback.
- Methane (CH<sub>4</sub>) is a potent greenhouse gas. An enhanced CO<sub>2</sub> environment has been shown to have “neither positive nor negative consequences” on atmospheric methane concentrations. Higher temperatures have been shown to result in reduced methane release from peatbeds. Methane emissions from cattle have been reduced considerably by altering diet, immunization, and genetic selection.

### Chapter 3. Observations: Temperature Records

- The IPCC claims to find evidence in temperature records that the warming of the twentieth century was “unprecedented” and more rapid than during any previous period in the past 1,300 years. But the evidence it cites, including the “hockey-stick” representation of earth’s temperature record by Mann *et al.*, has been discredited and contradicted by many independent scholars.
- A corrected temperature record shows temperatures around the world were warmer during the Medieval Warm Period of approximately 1,000 years ago than they are today, and have averaged 2-3°F warmer than today’s temperatures over the past 10,000 years.
- Evidence of a global Medieval Warm Period is extensive and irrefutable. Scientists working with a variety of independent methodologies have found it in proxy records from Africa, Antarctica, the Arctic, Asia, Europe, North America, and South America.
- The IPCC cites as evidence of modern global warming data from surface-based recording stations yielding a 1905-2005 temperature increase of 0.74°C +/- 0.18°C. But this temperature record is known to be positively

biased by insufficient corrections for the non-greenhouse-gas-induced urban heat island (UHI) effect. It may be impossible to make proper corrections for this deficiency, as the UHI of even small towns dwarfs any concomitant augmented greenhouse effect that may be present.

- Highly accurate satellite data, adjusted for orbit drift and other factors, show a much more modest warming trend in the last two decades of the twentieth century and a dramatic decline in the warming trend in the first decade of the twenty-first century.
- The “fingerprint” or pattern of warming observed in the twentieth century differs from the pattern predicted by global climate models designed to simulate CO<sub>2</sub>-induced global warming. Evidence reported by the U.S. Climate Change Science Program (CCSP) is unequivocal: All greenhouse models show an increasing warming trend with altitude in the tropics, peaking around 10 km at roughly twice the surface value. However, the temperature data from balloons give the opposite result: no increasing warming, but rather a slight cooling with altitude.
- Temperature records in Greenland and other Arctic areas reveal that temperatures reached a maximum around 1930 and have decreased in recent decades. Longer-term studies depict oscillatory cooling since the Climatic Optimum of the mid-Holocene (~9000-5000 years BP), when it was perhaps 2.5° C warmer than it is now.
- The average temperature history of Antarctica provides no evidence of twentieth century warming. While the Antarctic peninsula shows recent warming, several research teams have documented a cooling trend for the interior of the continent since the 1970s.

### **Chapter 4. Observations: Glaciers, Sea Ice, Precipitation, and Sea Level**

- Glaciers around the world are continuously advancing and retreating, with a general pattern of retreat since the end of the Little Ice Age. There is no evidence of a increased rate of melting overall since CO<sub>2</sub> levels rose above their pre-industrial levels, suggesting CO<sub>2</sub> is not responsible for glaciers melting.

- Sea ice area and extent have continued to increase around Antarctica over the past few decades. Evidence shows that much of the reported thinning of Arctic sea ice that occurred in the 1990s was a natural consequence of changes in ice dynamics caused by an atmospheric regime shift, of which there have been several in decades past and will likely be several in the decades to come, totally irrespective of past or future changes in the air’s CO<sub>2</sub> content. The Arctic appears to have recovered from its 2007 decline.
- Global studies of precipitation trends show no net increase and no consistent trend with CO<sub>2</sub>, contradicting climate model predictions that warming should cause increased precipitation. Research on Africa, the Arctic, Asia, Europe, and North and South America all find no evidence of a significant impact on precipitation that could be attributed to anthropogenic global warming.
- The cumulative discharge of the world’s rivers remained statistically unchanged between 1951 and 2000, a finding that contradicts computer forecasts that a warmer world would cause large changes in global streamflow characteristics. Droughts and floods have been found to be less frequent and severe during the Current Warm Period than during past periods when temperatures were even higher than they are today.
- The results of several research studies argue strongly against claims that CO<sub>2</sub>-induced global warming would cause catastrophic disintegration of the Greenland and Antarctic Ice Sheets. In fact, in the case of Antarctica, they suggest just the opposite—i.e., that CO<sub>2</sub>-induced global warming would tend to buffer the world against such an outcome.
- The mean rate of global sea level rise has not accelerated over the recent past. The determinants of sea level are poorly understood due to considerable uncertainty associated with a number of basic parameters that are related to the water balance of the world’s oceans and the meltwater contribution of Greenland and Antarctica. Until these uncertainties are satisfactorily resolved, we cannot be confident that short-lived changes in global temperature produce corresponding changes in sea level.

## Chapter 5. Solar Variability and Climate Cycles

- The IPCC claims the radiative forcing due to changes in the solar output since 1750 is  $+0.12 \text{ Wm}^{-2}$ , an order of magnitude smaller than its estimated net anthropogenic forcing of  $+1.66 \text{ Wm}^{-2}$ . A large body of research suggests that the IPCC has got it backwards, that it is the sun's influence that is responsible for the lion's share of climate change during the past century and beyond.
- The total energy output of the sun changes by only 0.1 percent during the course of the solar cycle, although larger changes may be possible over periods of centuries. On the other hand, the ultraviolet radiation from the sun can change by several percent over the solar cycle – as indeed noted by observing changes in stratospheric ozone. The largest changes, however, occur in the intensity of the solar wind and interplanetary magnetic field.
- Reconstructions of ancient climates reveal a close correlation between solar magnetic activity and solar irradiance (or brightness), on the one hand, and temperatures on earth, on the other. Those correlations are much closer than the relationship between carbon dioxide and temperature.
- Cosmic rays could provide the mechanism by which changes in solar activity affect climate. During periods of greater solar magnetic activity, greater shielding of the earth occurs, resulting in less cosmic rays penetrating to the lower atmosphere, resulting in fewer cloud condensation nuclei being produced, resulting in fewer and less reflective low-level clouds occurring, which leads to more solar radiation being absorbed by the surface of the earth, resulting (finally) in increasing near-surface air temperatures and global warming.
- Strong correlations between solar variability and precipitation, droughts, floods, and monsoons have all been documented in locations around the world. Once again, these correlations are much stronger than any relationship between these weather phenomena and  $\text{CO}_2$ .
- The role of solar activity in causing climate change is so complex that most theories of solar forcing must be considered to be as yet unproven. But it would also be appropriate for climate scientists to admit the same about the role of

rising atmospheric  $\text{CO}_2$  concentrations in driving recent global warming.

## Chapter 6. Observations: Extreme Weather

- The IPCC predicts that a warmer planet will lead to more extreme weather, characterized by more frequent and severe episodes of drought, flooding, cyclones, precipitation variability, storms, snow, storm surges, temperature variability, and wildfires. But has the last century – during which the IPCC claims the world experienced more rapid warming than any time in the past two millennia – experienced significant trends in any of these extreme weather events?
- Droughts have not become more extreme or erratic in response to global warming. Real-world evidence from Africa, Asia, and other continents find no trend toward more frequent or more severe droughts. In most cases, the worst droughts in recorded meteorological history were much milder than droughts that occurred periodically during much colder times.
- Floods were more frequent and more severe during the Little Ice Age than they have been during the Current Warm Period. Flooding in Asia, Europe, and North America has tended to be less frequent and less severe during the twentieth century.
- The IPCC says “it is likely that future tropical cyclones (typhoons and hurricanes) will become more intense, with larger peak wind speeds and more heavy precipitation associated with ongoing increase of tropical sea surface temperatures.” But despite the supposedly “unprecedented” warming of the twentieth century, there has been no increase in the intensity or frequency of tropical cyclones globally or in any of the specific oceans.
- A number of real-world observations demonstrate that El Niño-Southern Oscillation (ENSO) conditions during the latter part of the twentieth century were not unprecedented in terms of their frequency or magnitude. Long-term records suggest that when the earth was significantly warmer than it is currently, ENSO events were substantially reduced or perhaps even absent.
- There is no support for the model-based projection that precipitation in a warming world becomes more variable and intense. In fact, some

observational data suggest just the opposite, and provide support for the proposition that precipitation responds more to cyclical variations in solar activity.

- As the earth has warmed over the past 150 years, during its recovery from the global chill of the Little Ice Age, there has been no significant increase in either the frequency or intensity of stormy weather.
- Between 1950 and 2002, during which time the air's CO<sub>2</sub> concentration rose by 20 percent, there was no net change in either the mean onset date or duration of snow cover for the continent of North America. There appears to have been a downward trend in blizzards.
- Storm surges have not increased in either frequency or magnitude as CO<sub>2</sub> concentrations in the atmosphere have risen. In the majority of cases investigated, they have tended to decrease.
- Air temperature variability almost always *decreases* when mean air temperature *rises*, be it in cases of temperature change over tens of thousands of years or over mere decades, or even between individual cooler and warmer years when different ENSO states are considered. The claim that global warming will lead to more extremes of climate and weather, including more extremes of temperature itself, is not supported by real-world data.
- Although one can readily identify specific parts of the planet that have experienced both significant increases and decreases in land area burned by wildfires over the last two to three decades of the twentieth century, for the globe as a whole there was no relationship between global warming and total area burned over this period.

### Chapter 7. Biological Effects of Carbon Dioxide Enhancement

- A 300-ppm increase in the air's CO<sub>2</sub> content typically raises the productivity of most herbaceous plants by about one-third; and this positive response occurs in plants that utilize all three of the major biochemical pathways (C<sub>3</sub>, C<sub>4</sub>, CAM) of photosynthesis. For woody plants, the response is even greater. The productivity benefits of CO<sub>2</sub> enrichment are also experienced by aquatic plants, including freshwater algae and

macrophytes, and marine microalgae and macroalgae.

- The amount of carbon plants gain per unit of water lost—or water-use efficiency—typically rises as the CO<sub>2</sub> content of the air rises, greatly increasing their ability to withstand drought. In addition, the CO<sub>2</sub>-induced percentage increase in plant biomass production is often greater under water-stressed conditions than it is when plants are well watered.
- Atmospheric CO<sub>2</sub> enrichment helps ameliorate the detrimental effects of several environmental stresses on plant growth and development, including high soil salinity, high air temperature, low light intensity and low levels of soil fertility. Elevated levels of CO<sub>2</sub> have additionally been demonstrated to reduce the severity of low temperature stress, oxidative stress, and the stress of herbivory. In fact, the percentage growth enhancement produced by an increase in the air's CO<sub>2</sub> concentration is often even greater under stressful and resource-limited conditions than it is when growing conditions are ideal.
- As the air's CO<sub>2</sub> content continues to rise, plants will likely exhibit enhanced rates of photosynthesis and biomass production that will not be diminished by any global warming that might occur concurrently. In fact, if the ambient air temperature rises, the growth-promoting effects of atmospheric CO<sub>2</sub> enrichment will likely also rise, becoming more and more robust.
- The ongoing rise in the air's CO<sub>2</sub> content likely will not favor the growth of weedy species over that of crops and native plants.
- The growth of plants is generally not only enhanced by CO<sub>2</sub>-induced increases in net photosynthesis during the light period of the day, it is also enhanced by CO<sub>2</sub>-induced decreases in respiration during the dark period.
- The ongoing rise in the air's CO<sub>2</sub> content, as well as any degree of warming that might possibly accompany it, will not materially alter the rate of decomposition of the world's soil organic matter and will probably enhance biological carbon sequestration. Continued increases in the air's CO<sub>2</sub> concentration and temperature will not result in massive losses of carbon from earth's peatlands. To the contrary, these environmental

## Executive Summary

changes—if they persist—would likely work together to enhance carbon capture.

- Other biological effects of CO<sub>2</sub> enhancement include enhanced plant nitrogen-use efficiency, longer residence time of carbon in the soil, and increased populations of earthworms and soil nematodes.
- The aerial fertilization effect of the ongoing rise in the air's CO<sub>2</sub> concentration (which greatly enhances vegetative productivity) and its anti-transpiration effect (which enhances plant water-use efficiency and enables plants to grow in areas that were once too dry for them) are stimulating plant growth across the globe in places that previously were too dry or otherwise unfavorable for plant growth, leading to a significant greening of the Earth.
- Elevated CO<sub>2</sub> reduces, and nearly always overrides, the negative effects of ozone pollution on plant photosynthesis, growth and yield. It also reduces atmospheric concentrations of isoprene, a highly reactive non-methane hydrocarbon that is emitted in copious quantities by vegetation and is responsible for the production of vast amounts of tropospheric ozone.
- Real-world data collected by the United Nations Environmental Program (UNEP) show the rate of extinctions at the end of the twentieth century was the lowest since the sixteenth century—despite 150 years of rising world temperatures, growing populations, and industrialization. Many, and probably most, of the world's species benefited from rising temperatures in the twentieth century.
- As long as the atmosphere's CO<sub>2</sub> concentration rises in tandem with its temperature, most plants will not need to migrate toward cooler conditions, as their physiology will change in ways that make them better adapted to warmer conditions. Plants will likely spread poleward in latitude and upward in elevation at the cold-limited boundaries of their ranges, thanks to longer growing seasons and less frost, while their heat-limited boundaries will probably remain pretty much as they are now or shift only slightly.
- Land animals also tend to migrate poleward and upward, to areas where cold temperatures prevented them from going in the past. They follow earth's plants, while the heat-limited boundaries of their ranges are often little affected, allowing them to also expand their ranges.
- The persistence of coral reefs through geologic time—when temperatures were as much as 10°-15°C warmer than at present, and atmospheric CO<sub>2</sub> concentrations were two to seven times higher than they are currently—provides substantive evidence that these marine entities can successfully adapt to a dramatically changing global environment.
- The 18- to 59-cm warming-induced sea-level rise that is predicted for the coming century by the IPCC falls well within the range (2 to 6 mm per year) of typical coral vertical extension rates, which exhibited a modal value of 7 to 8 mm per year during the Holocene and can be more than double that value in certain branching corals. Rising sea levels should therefore present no difficulties for coral reefs.
- The rising CO<sub>2</sub> content of the atmosphere may induce very small changes in the well-buffered ocean chemistry (pH) that could slightly reduce coral calcification rates; but potential positive effects of hydrospheric CO<sub>2</sub> enrichment may more than compensate for this modest negative phenomenon. Real-world observations indicate

### Chapter 8. Species Extinction

- The IPCC claims “new evidence suggests that climate-driven extinctions and range retractions are already widespread” and the “projected impacts on biodiversity are significant and of key relevance, since global losses in biodiversity are irreversible (very high confidence).” These claims are not supported by scientific research.
- The world's species have proven to be remarkably resilient to climate change. Most wild species are at least one million years old, which means they have all been through hundreds of climate cycles involving temperature changes on par with or greater than those experienced in the twentieth century.
- The four known causes of extinctions are huge asteroids striking the planet, human hunting, human agriculture, and the introduction of alien species (e.g., lamprey eels in the Great Lakes and pigs in Hawaii). None of these causes are connected with either global temperatures or atmospheric CO<sub>2</sub> concentrations.

that elevated CO<sub>2</sub> and elevated temperatures are having a positive effect on most corals.

- Polar bears have survived changes in climate that exceed those that occurred during the twentieth century or are forecast by the IPCC's computer models.
- Most populations of polar bears are growing, not shrinking, and the biggest influence on polar bear populations is not temperature but hunting by humans, which historically has taken a large toll on polar bear populations.
- Forecasts of dwindling polar bear populations assume trends in sea ice and temperature that are counterfactual, rely on unvalidated computer climate models that are known to be unreliable, and violate most of the principles of scientific forecasting.

### Chapter 9. Human Health Effects

- The IPCC alleges that “climate change currently contributes to the global burden of disease and premature deaths” and will “increase malnutrition and consequent disorders.” In fact, the overwhelming weight of evidence shows that higher temperatures and rising CO<sub>2</sub> levels have played an indispensable role in making it possible to feed a growing global population without encroaching on natural ecosystems.
- Global warming reduces the incidence of cardiovascular disease related to low temperatures and wintry weather by a much greater degree than it increases the incidence of cardiovascular disease associated with high temperatures and summer heat waves.
- Mortality due to respiratory diseases decrease as temperatures rise and as temperature variability declines.
- Claims that malaria and tick-borne diseases are spreading or will spread across the globe as a result of CO<sub>2</sub>-induced warming are not supported in the scientific literature.
- Total heat-related mortality rates have been shown to be lower in warmer climates and to be unaffected by rising temperatures during the twentieth century.
- The historical increase in the air's CO<sub>2</sub> content has improved human nutrition by raising crop

yields during the past 150 years on the order of 70 percent for wheat, 28 percent for cereals, 33 percent for fruits and melons, 62 percent for legumes, 67 percent for root and tuber crops, and 51 percent for vegetables.

- The quality of plant food in the CO<sub>2</sub>-enriched world of the future, in terms of its protein and antioxidant (vitamin) contents, will be no lower and probably will be higher than in the past.
- There is evidence that some medicinal substances in plants will be present in significantly greater concentrations, and certainly in greater absolute amounts, than they are currently.
- The historical increase of the air's CO<sub>2</sub> content has probably helped lengthen human lifespans since the advent of the Industrial Revolution, and its continued upward trend will likely provide more of the same benefit.
- Higher levels of CO<sub>2</sub> in the air help to advance all three parts of a strategy to resolve the tension between the need to feed a growing population and the desire to preserve natural ecosystems: increasing crop yield per unit of land area, increasing crop yield per unit of nutrients applied, and increasing crop yield per unit of water used.
- Biofuels for transportation (chiefly ethanol, biodiesel, and methanol) are being used in growing quantities in the belief that they provide environmental benefits. In fact, those benefits are very dubious. By some measures, “the net effect of biofuels production ... is to increase CO<sub>2</sub> emissions for decades or centuries relative to the emissions caused by fossil fuel use.”
- Biofuels compete with livestock growers and food processors for corn, soybeans, and other feedstocks, leading to higher food prices. Rising food prices in 2008 led to food riots in several developing countries. The production of biofuels also consumes enormous quantities of water compared with the production of gasoline.
- There can be little doubt that ethanol mandates and subsidies have made both food and energy more, not less, expensive and therefore less available to a growing population. The extensive damage to natural ecosystems already caused by this poor policy decision, and the much greater destruction yet to come, are a high price to pay for refusing to understand and utilize the true science of climate change.

# Global Climate Models and Their Limitations

---

## 1. Global Climate Models and Their Limitations

- 1.1. Models and Forecasting
- 1.2. Radiation
- 1.3. Clouds
- 1.4. Precipitation

### Introduction

Because the earth-ocean-atmosphere system is so vast and complex, it is impossible to conduct a small-scale experiment that reveals how the world's climate will change as the air's greenhouse gas (GHG) concentrations continue to rise. As a result, scientists try to forecast the effect of rising GHG by looking backwards at climate history to see how the climate responded to previous "forcings" of a similar kind, or by creating computer models that define a "virtual" earth-ocean-atmosphere system and run scenarios or "story lines" based on assumptions about future events.

The Intergovernmental Panel on Climate Change (IPCC) places great confidence in the ability of general circulation models (GCMs) to simulate future climate and attribute observed climate change to anthropogenic emissions of greenhouse gases. It says "climate models are based on well-established physical principles and have been demonstrated to reproduce observed features of recent climate ... and past climate changes ... There is considerable confidence that Atmosphere-Ocean General Circulation Models (AOGCMs) provide credible quantitative estimates of future climate change, particularly at continental and larger scales" (IPCC, 2007-I, p. 591).

To be of any validity, GCMs must incorporate all of the many physical, chemical, and biological processes that influence climate in the real world, and they must do so correctly. A review of the scientific

literature reveals numerous deficiencies and shortcomings in today's state-of-the-art models, some of which deficiencies could even alter the sign of projected climate change. In this chapter, we first ask if computer models are capable *in principle* of producing reliable forecasts and then examine three areas of model inadequacies: radiation, clouds, and precipitation.

### 1.1. Models and Forecasting

J. Scott Armstrong, professor, The Wharton School, University of Pennsylvania and a leading figure in the discipline of professional forecasting, has pointed out that forecasting is a practice and discipline in its own right, with its own institute (International Institute of Forecasters, founded in 1981), peer-reviewed journal (*International Journal of Forecasting*), and an extensive body of research that has been compiled into a set of scientific procedures, currently

numbering 140, that must be used to make reliable forecasts (*Principles of Forecasting: A Handbook for Researchers and Practitioners*, by J. Scott Armstrong, Kluwer Academic Publishers, 2001).

According to Armstrong, when physicists, biologists, and other scientists who do not know the rules of forecasting attempt to make climate predictions based on their training and expertise, their forecasts are no more reliable than those made by nonexperts, even when they are communicated through complex computer models (Armstrong, 2001). In other words, forecasts by scientists, even large numbers of very distinguished scientists, are not necessarily *scientific* forecasts. In support of his position, Armstrong and a colleague cite research by Philip E. Tetlock (2005), a psychologist and professor of organizational behavior at the University of California, Berkeley, who “recruited 288 people whose professions included ‘commenting or offering advice on political and economic trends.’ He asked them to forecast the probability that various situations would or would not occur, picking areas (geographic and substantive) within and outside their areas of expertise. By 2003, he had accumulated more than 82,000 forecasts. The experts barely if at all outperformed non-experts and neither group did well against simple rules” (Green and Armstrong, 2007). The failure of expert opinion to lead to reliable forecasts has been confirmed in scores of empirical studies (Armstrong, 2006; Craig *et al.*, 2002; Cerf and Navasky, 1998; Ascher, 1978) and illustrated in historical examples of incorrect forecasts made by leading experts (Cerf and Navasky, 1998).

In 2007, Armstrong and Kesten C. Green of Monash University conducted a “forecasting audit” of the IPCC Fourth Assessment Report (Green and Armstrong, 2007). The authors’ search of the contribution of Working Group I to the IPCC “found no references ... to the primary sources of information on forecasting methods” and “the forecasting procedures that were described [in sufficient detail to be evaluated] violated 72 principles. Many of the violations were, by themselves, critical.”

One principle of scientific forecasting Green and Armstrong say the IPCC violated is “Principle 1.3 Make sure forecasts are independent of politics.” The two authors write, “this principle refers to keeping the forecasting process separate from the planning process. The term ‘politics’ is used in the broad sense of the exercise of power.” Citing David Henderson (Henderson, 2007), a former head of economics and

statistics at the Organization for Economic Cooperation and Development (OECD), they say “the IPCC process is directed by non-scientists who have policy objectives and who believe that anthropogenic global warming is real and danger.” They conclude:

The forecasts in the Report were not the outcome of scientific procedures. In effect, they were the opinions of scientists transformed by mathematics and obscured by complex writing. Research on forecasting has shown that experts’ predictions are not useful in situations involving uncertainty and complexity. We have been unable to identify any scientific forecasts of global warming. Claims that the Earth will get warmer have no more credence than saying that it will get colder.

Scientists working in fields characterized by complexity and uncertainty are apt to confuse the output of *models*—which are nothing more than a statement of how the modeler believes a part of the world works—with real-world trends and forecasts (Bryson, 1993). Computer climate modelers certainly fall into this trap, and they have been severely criticized for failing to notice that their models fail to replicate real-world phenomena by many scientists, including Balling (2005), Christy (2005), Essex and McKittrick (2007), Frauenfeld (2005), Michaels (2000, 2005, 2009), Pilkey and Pilkey-Jarvis (2007), Posmentier and Soon (2005), and Spencer (2008).

Canadian science writer Lawrence Solomon (2008) interviewed many of the world’s leading scientists active in scientific fields relevant to climate change and asked them for their views on the reliability of the computer models used by the IPCC to detect and forecast global warming. Their answers showed a high level of skepticism:

- Prof. Freeman Dyson, professor of physics at the Institute for Advanced Study at Princeton University, one of the world’s most eminent physicists, said the models used to justify global warming alarmism are “full of fudge factors” and “do not begin to describe the real world.”
- Dr. Zbigniew Jaworowski, chairman of the Scientific Council of the Central Laboratory for Radiological Protection in Warsaw and former chair of the United Nations Scientific Committee on the Effects of Atomic Radiation, a world-renowned expert on the use of ancient ice cores for climate research, said the U.N. “based its global-warming hypothesis on arbitrary

assumptions and these assumptions, it is now clear, are false.”

- Dr. Richard Lindzen, a professor of meteorology at M.I.T. and member of the National Research Council Board on Atmospheric Sciences and Climate, said the IPCC is “trumpeting catastrophes that couldn’t happen even if the models were right.”
- Prof. Hendrik Tennekes, director of research at the Royal Netherlands Meteorological Institute, said “there exists no sound theoretical framework for climate predictability studies” used for global warming forecasts.
- Dr. Richard Tol, principal researcher at the Institute for Environmental Studies at Vrije Universiteit and adjunct professor at the Center for Integrated Study of the Human Dimensions of Global Change at Carnegie Mellon University, said the IPCC’s Fourth Assessment Report is “preposterous ... alarmist and incompetent.”
- Dr. Antonino Zichichi, emeritus professor of physics at the University of Bologna, former president of the European Physical Society, and one of the world’s foremost physicists, said global warming models are “incoherent and invalid.”

Princeton’s Freeman Dyson has written elsewhere, “I have studied the climate models and I know what they can do. The models solve the equations of fluid dynamics, and they do a very good job of describing the fluid motions of the atmosphere and the oceans. They do a very poor job of describing the clouds, the dust, the chemistry, and the biology of fields and farms and forests. They do not begin to describe the real world that we live in” (Dyson, 2007).

Many of the scientists cited above observe that computer models can be “tweaked” to reconstruct climate histories after the fact, as the IPCC points out in the passage quoted at the beginning of this chapter. But this provides no assurance that the new model will do a better job forecasting *future* climates, and indeed points to how unreliable the models are. Individual climate models often have widely differing assumptions about basic climate mechanisms but are then “tweaked” to produce similar forecasts. This is nothing like how real scientific forecasting is done.

Kevin Trenberth, a lead author along with Philip D. Jones of chapter 3 of the Working Group I contribution to the IPCC’s Fourth Assessment Report, replied to some of these scathing criticisms on the blog of the science journal *Nature*. He argued that “the IPCC does not make forecasts” but “instead proffers ‘what if’ projections of future climate that correspond to certain emissions scenarios,” and then hopes these “projections” will “guide policy and decision makers” (Trenberth, 2007). He says “there are no such predictions [in the IPCC reports] although the projections given by the Intergovernmental Panel on Climate Change (IPCC) are often treated as such. The distinction is important.”

This defense is hardly satisfactory. As Green and Armstrong point out, “the word ‘forecast’ and its derivatives occurred 37 times, and ‘predict’ and its derivatives occurred 90 times in the body of Chapter 8” of the Working Group I report, and a survey of climate scientists conducted by those same authors found “most of our respondents (29 of whom were IPCC authors or reviewers) nominated the IPCC report as the most credible source of forecasts (not ‘scenarios’ or ‘projections’) of global average temperature.” They conclude that “the IPCC does provide forecasts.” We agree, and add that those forecasts are unscientific and therefore likely to be wrong.

## 1.2. Radiation

One problem facing GCMs is how to accurately simulate the physics of earth's radiative energy balance. Of this task, Harries (2000) says "progress is excellent, on-going research is fascinating, but we have still a great deal to understand about the physics of climate."

Harries says "we must exercise great caution over the true depth of our understanding, and our ability to forecast future climate trends." As an example, he states that our knowledge of high cirrus clouds is very poor, noting that "we could easily have uncertainties of many tens of  $Wm^{-2}$  in our description of the radiative effect of such clouds, and how these properties may change under climate forcing." This state of affairs is disconcerting in light of the fact that the radiative effect of a doubling of the air's  $CO_2$  content is in the lower single-digit range of  $Wm^{-2}$ , and, to quote Harries, "uncertainties as large as, or larger than, the doubled  $CO_2$  forcing could easily exist in our modeling of future climate trends, due to uncertainties in the feedback processes." Because of the vast complexity of the subject, Harries says "even if [our] understanding were perfect, our ability to describe the system sufficiently well in even the largest computer models is a problem."

A related problem is illustrated by the work of Zender (1999), who characterized the spectral, vertical, regional and seasonal atmospheric heating caused by the oxygen collision pairs  $O_2 \cdot O_2$  and  $O_2 \cdot N_2$ , which had earlier been discovered to absorb a small but significant fraction of the globally incident solar radiation. In addition, water vapor dimers (a double molecule of  $H_2O$ ) shows strong absorption bands in the near-infrared of the solar spectrum. Zender revealed that these molecular collisions lead

to the absorption of about  $1 \text{ Wm}^{-2}$  of solar radiation, globally and annually averaged. This discovery, in Zender's words, "alters the long-standing view that  $\text{H}_2\text{O}$ ,  $\text{O}_3$ ,  $\text{O}_2$ ,  $\text{CO}_2$  and  $\text{NO}_2$  are the only significant gaseous solar absorbers in earth's atmosphere," and he suggests that the phenomenon "should therefore be included in ... large-scale atmospheric models used to simulate climate and climate change."

In another revealing study, Wild (1999) compared the observed amount of solar radiation absorbed in the atmosphere over equatorial Africa with what was predicted by three GCMs and found the model predictions were much too small. Indeed, regional and seasonal model underestimation biases were as high as  $30 \text{ Wm}^{-2}$ , primarily because the models failed to properly account for spatial and temporal variations in atmospheric aerosol concentrations. In addition, Wild found the models likely underestimated the amount of solar radiation absorbed by water vapor and clouds.

Similar large model underestimations were discovered by Wild and Ohmura (1999), who analyzed a comprehensive observational dataset consisting of solar radiation fluxes measured at 720 sites across the earth's surface and corresponding top-of-the-atmosphere locations to assess the true amount of solar radiation absorbed within the atmosphere. These results were compared with estimates of solar radiation absorption derived from four GCMs and, again, it was shown that "GCM atmospheres are generally too transparent for solar radiation," as they produce a rather substantial mean error close to 20 percent below actual observations.

Another solar-related deficiency of GCMs is their failure to properly account for solar-driven variations in earth-atmosphere processes that operate over a range of timescales extending from the 11-year solar cycle to century- and millennial-scale cycles (see Section 4.11, Solar Influence on Climate). Although the absolute solar flux variations associated with these phenomena are rather small, there are a number of "multiplier effects" that may significantly amplify their impacts.

According to Chambers *et al.* (1999), most of the many nonlinear responses to solar activity variability are inadequately represented in the global climate models used by the IPCC to predict future greenhouse gas-induced global warming, while at the same time other amplifier effects are used to model past glacial/interglacial cycles and even the hypothesized  $\text{CO}_2$ -induced warming of the future, where  $\text{CO}_2$  is not the major cause of the predicted temperature increase but rather an initial perturber of the climate system

that according to the IPCC sets other more powerful forces in motion that produce the bulk of the ultimate warming. There appears to be a double standard within the climate modeling community that may best be described as an inherent reluctance to deal even-handedly with different aspects of climate change. When multiplier effects suit their purposes, they use them; but when they don't suit their purposes, they don't use them.

Ghan *et al.* (2001) warn that "present-day radiative forcing by anthropogenic greenhouse gases is estimated to be  $2.1$  to  $2.8 \text{ Wm}^{-2}$ ; the direct forcing by anthropogenic aerosols is estimated to be  $-0.3$  to  $-1.5 \text{ Wm}^{-2}$ , while the indirect forcing by anthropogenic aerosols is estimated to be  $0$  to  $-1.5 \text{ Wm}^{-2}$ ," so that "estimates of the total global mean present-day anthropogenic forcing range from  $3 \text{ Wm}^{-2}$  to  $-1 \text{ Wm}^{-2}$ ," which implies a climate change somewhere between a modest warming and a slight cooling. They conclude that "the great uncertainty in the radiative forcing must be reduced if the observed climate record is to be reconciled with model predictions and if estimates of future climate change are to be useful in formulating emission policies."

Pursuit of this goal, Ghan *et al.* say, requires achieving "profound reductions in the uncertainties of direct and indirect forcing by anthropogenic aerosols," which is what they set out to do in their analysis of the situation, which consisted of "a combination of process studies designed to improve understanding of the key processes involved in the forcing, closure experiments designed to evaluate that understanding, and integrated models that treat all of the necessary processes together and estimate the forcing." At the conclusion of this laborious set of operations, Ghan *et al.* came up with some numbers that considerably reduce the range of uncertainty in the "total global mean present-day anthropogenic forcing," but that still implied a set of climate changes stretching from a small cooling to a modest warming. They also provided a long list of *other* things that must be done in order to obtain a more definitive result, after which they acknowledged that even this list "is hardly complete." In fact, they conclude, "one could easily add the usual list of uncertainties in the representation of clouds, etc." Consequently, the bottom line, in their words, is that "much remains to be done before the estimates are reliable enough to base energy policy decisions upon."

Also studying the aerosol-induced radiative forcing of climate were Vogelmann *et al.* (2003), who report that "mineral aerosols have complex, highly

varied optical properties that, for equal loadings, can cause differences in the surface IR flux between 7 and 25  $\text{Wm}^{-2}$  (Sokolik *et al.*, 1998).” They say “only a few large-scale climate models currently consider aerosol IR effects (e.g., Tegen *et al.*, 1996; Jacobson, 2001) despite their potentially large forcing.” Because of these facts, and in an attempt to persuade climate modelers to rectify the situation, Vogelmann *et al.* used high-resolution spectra to calculate the surface IR radiative forcing created by aerosols encountered in the outflow of air from northeastern Asia, based on measurements made by the Marine-Atmospheric Emitted Radiance Interferometer aboard the NOAA Ship *Ronald H. Brown* during the Aerosol Characterization Experiment-Asia. In doing so, they determined, in their words, that “daytime surface IR forcings are often a few  $\text{Wm}^{-2}$  and can reach almost 10  $\text{Wm}^{-2}$  for large aerosol loadings,” which values they say “are comparable to or larger than the 1 to 2  $\text{Wm}^{-2}$  change in the globally averaged surface IR forcing caused by greenhouse gas increases since pre-industrial times.” In a massive understatement of fact, the researchers concluded that their results “highlight the importance of aerosol IR forcing which should be included in climate model simulations.” If a forcing of this magnitude is not included in current state-of-the-art climate models, what other major forcings are they ignoring?

Two papers published one year earlier and appearing in the same issue of *Science* (Chen *et al.*, 2002; Wielicki *et al.*, 2002) revealed what Hartmann (2002) called a pair of “tropical surprises.” The first of the seminal discoveries was the common finding of both groups of researchers that the amount of thermal radiation emitted to space at the top of the tropical atmosphere increased by about 4  $\text{Wm}^{-2}$  between the 1980s and the 1990s. The second was that the amount of reflected sunlight decreased by 1 to 2  $\text{Wm}^{-2}$  over the same period, with the net result that more total radiant energy exited the tropics in the latter decade. In addition, the measured thermal radiative energy loss at the top of the tropical atmosphere was of the same magnitude as the thermal radiative energy gain that is generally predicted to result from an instantaneous doubling of the air’s  $\text{CO}_2$  content. Yet as Hartmann notes, “only very small changes in average tropical surface temperature were observed during this time.” How did this occur?

The change in solar radiation reception was driven by reductions in cloud cover, which allowed more solar radiation to reach the surface of the earth’s tropical region and warm it. These changes were

produced by what Chen *et al.* determined to be “a decadal-time-scale strengthening of the tropical Hadley and Walker circulations.” Another helping-hand was likely provided by the past quarter-century’s slowdown in the meridional overturning circulation of the upper 100 to 400 meters of the tropical Pacific Ocean (McPhaden and Zhang, 2002), which circulation slowdown also promotes tropical sea surface warming by reducing the rate-of-supply of relatively colder water to the region of equatorial upwelling.

These observations provide several new phenomena for the models to replicate as a test of their ability to properly represent the real world. In the words of McPhaden and Zhang, the time-varying meridional overturning circulation of the upper Pacific Ocean provides “an important dynamical constraint for model studies that attempt to simulate recent observed decadal changes in the Pacific.”

In an eye-opening application of this principle, Wielicki *et al.* (2002) tested the ability of four state-of-the-art climate models and one weather assimilation model to reproduce the observed decadal changes in top-of-the-atmosphere thermal and solar radiative energy fluxes that occurred over the past two decades. No significant decadal variability was exhibited by *any* of the models; and they *all* failed to reproduce even the cyclical seasonal change in tropical albedo. The administrators of the test kindly concluded that “the missing variability in the models highlights the critical need to improve cloud modeling in the tropics so that prediction of tropical climate on interannual and decadal time scales can be improved.” Hartmann was considerably more candid in his scoring of the test, saying flatly that the results indicated “the models are deficient.” Expanding on this assessment, he noted that “if the energy budget can vary substantially in the absence of obvious forcing,” as it did over the past two decades, “then the climate of earth has modes of variability that are not yet fully understood and cannot yet be accurately represented in climate models.”

Also concentrating on the tropics, Bellon *et al.* (2003) note that “observed tropical sea-surface temperatures (SSTs) exhibit a maximum around 30°C,” and that “this maximum appears to be robust on various timescales, from intraseasonal to millennial.” Hence, they say, “identifying the stabilizing feedback(s) that help(s) maintain this threshold is essential in order to understand how the tropical climate reacts to an external perturbation,” which knowledge is needed for understanding how

the global climate reacts to perturbations such as those produced by solar variability and the ongoing rise in the air's CO<sub>2</sub> content. This contention is further substantiated by the study of Pierrehumbert (1995), which "clearly demonstrates," in the words of Bellon *et al.*, "that the tropical climate is not determined locally, but globally." Also, they note that Pierrehumbert's work demonstrates that interactions between moist and dry regions are an essential part of tropical climate stability, which points to the "adaptive infrared iris" concept of Lindzen *et al.* (2001), which is reported in Section 1.2.

Noting that previous box models of tropical climate have shown it to be rather sensitive to the relative areas of moist and dry regions of the tropics, Bellon *et al.* analyzed various feedbacks associated with this sensitivity in a four-box model of the tropical climate "to show how they modulate the response of the tropical temperature to a radiative perturbation." In addition, they investigated the influence of the model's surface-wind parameterization in an attempt to shed further light on the nature of the underlying feedbacks that help define the global climate system that is responsible for the tropical climate observations of constrained maximum sea surface temperatures (SSTs).

Bellon *et al.*'s work, as they describe it, "suggests the presence of an important and as-yet-unexplored feedback in earth's tropical climate, that could contribute to maintain the 'lid' on tropical SSTs." They say the demonstrated "dependence of the surface wind on the large-scale circulation has an important effect on the sensitivity of the tropical system," specifically stating that "this dependence reduces significantly the SST sensitivity to radiative perturbations by enhancing the evaporation feedback," which injects more heat into the atmosphere and allows the atmospheric circulation to export more energy to the subtropical free troposphere, where it can be radiated to space by water vapor.

This literature review makes clear that the case is not closed on either the source or the significance of the maximum "allowable" SSTs of tropical regions. Neither, consequently, is the case closed on the degree to which the planet may warm in response to continued increases in the atmospheric concentrations of carbon dioxide and other greenhouse gases, in stark contrast to what is suggested by the climate models promoted by the IPCC.

In conclusion, there are a number of major inadequacies in the ways the earth's radiative energy

balance is treated in contemporary general circulation models of the atmosphere, as well as numerous other telling inadequacies stemming from the non-treatment of pertinent phenomena that are nowhere to be found in the models. IPCC-inspired predictions of catastrophic climatic changes due to continued anthropogenic CO<sub>2</sub> emissions are beyond what can be soundly supported by the current state of the climate modeling enterprise.

Additional information on this topic, including reviews of newer publications as they become available, can be found at <http://www.co2science.org/subject/m/inadeqradiation.php>.

### 1.3. Clouds

Correctly parameterizing the influence of clouds on climate is an elusive goal that the creators of atmospheric general circulation models (GCMs) have yet to achieve. One reason for their lack of success has to do with model resolution on vertical and horizontal space scales. Lack of adequate resolution forces modelers to parameterize the ensemble large-scale effects of processes that occur on smaller scales than their models are capable of handling. This is particularly true of physical processes such as cloud formation and cloud-radiation interactions. Several studies suggest that older model parameterizations did not succeed in this regard (Groisman *et al.*, 2000), and subsequent studies suggest they still are not succeeding.

Lane *et al.* (2000) evaluated the sensitivities of the cloud-radiation parameterizations utilized in contemporary GCMs to changes in vertical model resolution, varying the latter from 16 to 60 layers in

increments of four and comparing the results to observed values. This effort revealed that cloud fraction varied by approximately 10 percent over the range of resolutions tested, which corresponded to about 20 percent of the observed cloud cover fraction. Similarly, outgoing longwave radiation varied by 10 to 20  $\text{Wm}^{-2}$  as model vertical resolution was varied, amounting to approximately 5 to 10 percent of observed values, while incoming solar radiation experienced similar significant variations across the range of resolutions tested. The model results did not converge, even at a resolution of 60 layers.

In an analysis of the multiple roles played by cloud microphysical processes in determining tropical climate, Grabowski (2000) found much the same thing, noting there were serious problems related to the degree to which computer models failed to correctly incorporate cloud microphysics. These observations led him to conclude that “it is unlikely that traditional convection parameterizations can be used to address this fundamental question in an effective way.” He also became convinced that “classical convection parameterizations do not include realistic elements of cloud physics and they represent interactions among cloud physics, radiative processes, and surface processes within a very limited scope.” Consequently, he says, “model results must be treated as qualitative rather than quantitative.”

Reaching rather similar conclusions were Gordon *et al.* (2000), who determined that many GCMs of the late 1990s tended to under-predict the presence of subtropical marine stratocumulus clouds and failed to simulate the seasonal cycle of clouds. These deficiencies are extremely important because these particular clouds exert a major cooling influence on the surface temperatures of the sea below them. In the situation investigated by Gordon and his colleagues, the removal of the low clouds, as occurred in the normal application of their model, led to sea surface temperature increases on the order of 5.5°C.

Further condemnation of turn-of-the-century model treatments of clouds came from Harries (2000), previously cited in Section 1.1, who wrote that our knowledge of high cirrus clouds is very poor and that “we could easily have uncertainties of many tens of  $\text{Wm}^{-2}$  in our description of the radiative effect of such clouds, and how these properties may change under climate forcing.”

Moving into the twenty-first century, Lindzen *et al.* (2001) analyzed cloud cover and sea surface temperature (SST) data over a large portion of the Pacific Ocean, finding a strong inverse relationship

between upper-level cloud area and mean SST, such that the area of cirrus cloud coverage normalized by a measure of the area of cumulus coverage decreased by about 22 percent for each degree C increase in cloudy region SST. Essentially, as the researchers described it, “the cloudy-moist region appears to act as an infrared adaptive iris that opens up and closes down the regions free of upper-level clouds, which more effectively permit infrared cooling, in such a manner as to resist changes in tropical surface temperature.” The sensitivity of this negative feedback was calculated by Lindzen *et al.* to be substantial. In fact, they estimated it would “more than cancel all the positive feedbacks in the more sensitive current climate models” that were being used to predict the consequences of projected increases in atmospheric CO<sub>2</sub> concentration.

Lindzen’s challenge to what had become climatic political correctness could not go uncontested, and Hartmann and Michelsen (2002) quickly claimed the correlation noted by Lindzen *et al.* resulted from variations in subtropical clouds that are not physically connected to deep convection near the equator, and that it was thus “unreasonable to interpret these changes as evidence that deep tropical convective anvils contract in response to SST increases.” Fu *et al.* (2002) also chipped away at the adaptive infrared iris concept, arguing that “the contribution of tropical high clouds to the feedback process would be small since the radiative forcing over the tropical high cloud region is near zero and not strongly positive,” while also claiming to show that water vapor and low cloud effects were overestimated by Lindzen *et al.* by at least 60 percent and 33 percent, respectively. As a result, they obtained a feedback factor in the range of -0.15 to -0.51, compared to Lindzen *et al.*’s much larger negative feedback factor of -0.45 to -1.03.

In a contemporaneously published reply to this critique, Chou *et al.* (2002) stated that Fu *et al.*’s approach of specifying longwave emission and cloud albedos “appears to be inappropriate for studying the iris effect,” and that since “thin cirrus are widespread in the tropics and ... low boundary clouds are optically thick, the cloud albedo calculated by [Fu *et al.*] is too large for cirrus clouds and too small for boundary layer clouds,” so that “the near-zero contrast in cloud albedos derived by [Fu *et al.*] has the effect of underestimating the iris effect.” In the end, however, Chou *et al.* agreed that Lindzen *et al.* “may indeed have overestimated the iris effect somewhat, though hardly by as much as that suggested by [Fu *et al.*].”

Although there has thus been some convergence in the two opposing views of the subject, the debate over the reality and/or magnitude of the adaptive infrared iris effect continues. It is amazing that some political leaders proclaim the debate over global warming is “over” when some of the meteorological community’s best minds continue to clash over the nature and magnitude of a phenomenon that could entirely offset the effects of anthropogenic CO<sub>2</sub> emissions.

Grassl (2000), in a review of the then-current status of the climate-modeling enterprise two years before the infrared iris effect debate emerged, noted that changes in many climate-related phenomena, including cloud optical and precipitation properties caused by changes in the spectrum of cloud condensation nuclei, were insufficiently well known to provide useful insights into future conditions. His advice in the light of this knowledge gap was that “we must continuously evaluate and improve the GCMs we use,” although he was forced to acknowledge that contemporary climate model results were already being “used by many decision-makers, including governments.”

Although some may think that what we currently know about the subject is sufficient for predictive purposes, a host of questions posed by Grassl—for which we still lack definitive answers—demonstrates that this assumption is erroneous. As but a single example, Charlson *et al.* (1987) described a negative feedback process that links biologically-produced dimethyl sulfide (DMS) in the oceans with climate. (See Section 2.3 for a more complete discussion.) The basic tenet of this hypothesis is that the global radiation balance is significantly influenced by the albedo of marine stratus clouds, and that the albedo of these clouds is a function of cloud droplet concentration, which is dependent upon the availability of condensation nuclei that have their origin in the flux of DMS from the world’s oceans to the atmosphere.

Acknowledging that the roles played by DMS oxidation products within the context described above are indeed “diverse and complex” and in many instances “not well understood,” Ayers and Gillett (2000) summarized empirical evidence supporting Charlson *et al.*’s hypothesis that was derived from data collected at Cape Grim, Tasmania, and from reports of other pertinent studies in the peer-reviewed scientific literature. According to their findings, the “major links in the feedback chain proposed by Charlson *et al.* (1987) have a sound physical basis,”

and there is “compelling observational evidence to suggest that DMS and its atmospheric products participate significantly in processes of climate regulation and reactive atmospheric chemistry in the remote marine boundary layer of the Southern Hemisphere.”

The empirical evidence analyzed by Ayers and Gillett highlights an important suite of negative feedback processes that act in opposition to model-predicted CO<sub>2</sub>-induced global warming over the world’s oceans; and these processes are not fully incorporated into even the very best of the current crop of climate models, nor are analogous phenomena that occur over land included in them, such as those discussed by Idso (1990). (See also, in this regard, Section 2.7 of this report.)

Further to this point, O’Dowd *et al.* (2004) measured size-resolved physical and chemical properties of aerosols found in northeast Atlantic marine air arriving at the Mace Head Atmospheric Research station on the west coast of Ireland during phytoplanktonic blooms at various times of the year. In doing so, they found that in the winter, when biological activity was at its lowest, the organic fraction of the submicrometer aerosol mass was about 15 percent. During the spring through autumn, however, when biological activity was high, they found that “the organic fraction dominates and contributes 63 percent to the submicrometer aerosol mass (about 45 percent is water-insoluble and about 18 percent water-soluble).” Based on these findings, they performed model simulations that indicated that the marine-derived organic matter “can enhance the cloud droplet concentration by 15 percent to more than 100 percent and is therefore an important component of the aerosol-cloud-climate feedback system involving marine biota.”

As for the significance of their findings, O’Dowd *et al.* state that their data “completely change the picture of what influences marine cloud condensation nuclei given that water-soluble organic carbon, water-insoluble organic carbon and surface-active properties, all of which influence the cloud condensation nuclei activation potential, are typically not parameterized in current climate models,” or as they say in another place in their paper, “an important source of organic matter from the ocean is omitted from current climate-modeling predictions and should be taken into account.”

Another perspective on the cloud-climate conundrum is provided by Randall *et al.* (2003), who state at the outset of their review of the subject that

“the representation of cloud processes in global atmospheric models has been recognized for decades as the source of much of the uncertainty surrounding predictions of climate variability.” They report, however, that “despite the best efforts of [the climate modeling] community ... the problem remains largely unsolved.” What is more, they say, “at the current rate of progress, cloud parameterization deficiencies will continue to plague us for many more decades into the future.”

“Clouds are complicated,” Randall *et al.* declare, as they begin to describe what they call the “appalling complexity” of the cloud parameterization situation. They state that “our understanding of the interactions of the hot towers [of cumulus convection] with the global circulation is still in a fairly primitive state,” and not knowing all that much about *what goes up*, it’s not surprising we also don’t know much about *what comes down*, as they report that “downdrafts are either not parameterized or crudely parameterized in large-scale models.”

With respect to stratiform clouds, the situation is no better, as their parameterizations are described by Randall *et al.* as “very rough caricatures of reality.” As for interactions between convective and stratiform clouds, during the 1970s and ‘80s, Randall *et al.* report that “cumulus parameterizations were extensively tested against observations without even accounting for the effects of the attendant stratiform clouds.” Even at the time of their study, they had to report that the concept of detrainment was “somewhat murky” and the conditions that trigger detrainment were “imperfectly understood.” “At this time,” as they put it, “no existing GCM includes a satisfactory parameterization of the effects of mesoscale cloud circulations.”

Randall *et al.* additionally say that “the large-scale effects of microphysics, turbulence, and radiation should be parameterized as closely coupled processes acting in concert,” but they report that only a few GCMs have even attempted to do so. Why? Because, as they continue, “the cloud parameterization problem is overwhelmingly complicated,” and “cloud parameterization developers,” as they call them, are still “struggling to identify the most important processes on the basis of woefully incomplete observations.” To drive this point home, they say “there is little question why the cloud parameterization problem is taking a long time to solve: It is very, very hard.” In fact, the four scientists conclude that “a sober assessment suggests that with current approaches the cloud

parameterization problem will not be ‘solved’ in any of our lifetimes.”

To show that the basis for this conclusion is robust, and cannot be said to rest on the less-than-enthusiastic remarks of a handful of exasperated climate modelers, we report the results of additional studies of the subject that were published *subsequent* to the analysis of Randall *et al.*, and which therefore could have readily refuted their assessment of the situation if they felt that such was appropriate.

Siebesma *et al.* (2004) report that “simulations with nine large-scale models [were] carried out for June/July/August 1998 and the quality of the results [was] assessed along a cross-section in the subtropical and tropical North Pacific ranging from (235°E, 35°N) to (187.5°E, 1°S),” in order to “document the performance quality of state-of-the-art GCMs in modeling the first-order characteristics of subtropical and tropical cloud systems.” The main conclusions of this study, according to Siebesma *et al.*, were that “(1) almost all models strongly underpredicted both cloud cover and cloud amount in the stratocumulus regions while (2) the situation is opposite in the trade-wind region and the tropics where cloud cover and cloud amount are overpredicted by most models.” In fact, they report that “these deficiencies result in an overprediction of the downwelling surface short-wave radiation of typically  $60 \text{ Wm}^{-2}$  in the stratocumulus regimes and a similar underprediction of  $60 \text{ Wm}^{-2}$  in the trade-wind regions and in the intertropical convergence zone (ITCZ),” which discrepancies are to be compared with a radiative forcing of only a couple of  $\text{Wm}^{-2}$  for a 300 ppm increase in the atmosphere’s  $\text{CO}_2$  concentration. In addition, they state that “similar biases for the short-wave radiation were found at the top of the atmosphere, while discrepancies in the outgoing long-wave radiation are most pronounced in the ITCZ.”

The 17 scientists who wrote Siebesma *et al.*, hailing from nine different countries, also found “the representation of clouds in general-circulation models remains one of the most important *as yet unresolved* [our italics] issues in atmospheric modeling.” This is partially due, they continue, “to the overwhelming variety of clouds observed in the atmosphere, but even more so due to the large number of physical processes governing cloud formation and evolution as well as the great complexity of their interactions.” Hence, they conclude that through repeated critical evaluations of the type they conducted, “the scientific community will be forced to develop further physically sound parameterizations that *ultimately*

[our italics] result in models that are capable of simulating our climate system with increasing realism.”

In an effort to assess the status of state-of-the-art climate models in simulating cloud-related processes, Zhang *et al.* (2005) compared basic cloud climatologies derived from 10 atmospheric GCMs with satellite measurements obtained from the International Satellite Cloud Climatology Project (ISCCP) and the Clouds and Earth’s Radiant Energy System (CERES) program. ISCCP data were available from 1983 to 2001, while data from the CERES program were available for the winter months of 2001 and 2002 and for the summer months of 2000 and 2001. The purpose of their analysis was two-fold: (1) to assess the current status of climate models in simulating clouds so that future progress can be measured more objectively, and (2) to reveal serious deficiencies in the models so as to improve them.

The work of 20 climate modelers involved in this exercise reveals a huge list of major model imperfections. First, Zhang *et al.* report a four-fold difference in high clouds among the models, and that the majority of the models simulated only 30 to 40 percent of the observed middle clouds, with some models simulating less than a quarter of observed middle clouds. For low clouds, they report that half the models underestimated them, such that the grand mean of low clouds from all models was only 70 to 80 percent of what was observed. Furthermore, when stratified in optical thickness ranges, the majority of the models simulated optically thick clouds more than twice as frequently as was found to be the case in the satellite observations, while the grand mean of all models simulated about 80 percent of optically intermediate clouds and 60 percent of optically thin clouds. And in the case of *individual* cloud types, the group of researchers reports that “differences of seasonal amplitudes among the models and satellite measurements can reach several hundred percent.” As a result of these and other observations, Zhang *et al.* conclude that “much more needs to be done to fully understand the physical causes of model cloud biases presented here and to improve the models.”

L’Ecuyer and Stephens (2007) used multi-sensor observations of visible, infrared, and microwave radiance obtained from the Tropical Rainfall Measuring Mission satellite for the period from January 1998 through December 1999, in order to evaluate the sensitivity of atmospheric heating—and the factors that modify it—to changes in east-west sea surface temperature gradients associated with the

strong 1998 El Niño event in the tropical Pacific, as expressed by the simulations of nine general circulation models of the atmosphere that were utilized in the IPCC's most recent Fourth Assessment Report. This protocol, in their words, "provides a natural example of a short-term climate change scenario in which clouds, precipitation, and regional energy budgets in the east and west Pacific are observed to respond to the eastward migration of warm sea surface temperatures."

Results indicated that "a majority of the models examined do not reproduce the apparent westward transport of energy in the equatorial Pacific during the 1998 El Niño event." They also found that "the intermodel variability in the responses of precipitation, total heating, and vertical motion is often larger than the intrinsic ENSO signal itself, implying an inherent lack of predictive capability in the ensemble with regard to the response of the mean zonal atmospheric circulation in the tropical Pacific to ENSO." In addition, they reported that "many models also misrepresent the radiative impacts of clouds in both regions [the east and west Pacific], implying errors in total cloudiness, cloud thickness, and the relative frequency of occurrence of high and low clouds." As a result of these much-less-than-adequate findings, the two researchers from Colorado State University's Department of Atmospheric Science conclude that "deficiencies remain in the representation of relationships between radiation, clouds, and precipitation in current climate models," and they say that these deficiencies "cannot be ignored when interpreting their predictions of future climate."

In another recent paper, this one published in the *Journal of the Atmospheric Sciences*, Zhou *et al.* (2007) state that "clouds and precipitation play key roles in linking the earth's energy cycle and water cycles," noting that "the sensitivity of deep convective cloud systems and their associated precipitation efficiency in response to climate change are key factors in predicting the future climate." They also report that cloud resolving models or CRMs "have become one of the primary tools to develop the physical parameterizations of moist and other subgrid-scale processes in global circulation and climate models," and that CRMs could someday be used in place of traditional cloud parameterizations in such models.

In this regard, the authors note that "CRMs still need parameterizations on scales smaller than their grid resolutions and have many known and unknown

deficiencies." To help stimulate progress in these areas, the nine scientists compared the cloud and precipitation properties observed from the Clouds and the Earth's Radiant Energy System (CERES) and Tropical Rainfall Measuring Mission (TRMM) instruments against simulations obtained from the three-dimensional Goddard Cumulus Ensemble (GCE) model during the South China Sea Monsoon Experiment (SCSMEX) field campaign of 18 May-18 June 1998.

The authors report that: (1) "the GCE rainfall spectrum includes a greater proportion of heavy rains than PR (Precipitation Radar) or TMI (TRMM Microwave Imager) observations"; (2) "the GCE model produces excessive condensed water loading in the column, especially the amount of graupel as indicated by both TMI and PR observations"; (3) "the model also cannot simulate the bright band and the sharp decrease of radar reflectivity above the freezing level in stratiform rain as seen from PR"; (4) "the model has much higher domain-averaged OLR (outgoing longwave radiation) due to smaller total cloud fraction"; (5) "the model has a more skewed distribution of OLR and effective cloud top than CERES observations, indicating that the model's cloud field is insufficient in area extent"; (6) "the GCE is ... not very efficient in stratiform rain conditions because of the large amounts of slowly falling snow and graupel that are simulated"; and finally, and in summation, (7) "large differences between model and observations exist in the rain spectrum and the vertical hydrometeor profiles that contribute to the associated cloud field."

Even more recently, a study by Spencer and Braswell (2008) observed that "our understanding of how sensitive the climate system is to radiative perturbations has been limited by large uncertainties regarding how clouds and other elements of the climate system feed back to surface temperature change (e.g., Webster and Stephens, 1984; Cess *et al.*, 1990; Senior and Mitchell, 1993; Stephens, 2005; Soden and Held, 2006; Spencer *et al.*, 2007)." The two scientists from the Earth System Science Center at the University of Alabama in Huntsville, Alabama then point out that computer models typically assume that if the *causes* of internal sources of variability ( $X$  terms) are uncorrelated to surface temperature changes, then they will not affect the accuracy of regressions used to estimate the relationship between radiative flux changes and surface temperature ( $T$ ). But "while it is true that the processes that *cause* the  $X$  terms are, by [Forster and Gregory (2006)]

definition, uncorrelated to  $T$ , the *response* of  $T$  to those forcings cannot be uncorrelated to  $T$  – for the simple reason that it is a radiative forcing that causes changes in  $T$  [italics in the original].” They ask “to what degree could nonfeedback sources of radiative flux variability contaminate feedback estimates?”

Spencer and Braswell use a “very simple time-dependent model of temperature deviations away from an equilibrium state” to estimate the effects of “daily random fluctuations in an unknown nonfeedback radiative source term  $N$ , such as those one might expect from stochastic variations in low cloud cover.” Repeated runs of the model found the diagnosed feedback departed from the true, expected feedback value of the radiative forcing, with the difference increasing as the amount of nonfeedback radiative flux noise was increased. “It is significant,” the authors write, “that all model errors for runs consistent with satellite-observed variability are in the direction of positive feedback, raising the possibility that current observational estimates of cloud feedback are biased in the positive direction.” In other words, as the authors say in their abstract, “current observational diagnoses of cloud feedback – and possibly other feedbacks – could be significantly biased in the positive direction.”

In light of these findings, it is clear that CRMs still have a long way to go before they are ready to properly assess the roles of various types of clouds and forms of precipitation in the future evolution of earth’s climate in response to variations in anthropogenic and background forcings. This evaluation is not meant to denigrate the CRMs, it is merely done to indicate that the climate modeling enterprise is not yet at the stage where faith should be placed in what it currently suggests about earth’s climatic response to the ongoing rise in the air’s  $\text{CO}_2$  content.

The hope of the climate-modeling community of tomorrow resides, according to Randall *et al.*, in something called “cloud system-resolving models” or CSRMs, which can be compared with single-column models or SCMs that can be “surgically extracted from their host GCMs.” These advanced models, as they describe them, “have resolutions fine enough to represent individual cloud elements, and space-time domains large enough to encompass many clouds over many cloud lifetimes.” Of course, these improvements mean that “the computational cost of running a CSRMs is hundreds or thousands of times greater than that of running an SCM.” Nevertheless, in a few more decades, according to Randall *et al.*, “it

will become possible to use such global CSRMs to perform century-scale climate simulations, relevant to such problems as anthropogenic climate change.”

A few more decades, however, is a little long to wait to address an issue that nations of the world are confronting now. Hence, Randall *et al.* say that an approach that could be used very soon (to possibly determine whether or not there even is a problem) is to “run a CSRMs as a ‘superparameterization’ inside a GCM,” which configuration they call a “super-GCM.” Not wanting to be accused of impeding scientific progress, we say “go for it,” but only with the proviso that the IPCC should admit it is truly needed in order to obtain a definitive answer to the question of  $\text{CO}_2$ -induced “anthropogenic climate change.” In other words, the scientific debate over the causes and processes of global warming is still ongoing and there is no scientific case for governments to regulate greenhouse gas emissions in an expensive and likely futile attempt to alter the course of future climate.

We believe, with Randall *et al.*, that our knowledge of many aspects of earth’s climate system is sadly deficient. Climate models currently do not provide a reliable scientific basis for implementing programs designed to restrict anthropogenic  $\text{CO}_2$  emissions. The cloud parameterization problem by itself is so complex that no one can validly claim that humanity’s continued utilization of fossil-fuel energy will result in massive counter-productive climatic changes. There is no justification for that conclusion in reliable theoretical models.

Additional information on this topic, including reviews of newer publications as they become available, can be found at <http://www.co2science.org/subject/m/inadeqclouds.php>.

## 1.4. Precipitation

One of the predictions of atmospheric general circulation models (GCMs) is that the planet's

hydrologic cycle will intensify as the world warms, leading to an increase in the frequency and intensity of extreme precipitation events. In an early review of the subject, Walsh and Pittock (1998) reported “there is some evidence from climate model studies that, in a warmer climate, rainfall events will be more intense,” and that “there is considerable evidence that the frequency of extreme rainfall events may increase in the tropics.” Upon further study, however, they were forced to conclude that “because of the insufficient resolution of climate models and their generally crude representation of sub-grid scale and convective processes, little confidence can be placed in any definite predictions of such effects.”

Two years later, Lebel *et al.* (2000) compared rainfall simulations produced by a GCM with real-world observations from West Africa for the period 1960-1990. Their analysis revealed that the model output was affected by a number of temporal and spatial biases that led to significant differences between observed and modeled data. The simulated rainfall totals, for example, were significantly greater than what was typically observed, exceeding real-world values by 25 percent during the dry season and 75 percent during the rainy season. In addition, the seasonal cycle of precipitation was not well simulated, as the researchers found that the simulated rainy season began too early and that the increase in precipitation was not rapid enough. Shortcomings were also evident in the GCM’s inability to accurately simulate convective rainfall events, as it typically predicted too much precipitation. Furthermore, it was found that “interannual variability [was] seriously disturbed in the GCM as compared to what it [was] in the observations.” As for why the GCM performed so poorly in these several respects, Lebel *et al.* gave two main reasons: parameterization of rainfall processes in the GCM was much too simple, and spatial resolution was much too coarse.

Three years later, Woodhouse (2003) generated a tree-ring-based history of snow water equivalent (SWE) characteristic of the first day of April for each year of the period 1569-1999 for the drainage basin of the Gunnison River of western Colorado, USA. Then, because “an understanding of the long-term characteristics of snowpack variability is useful for guiding expectations for future variability,” as she phrased it, she analyzed the reconstructed SWE data in such a way as to determine if there was anything unusual about the SWE record of the twentieth century, which the IPCC claims experienced a

warming that was unprecedented over the past two millennia.

Woodhouse found “the twentieth century is notable for several periods that lack extreme years.” Specifically, she determined that “the twentieth century is notable for several periods that contain few or no extreme years, for both low and high SWE extremes,” and she reports that “the twentieth century also contains the lowest percent of extreme low SWE years.” These results are in direct contradiction of what GCMs typically predict should occur in response to global warming. Their failure in this regard is especially damning because it occurred during a period of global warming that is said to have been the most significant of the past 20 centuries.

Two years later, and as a result of the fact that the 2004 summer monsoon season of India experienced a 13 percent precipitation deficit that was not predicted by any of the empirical or dynamical models regularly used in making rainfall forecasts, Gadgil *et al.* (2005) performed a historical analysis of the models forecast skill over the period 1932-2004. Despite model advancements and an ever-improving understanding of monsoon variability, they found the models’ skill in forecasting the Indian monsoon’s characteristics had not improved since the very first versions of the models were applied to the task some seven decades earlier. The empirical models Gadgil *et al.* evaluated generated large differences between monsoon rainfall measurements and model predictions. In addition, the models often failed to correctly predict even the *sign* of the precipitation anomaly, frequently predicting excess rainfall when drought occurred and drought when excess rainfall was received.

The dynamical models fared even worse. In comparing observed monsoon rainfall totals with simulated values obtained from 20 state-of-the-art GCMs and a supposedly superior coupled atmosphere-ocean model, Gadgil *et al.* reported that not a single one of those many models was able “to simulate correctly the interannual variation of the summer monsoon rainfall over the Indian region.” And as with the empirical models, the dynamical models also frequently failed to correctly capture even the *sign* of the observed rainfall anomalies. In addition, the researchers report that Brankovic and Molteni (2004) attempted to model the Indian monsoon with a much higher-resolution GCM, but its output also proved to be “not realistic.”

Lau *et al.* (2006) considered the Sahel drought of the 1970s-’90s to provide “an ideal test bed for

evaluating the capability of CGCMs [coupled general circulation models] in simulating long-term drought, and the veracity of the models' representation of coupled atmosphere-ocean-land processes and their interactions." They chose to "explore the roles of sea surface temperature coupling and land surface processes in producing the Sahel drought in CGCMs that participated in the twentieth-century coupled climate simulations of the Intergovernmental Panel on Climate Change [IPCC] Assessment Report 4," in which the 19 CGCMs "are driven by combinations of realistic prescribed external forcing, including anthropogenic increase in greenhouse gases and sulfate aerosols, long-term variation in solar radiation, and volcanic eruptions."

In performing this analysis, the climate scientists found, in their words, that "only eight models produce a reasonable Sahel drought signal, seven models produce excessive rainfall over [the] Sahel during the observed drought period, and four models show no significant deviation from normal." In addition, they report that "even the model with the highest skill for the Sahel drought could only simulate the increasing trend of severe drought events but not the magnitude, nor the beginning time and duration of the events." All 19 of the CGCMs employed in the IPCC's Fourth Assessment Report, in other words, failed to adequately simulate the basic characteristics of "one of the most pronounced signals of climate change" of the past century—as defined by its start date, severity and duration."

Wentz *et al.* (2007), in a study published in *Science*, noted that the Coupled Model Intercomparison Project, as well as various climate modeling analyses, predicted an increase in precipitation on the order of 1 to 3 percent per °C of surface global warming. They decided to see what had happened in the real world in this regard over the prior 19 years (1987-2006) of supposedly unprecedented global warming, when data from the Global Historical Climatology Network and satellite measurements of the lower troposphere indicated there had been a global temperature rise on the order of 0.20°C per decade.

Using satellite observations obtained from the Special Sensor Microwave Imager (SSM/I), the four Remote Sensing Systems scientists derived precipitation trends for the world's oceans over this period, and using data obtained from the Global Precipitation Climatology Project that were acquired from both satellite and rain gauge measurements, they derived precipitation trends for earth's continents.

Appropriately combining the results of these two endeavors, they derived a real-world increase in precipitation on the order of 7 percent per °C of surface global warming, which is somewhere between 2.3 and 7.0 times *larger* than what is predicted by state-of-the-art climate models.

How was this huge discrepancy to be resolved? Wentz *et al.* concluded that the only way to bring the two results into harmony was for there to have been a 19-year decline in global wind speeds. But when looking at the past 19 years of SSM/I wind retrievals, they found just the opposite, an *increase* in global wind speeds. In quantitative terms, the two results were about as opposite as they could possibly be, as they report that "when averaged over the tropics from 30°S to 30°N, the winds increased by 0.04 m s<sup>-1</sup> (0.6 percent) decade<sup>-1</sup>, and over all oceans the increase was 0.08 m s<sup>-1</sup> (1.0 percent) decade<sup>-1</sup>," while global coupled ocean-atmosphere models or GCMs, in their words, "predict that the 1987-to-2006 warming should have been accompanied by a decrease in winds on the order of 0.8 percent decade<sup>-1</sup>."

In discussing these results, Wentz *et al.* say "the reason for the discrepancy between the observational data and the GCMs is not clear." They also observe that this dramatic difference between the real world of nature and the virtual world of climate modeling "has enormous impact" and the questions raised by the discrepancy "are far from being settled."

Allan and Soden (2007) quantified trends in precipitation within ascending and descending branches of the planet's tropical circulation and compared their results with simulations of the present day and projections of future changes provided by up to 16 state-of-the-art climate models. The precipitation data for this analysis came from the Global Precipitation Climatology Project (GPCP) of Adler *et al.* (2003) and the Climate Prediction Center Merged Analysis of Precipitation (CMAP) data of Xie and Arkin (1998) for the period 1979-2006, while for the period 1987-2006 they came from the monthly mean intercalibrated Version 6 Special Sensor Microwave Imager (SSM/I) precipitation data described by Wentz *et al.* (2007).

The researchers reported "an emerging signal of rising precipitation trends in the ascending regions and decreasing trends in the descending regions are detected in the observational datasets," but that "these trends are substantially larger in magnitude than present-day simulations and projections into the 21st century," especially in the case of the descending regions. More specifically, for the tropics "the GPCP

trend is about 2-3 times larger than the model ensemble mean trend, consistent with previous findings (Wentz *et al.*, 2007) and also supported by the analysis of Yu and Weller (2007),” who additionally contend that “observed increases of evaporation over the ocean are substantially greater than those simulated by climate models.” What is more, Allan and Soden note that “observed precipitation changes over land also appear larger than model simulations over the 20th century (Zhang *et al.*, 2007).”

Noting that the difference between the models and real-world measurements “has important implications for future predictions of climate change,” Allan and Soden say “the discrepancy cannot be explained by changes in the reanalysis fields used to subsample the observations but instead must relate to errors in the satellite data or in the model parameterizations.” This same dilemma was also faced by Wentz *et al.* (2007); and they too stated that the resolution of the issue “has enormous impact” and likewise concluded that the questions raised by the discrepancy “are far from being settled.”

Lin (2007) states that “a good simulation of tropical mean climate by the climate models is a prerequisite for their good simulations/predictions of tropical variabilities and global teleconnections,” but “unfortunately, the tropical mean climate has not been well simulated by the coupled general circulation models (CGCMs) used for climate predictions and projections,” noting that “most of the CGCMs produce a double-intertropical convergence zone (ITCZ) pattern,” and acknowledging that “a synthetic view of the double-ITCZ problem is still elusive.”

To explore the nature of this problem in greater depth, and in hope of making some progress in resolving it, Lin analyzed tropical mean climate simulations of the 20-year period 1979-99 provided by 22 IPCC Fourth Assessment Report CGCMs, together with concurrent Atmospheric Model Intercomparison Project (AMIP) runs from 12 of them. This work revealed, in Lin’s words, that “most of the current state-of-the-art CGCMs have some degree of the double-ITCZ problem, which is characterized by excessive precipitation over much of the Tropics (e.g., Northern Hemisphere ITCZ, Southern Hemisphere SPCZ [South Pacific Convergence Zone], Maritime Continent, and equatorial Indian Ocean), and often associated with insufficient precipitation over the equatorial Pacific,” as well as “overly strong trade winds, excessive LHF [latent heat flux], and insufficient SWF [shortwave

flux], leading to significant cold SST (sea surface temperature) bias in much of the tropical oceans.”

The authors further note that “most of the models also simulate insufficient latitudinal asymmetry in precipitation and SST over the eastern Pacific and Atlantic Oceans,” and further, that “the AMIP runs also produce excessive precipitation over much of the Tropics including the equatorial Pacific, which also leads to overly strong trade winds, excessive LHF, and insufficient SWF,” which suggests that “the excessive tropical precipitation is an intrinsic error of the atmospheric models.” And if that is not enough, Lin adds that “over the eastern Pacific stratus region, most of the models produce insufficient stratus-SST feedback associated with insufficient sensitivity of stratus cloud amount to SST.”

With the solutions to all of these long-standing problems continuing to remain “elusive,” and with Lin suggesting that the sought-for solutions are in fact prerequisites for “good simulations/predictions” of future climate, there is significant reason to conclude that current state-of-the-art CGCM predictions of CO<sub>2</sub>-induced global warming should not be considered reliable.

In conclusion, in spite of the billions of dollars spent by the United States alone on developing and improving climate models, the models’ ability to correctly simulate even the largest and most regionally-important of earth’s atmospheric phenomena—the tropical Indian monsoon—hasn’t improved at all. The scientific literature is filled with studies documenting the inability of even the most advanced GCMs to accurately model radiation, clouds, and precipitation. Failure to model any one of these elements would be grounds for rejecting claims that the IPCC provides the evidence needed to justify regulation of anthropogenic greenhouse gas emissions.

## Feedback Factors and Radiative Forcing

---

### 2. Feedback Factors and Radiative Forcing

- 2.1. Clouds
- 2.2. Carbonyl Sulfide
- 2.3. Diffuse Light
- 2.4. Iodocompounds
- 2.5. Nitrous Oxide
- 2.6. Methane
- 2.7. Dimethyl Sulfide
- 2.8. Aerosols

### Introduction

According to the Intergovernmental Panel on Climate Change (IPCC), “the combined radiative forcing due to increases in carbon dioxide, methane, and nitrous oxide is +2.30 [+2.07 to +2.35] W m<sup>-2</sup>, and its rate of increase during the industrial era is *very likely* to have been unprecedented in more than 10,000 years [italics in the original]” (IPCC, 2007-I, p. 3). The IPCC calculates that this sensitivity of earth’s climate system to greenhouse gases (GHG) means that if CO<sub>2</sub> concentrations were to double, the rise in global average surface temperature “is *likely* to be in the range 2°C to 4.5°C with a best estimate of about 3°C, and is *very unlikely* to be less than 1.5°C [italics in the original]” (Ibid., p. 12).

Many scientific studies suggest this model-derived sensitivity is too large and feedbacks in the climate system reduce it to values that are an order of magnitude smaller. This chapter reviews those feedbacks most often mentioned in the scientific literature, some of which have the ability to totally offset the radiative forcing expected from the rise in atmospheric CO<sub>2</sub>.

### 2.1. Clouds

Based on data obtained from the Tropical Ocean Global Atmosphere—Coupled Ocean-Atmosphere Response Experiment, Sud *et al.* (1999) demonstrated that deep convection in the tropics acts as a thermostat to keep sea surface temperature (SST) oscillating between approximately 28° and 30°C. Their analysis suggests that as SSTs reach 28°-29°C, the cloud-base airmass is charged with the moist static energy needed for clouds to reach the upper troposphere, at which point the cloud cover reduces the amount of solar radiation received at the surface of the sea, while cool and dry downdrafts promote ocean surface cooling by increasing sensible and latent heat fluxes there. This “thermostat-like control,” as Sud *et al.* describe it, tends “to ventilate the tropical ocean efficiently and help contain the SST between 28°-30°C.” The phenomenon would

also be expected to prevent SSTs from rising any higher in response to enhanced CO<sub>2</sub>-induced radiative forcing.

Lindzen *et al.* (2001) used upper-level cloudiness data obtained from the Japanese Geostationary Meteorological Satellite and SST data obtained from the National Centers for Environmental Prediction to derive a strong inverse relationship between upper-level cloud area and the mean SST of cloudy regions of the eastern part of the western Pacific (30°S-30°N; 130°E-170°W), such that the area of cirrus cloud coverage normalized by a measure of the area of cumulus coverage decreases about 22 percent per degree C increase in the SST of the cloudy region. In describing this phenomenon, Lindzen *et al.* say “the cloudy-moist region appears to act as an infrared adaptive iris that opens up and closes down the regions free of upper-level clouds, which more effectively permit infrared cooling, in such a manner as to resist changes in tropical surface temperature.”

The findings of Lindzen *et al.* were subsequently criticized by Hartmann and Michelsen (2002) and Fu *et al.* (2002), and then Fu *et al.* were rebutted by Chou *et al.* (2002), an exchange that is summarized in Section 1.2 of this report. The debate over the infrared adaptive iris still rages in the scientific community, but Lindzen and his colleagues are not the only scientists who believe the cooling effect of clouds has been underestimated.

Croke *et al.* (1999) used land-based observations of cloud cover for three regions of the United States (coastal southwest, coastal northeast, and southern plains) to demonstrate that, over the period 1900-1987, cloud cover had a high correlation with global air temperature, with mean cloud cover rising from an initial value of 35 percent to a final value of 47 percent as the mean global air temperature rose by 0.5°C.

Herman *et al.* (2001) used Total Ozone Mapping Spectrometer 380-nm reflectivity data to determine changes in radiation reflected back to space over the period 1979 to 1992, finding that “when the 11.3-year solar-cycle and ENSO effects are removed from the time series, the zonally averaged annual linear-fit trends show that there have been increases in reflectivity (cloudiness) poleward of 40°N and 30°S, with some smaller but significant changes occurring in the equatorial and lower middle latitudes.” The overall long-term effect was an increase in radiation reflected back to space of 2.8 Wm<sup>-2</sup> per decade, which represents a large cloud-induced cooling influence.

Rosenfeld (2000) used satellite data obtained from the Tropical Rainfall Measuring Mission to look for terrestrial analogues of the cloud trails that form in the wakes of ships at sea as a consequence of their emissions of particulates that redistribute cloud-water into larger numbers of smaller droplets that do not rain out of the atmosphere as readily as they would in the absence of this phenomenon. Visualizations produced from the mission data clearly revealed the existence of enhanced cloud trails downwind of urban and industrial complexes in Turkey, Canada, and Australia, to which Rosenfeld gave the name *pollution tracks* in view of their similarity to *ship tracks*. Rosenfeld also demonstrated that the clouds comprising these pollution tracks were composed of droplets of reduced size that did indeed suppress precipitation by inhibiting further coalescence and ice precipitation formation. As Toon (2000) noted in a commentary on this study, these smaller droplets will not “rain out” as quickly and will therefore last longer and cover more of the earth, both of which effects tend to cool the globe.

In summation, as the earth warms, the atmosphere has a tendency to become more cloudy, which exerts a natural brake upon the rising temperature. Many of man’s aerosol-producing activities tend to do the same thing. Hence, there appear to be a number of cloud-mediated processes that help the planet “keep its cool.”

## 2.2. Carbonyl Sulfide

Some time ago, Idso (1990) suggested that the volatilization of reduced sulfur gases from earth's soils may be just as important as dimethyl sulfide (DMS) emissions from the world's oceans in enhancing cloud albedo and thereby cooling the planet and providing a natural brake on the tendency for anthropogenically enhanced greenhouse gases to drive global warming. (See Section 2.7.) On the basis of experiments that showed soil DMS emissions to be positively correlated with soil organic matter content, and noting that additions of organic matter to soils tend to increase the amount of sulfur gases they emit, Idso hypothesized that because atmospheric CO<sub>2</sub> enrichment augments plant growth and, as a result, vegetative inputs of organic matter to earth's soils, this phenomenon should produce an impetus for cooling, even in the absence of the surface warming that sets in motion the chain of events that produce the oceanic DMS-induced negative feedback that tends to cool the planet.

Two years later, Idso (1992) expanded this concept to include carbonyl sulfide (OCS), another biologically produced sulfur gas that is emitted from soils, noting that it too is likely to be emitted in increasingly greater quantities as earth's vegetation responds to the aerial fertilization effect of the ongoing rise in the air's CO<sub>2</sub> content, while pointing out that OCS is relatively inert in the troposphere, but that it eventually makes its way into the stratosphere, where it is transformed into solar-radiation-reflecting sulfate aerosol particles. He consequently concluded that the CO<sub>2</sub>-induced augmentation of soil OCS emissions constitutes a mechanism that can cool the

planet's surface (1) in the absence of an impetus for warming, (2) without producing additional clouds or (3) making them any brighter.

What have we subsequently learned about biologically mediated increases in carbonyl sulfide emissions? One important thing is that the OCS-induced cooling mechanism also operates at sea, just as the DMS-induced cooling mechanism does, and that it too possesses a warming-induced component in addition to its CO<sub>2</sub>-induced component.

In a study contemporary with that of Idso (1992), ocean-surface OCS concentrations were demonstrated by Andreae and Ferek (1992) to be highly correlated with surface-water primary productivity. So strong is this correlation, in fact, that Erickson and Eaton (1993) developed an empirical model for computing ocean-surface OCS concentrations based solely on surface-water chlorophyll concentrations and values of incoming solar radiation. It has also been learned that an even greater portion of naturally produced OCS is created in the atmosphere, where carbon disulfide and dimethyl sulfide—also largely of oceanic origin (Aydin *et al.*, 2002)—undergo photochemical oxidation (Khalil and Rasmussen, 1984; Barnes *et al.*, 1994). Hence, the majority of the tropospheric burden of OCS is ultimately dependent upon photosynthetic activity occurring near the surface of the world's oceans.

This is important because the tropospheric OCS concentration has risen by approximately 30 percent since the 1600s, from a mean value of 373 ppt over the period 1616-1694 to something on the order of 485 ppt today. This is a sizeable increase; and Aydin *et al.* (2002) note that only a fourth of it can be attributed to anthropogenic sources. Consequently, the rest of the observed OCS increase must have had a natural origin, a large portion of which must have ultimately been derived from the products and byproducts of marine photosynthetic activity, which must have increased substantially over the past three centuries. A solid case can be made for the proposition that both the increase in atmospheric CO<sub>2</sub> concentration and the increase in temperature experienced over this period were the driving forces for the concomitant increase in tropospheric OCS concentration and its likely subsequent transport to the stratosphere, where it could exert a cooling influence on the earth and that may have kept the warming of the globe considerably below what it might otherwise have been in the absence of this chain of events.

Another fascinating aspect of this multifaceted global “biothermostat” was revealed in a laboratory study of samples of the lichen *Ramalina menziesii*, which were collected from an open oak woodland in central California, USA, by Kuhn and Kesselmeier (2000). They found that when the lichens were optimally hydrated, they absorbed OCS from the air at a rate that gradually doubled as air temperature rose from approximately 3° to 25°C, whereupon their rate of OCS absorption began a precipitous decline that led to zero OCS absorption at 35°C.

The first portion of this response can be explained by the fact that most terrestrial plants prefer much warmer temperatures than a mere 3°C, so that as their surroundings warm and they grow better, they extract more OCS from the atmosphere in an attempt to promote even more warming and grow better still. At the point where warming becomes a detriment to them, however, they reverse this course of action and begin to rapidly reduce their rates of OCS absorption in an attempt to forestall warming-induced death. And since the consumption of OCS by lichens is under the physiological control of carbonic anhydrase—which is the key enzyme for OCS uptake in all higher plants, algae, and soil organisms—we could expect this phenomenon to be generally operative over most of the earth. Hence, this thermoregulatory function of the biosphere may well be powerful enough to define an upper limit above which the surface air temperature of the planet may be restricted from rising, even when changes in other forcing factors, such as increases in greenhouse gas concentrations, produce an impetus for it to do so.

Clearly, this multifaceted phenomenon is extremely complex, with different biological entities tending to both increase and decrease atmospheric OCS concentrations at one and the same time, while periodically reversing directions in this regard in response to climate changes that push the temperatures of their respective environments either above or below the various thermal optima at which they function best. This being the case, there is obviously much more we need to learn about the many plant physiological mechanisms that may be involved.

State-of-the-art climate models totally neglect the biological processes we have described here. Until we fully understand the ultimate impact of the OCS cycle on climate, and then incorporate them into the climate models, we cannot be certain how much of the warming experienced during the twentieth century, if any, can be attributed to anthropogenic causes.

Additional information on this topic, including reviews of newer publications as they become available, can be found at <http://www.co2science.org/subject/c/carbonylsulfide.php>.

## 2.3. Diffuse Light

The next negative feedback phenomenon is diffused light. It operates through a chain of five linkages, triggered by the incremental enhancement of the atmosphere's greenhouse effect that is produced by an increase in the air's CO<sub>2</sub> content. The first linkage is the proven propensity for higher levels of atmospheric CO<sub>2</sub> to enhance vegetative productivity, which phenomena are themselves powerful negative feedback mechanisms of the type we envision. Greater CO<sub>2</sub>-enhanced photosynthetic rates, for

example, enable plants to remove considerably more CO<sub>2</sub> from the air than they do under current conditions, while CO<sub>2</sub>-induced increases in plant water use efficiency allow plants to grow where it was previously too dry for them. (See Chapter 7 for extensive documentation of this phenomenon.) This establishes a potential for more CO<sub>2</sub> to be removed from the atmosphere by increasing the abundance of earth's plants and increasing their robustness.

The second linkage of the feedback loop is the ability of plants to emit gases to the atmosphere that are ultimately converted into "biosols," i.e., aerosols that owe their existence to the biological activities of earth's vegetation, many of which function as cloud condensation nuclei. It takes little imagination to realize that since the existence of these atmospheric particles is dependent upon the physiological activities of plants and their associated soil biota, the CO<sub>2</sub>-induced presence of more, and more-highly-productive, plants will lead to the production of more of these cloud-mediating particles, which can then result in more clouds which reflect sunlight and act to cool the planet.

The third linkage is the observed propensity for increases in aerosols and cloud particles to enhance the amount of diffuse solar radiation reaching the earth's surface. The fourth linkage is the ability of enhanced diffuse lighting to reduce the volume of shade within vegetative canopies. The fifth linkage is the tendency for less internal canopy shading to enhance whole-canopy photosynthesis, which finally produces the end result: a greater biological extraction of CO<sub>2</sub> from the air and the subsequent sequestration of its carbon, compliments of the intensified diffuse-light-driven increase in total canopy photosynthesis and subsequent transfers of the extra fixed carbon to plant and soil storage reservoirs.

How significant is this multi-link process? Roderick *et al.* (2001) provide a good estimate based on the utilization of a unique "natural experiment," a technique that has been used extensively by Idso (1998) to evaluate the climatic sensitivity of the entire planet. Specifically, Roderick and his colleagues considered the volcanic eruption of Mt. Pinatubo in June 1991, which ejected enough gases and fine materials into the atmosphere to produce sufficient aerosol particles to greatly increase the diffuse component of the solar radiation reaching the surface of the earth from that point in time through much of 1993, while only slightly reducing the receipt of total solar radiation. Based on a set of lengthy calculations, they concluded that the Mt. Pinatubo eruption may

well have resulted in the removal of an extra 2.5 Gt of carbon from the atmosphere due to its diffuse-light-enhancing stimulation of terrestrial vegetation in the year following the eruption, which would have reduced the ongoing rise in the air's CO<sub>2</sub> concentration that year by about 1.2 ppm.

Interestingly, this reduction is about the magnitude of the real-world perturbation that was actually observed (Sarmiento, 1993). What makes this observation even more impressive is the fact that the CO<sub>2</sub> reduction was coincident with an El Niño event; because, in the words of Roderick *et al.*, "previous and subsequent such events have been associated with *increases* in atmospheric CO<sub>2</sub>." In addition, the observed reduction in total solar radiation received at the earth's surface during this period would have had a tendency to reduce the amount of photosynthetically active radiation incident upon earth's plants, which would also have had a tendency to cause the air's CO<sub>2</sub> content to rise, as it would tend to lessen global photosynthetic activity.

Significant support for the new negative feedback phenomenon was swift in coming, as the very next year a team of 33 researchers published the results of a comprehensive study (Law *et al.*, 2002) that compared seasonal and annual values of CO<sub>2</sub> and water vapor exchange across sites in forests, grasslands, crops and tundra—which are part of an international network called FLUXNET—investigating the responses of these exchanges to variations in a number of environmental factors, including direct and diffuse solar radiation. The researchers reported that "net carbon uptake (net ecosystem exchange, the net of photosynthesis and respiration) was greater under diffuse than under direct radiation conditions," and in discussing this finding, which is the centerpiece of the negative feedback phenomenon we describe, they noted that "cloud-cover results in a greater proportion of diffuse radiation and constitutes a higher fraction of light penetrating to lower depths of the canopy (Oechel and Lawrence, 1985)." More importantly, they also reported that "Goulden *et al.* (1997), Fitzjarrald *et al.* (1995), and Sakai *et al.* (1996) showed that net carbon uptake was consistently higher during cloudy periods in a boreal coniferous forest than during sunny periods with the same PPFD [photosynthetic photon flux density]." In fact, they wrote that "Hollinger *et al.* (1994) found that daily net CO<sub>2</sub> uptake was greater on cloudy days, even though total PPFD was 21-45 percent lower on cloudy days than on clear days."

One year later, Gu *et al.* (2003) reported that they “used two independent and direct methods to examine the photosynthetic response of a northern hardwood forest (Harvard Forest, 42.5°N, 72.2°W) to changes in diffuse radiation caused by Mount Pinatubo’s volcanic aerosols,” finding that in the eruption year of 1991, “around noontime in the mid-growing season, the gross photosynthetic rate under the perturbed cloudless solar radiation regime was 23, 8, and 4 percent higher than that under the normal cloudless solar radiation regime in 1992, 1993, and 1994, respectively,” and that “integrated over a day, the enhancement for canopy gross photosynthesis by the volcanic aerosols was 21 percent in 1992, 6 percent in 1993 and 3 percent in 1994.” Commenting on the significance of these observations, Gu *et al.* noted that “because of substantial increases in diffuse radiation world-wide after the eruption and strong positive effects of diffuse radiation for a variety of vegetation types, it is likely that our findings at Harvard Forest represent a global phenomenon.”

In the preceding paragraph, we highlighted the fact that the diffuse-light-induced photosynthetic enhancement observed by Gu *et al.*, in addition to likely being global in scope, was caused by volcanic aerosols acting under cloudless conditions. Our reason for calling attention to these two facts is to clearly distinguish this phenomenon from a closely related one that is also described by Gu *et al.*; i.e., the propensity for the extra diffuse light created by increased cloud cover to further enhance photosynthesis, even though the total flux of solar radiation received at the earth’s surface may be reduced under such conditions. Based on still more real-world data, for example, Gu *et al.* note that “Harvard Forest photosynthesis also increases with cloud cover, with a peak at about 50 percent cloud cover.”

Although very impressive, in all of the situations discussed above the source of the enhanced atmospheric aerosol concentration was a singular significant event—specifically, a massive volcanic eruption—but what we really need to know is what happens under more normal conditions. This was the new and important question addressed the following year in the study of Niyogi *et al.* (2004): “Can we detect the effect of relatively routine aerosol variability on field measurements of CO<sub>2</sub> fluxes, and if so, how does the variability in aerosol loading affect CO<sub>2</sub> fluxes over different landscapes?”

To answer this question, the group of 16 researchers used CO<sub>2</sub> flux data from the AmeriFlux

network (Baldocchi *et al.*, 2001) together with cloud-free aerosol optical depth data from the NASA Robotic Network (AERONET; Holben *et al.*, 2001) to assess the effect of aerosol loading on the net assimilation of CO<sub>2</sub> by three types of vegetation: trees (broadleaf deciduous forest and mixed forest), crops (winter wheat, soybeans, and corn), and grasslands. Their work revealed that an aerosol-induced increase in diffuse radiative-flux fraction [DRF = ratio of diffuse (R<sub>d</sub>) to total or global (R<sub>g</sub>) solar irradiance] increased the net CO<sub>2</sub> assimilation of trees and crops, making them larger carbon sinks, but that it decreased the net CO<sub>2</sub> assimilation of grasslands, making them smaller carbon sinks.

How significant were the effects observed by Niyogi *et al.*? For a summer mid-range R<sub>g</sub> flux of 500 Wm<sup>-2</sup>, going from the set of all DRF values between 0.0 and 0.4 to the set of all DRF values between 0.6 and 1.0 resulted in an approximate 50 percent increase in net CO<sub>2</sub> assimilation by a broadleaf deciduous forest located in Tennessee, USA. Averaged over the entire daylight period, they further determined that the shift from the lower to the higher set of DRF values “enhances photosynthetic fluxes by about 30 percent at this study site.” Similar results were obtained for the mixed forest and the conglomerate of crops studied. Hence, they concluded that natural variability among commonly present aerosols can “routinely influence surface irradiance and hence the terrestrial CO<sub>2</sub> flux and regional carbon cycle.” And for these types of land-cover (forests and agricultural crops), that influence is to significantly increase the assimilation of CO<sub>2</sub> from the atmosphere.

In the case of grasslands, however, the effect was found to be just the opposite, with greater aerosol loading of the atmosphere leading to less CO<sub>2</sub> assimilation, due most likely, in the estimation of Niyogi *et al.*, to grasslands’ significantly different canopy architecture. With respect to the planet as a whole, however, the net effect is decidedly positive, as earth’s trees are the primary planetary players in the sequestration of carbon. Post *et al.* (1990), for example, noted that woody plants account for approximately 75 percent of terrestrial photosynthesis, which comprises about 90 percent of the global total (Sellers and McCarthy, 1990); those numbers make earth’s trees and shrubs responsible for fully two-thirds (0.75 x 90 percent = 67.5 percent) of the planet’s net primary production.

What is especially exciting about these real-world observations is that much of the commonly-present aerosol burden of the atmosphere is plant-derived.

Hence, it can be appreciated that earth's woody plants are themselves responsible for emitting to the air that which ultimately enhances their own photosynthetic prowess. In other words, earth's trees significantly control their own destiny; i.e., they alter the atmospheric environment in a way that directly enhances their opportunities for greater growth.

Society helps too, in this regard, for as we pump ever more CO<sub>2</sub> into the atmosphere, the globe's woody plants quickly respond to its aerial fertilization effect, becoming ever more productive, which leads to even more plant-derived aerosols being released to the atmosphere, which stimulates this positive feedback cycle to a still greater degree. Stated another way, earth's trees use some of the CO<sub>2</sub> emitted to the atmosphere by society to alter the aerial environment so as to enable them to remove even more CO<sub>2</sub> from the air. The end result is that earth's trees and humanity are working hand-in-hand to significantly increase the productivity of the biosphere. This is happening in spite of all other insults to the environment that work in opposition to enhanced biological activity.

In light of these several observations, it is clear that the historical and still-ongoing CO<sub>2</sub>-induced increase in atmospheric biosols should have had, and should be continuing to have, a significant cooling effect on the planet that exerts itself by both slowing the rate of rise of the air's CO<sub>2</sub> content and reducing the receipt of solar radiation at the earth's surface. Neither of these effects is fully and adequately included in any general circulation model of the atmosphere of which we are aware.

## 2.4. Iodocompounds

The climatic significance of iodinated compounds or iodocompounds was first described in the pages of *Nature* by O'Dowd *et al.* (2002). As related by Kolb (2002) in an accompanying perspective on their work, the 10-member research team discovered “a previously unrecognized source of aerosol particles” by unraveling “a photochemical phenomenon that occurs in sea air and produces aerosol particles composed largely of iodine oxides.” Specifically, the team used a smog chamber operated under coastal atmospheric conditions to demonstrate, as they report, that “new particles can form from condensable iodine-containing vapors, which are the photolysis products of biogenic iodocarbons emitted from marine algae.” With the help of aerosol formation models, they also demonstrated that concentrations of condensable iodine-containing vapors over the open ocean “are sufficient to influence marine particle formation.”

The significance of this work is that the aerosol particles O'Dowd *et al.* discovered can function as cloud condensation nuclei (CCN), helping to create new clouds that reflect more incoming solar radiation back to space and thereby cool the planet (a negative feedback). With respect to the negative feedback nature of this phenomenon, O'Dowd *et al.* cite the work of Laturus *et al.* (2000), which demonstrates that emissions of iodocarbons from marine biota “can increase by up to 5 times as a result of changes in

environmental conditions associated with global change.” Therefore, as O'Dowd *et al.* continue, “increasing the source rate of condensable iodine vapors will result in an increase in marine aerosol and CCN concentrations of the order of 20—60 percent.” Furthermore, they note that “changes in cloud albedo resulting from changes in CCN concentrations of this magnitude can lead to an increase in global radiative forcing similar in magnitude, but opposite in sign, to the forcing induced by greenhouse gases.”

Four years later, Smythe-Wright *et al.* (2006) measured trace gas and pigment concentrations in seawater, while identifying and enumerating picophytoprokaroyotes during two ship cruises in the Atlantic Ocean and one in the Indian Ocean, where they focused “on methyl iodide production and the importance of a biologically related source.” In doing so, they encountered methyl iodide concentrations as great as 45 pmol per liter in the top 150 meters of the oceanic water column that correlated well with the abundance of *Prochlorococcus*, which they report “can account for >80 percent of the variability in the methyl iodide concentrations.” They add that they “have confirmed the release of methyl iodide by this species in laboratory culture experiments.”

Extrapolating their findings to the globe as a whole, the six researchers “estimate the global ocean flux of iodine [I] to the marine boundary layer from this single source to be  $5.3 \times 10^{11}$  g I year<sup>-1</sup>,” which they say “is a large fraction of the total estimated global flux of iodine ( $10^{11}$ - $10^{12}$  g I year<sup>-1</sup>).” This observation is extremely important, because volatile iodinated compounds, in Smythe-Wright *et al.*'s words, “play a part in the formation of new particles and cloud condensation nuclei (CCN),” and because “an increase in the production of iodocompounds and the subsequent production of CCN would potentially result in a net cooling of the earth system and hence in a negative climate feedback mechanism, mitigating global warming.” More specifically, they suggest that “as ocean waters become warmer and more stratified, nutrient concentrations will fall and there will likely be a regime shift away from microalgae toward *Prochlorococcus*,” such that “colonization within the <50° latitude band will result in a ~15 percent increase in the release of iodine to the atmosphere,” with consequent “important implications for global climate change,” which, as previously noted, tend to counteract global warming.

Most recently, as part of the Third Pelagic Ecosystem CO<sub>2</sub> Enrichment Study, Wingenter *et al.* (2007) investigated the effects of atmospheric CO<sub>2</sub>

enrichment on marine microorganisms in nine marine mesocosms maintained within two-meter-diameter polyethylene bags submerged to a depth of 10 meters in a fjord at the Large-Scale Facilities of the Biological Station of the University of Bergen in Espesgrend, Norway. Three of these mesocosms were maintained at ambient levels of CO<sub>2</sub> (~375 ppm or base CO<sub>2</sub>), three were maintained at levels expected to prevail at the end of the current century (760 ppm or 2xCO<sub>2</sub>), and three were maintained at levels predicted for the middle of the next century (1150 ppm or 3xCO<sub>2</sub>). During the 25 days of this experiment, the researchers followed the development and subsequent decline of an induced bloom of the coccolithophorid *Emiliana huxleyi*, carefully measuring several physical, chemical, and biological parameters along the way. This work revealed that the iodocarbon chloriodomethane (CH<sub>2</sub>CII) experienced its peak concentration about six to 10 days after the coccolithophorid's chlorophyll-a maximum, and that its estimated abundance was 46 percent higher in the 2xCO<sub>2</sub> mesocosms and 131 percent higher in the 3xCO<sub>2</sub> mesocosms.

The international team of scientists concluded that the differences in the CH<sub>2</sub>CII concentrations “may be viewed as a result of changes to the ecosystems as a whole brought on by the CO<sub>2</sub> perturbations.” And because emissions of various iodocarbons have been found to lead to an enhancement of cloud condensation nuclei in the marine atmosphere, as demonstrated by O’Dowd *et al.* (2002) and Jimenez *et al.* (2003), it can be appreciated that the CO<sub>2</sub>-induced stimulation of the marine emissions of these substances provides a natural brake on the tendency for global warming to occur as a consequence of any forcing, as iodocarbons lead to the creation of more highly reflective clouds over greater areas of the world’s oceans.

In conclusion, as Wingenter *et al.* sum things up, the processes described above “may help contribute to the homeostasis of the planet.” And the finding of O’Dowd *et al.* that changes in cloud albedo “associated with global change” can lead to an increase in global radiative forcing that is “similar in magnitude, but opposite in sign, to the forcing induced by greenhouse gases,” suggests that CO<sub>2</sub>-induced increases in marine iodocarbon emissions likely contribute to maintaining that homeostasis.

Additional information on this topic, including reviews of newer publications as they become available, can be found at <http://www.co2science.org/subject/f/feedbackiodo.php>.

## 2.5. Nitrous Oxide

One of the main sources of nitrous oxide (N<sub>2</sub>O) is agriculture, which accounts for almost half of N<sub>2</sub>O emissions in some countries (Pipatti, 1997). With N<sub>2</sub>O originating from microbial N cycling in soil—mostly from aerobic nitrification or from anaerobic denitrification (Firestone and Davidson, 1989)—there is a concern that CO<sub>2</sub>-induced increases in carbon input to soil, together with increasing N input from other sources, will increase substrate availability for denitrifying bacteria and may result in higher N<sub>2</sub>O emissions from agricultural soils as the air’s CO<sub>2</sub> content continues to rise.

In a study designed to investigate this possibility, Kettunen *et al.* (2007a) grew mixed stands of timothy (*Phleum pratense*) and red clover (*Trifolium pratense*) in sandy-loam-filled mesocosms at low and

moderate soil nitrogen levels within greenhouses maintained at either 360 or 720 ppm CO<sub>2</sub>, while measuring harvestable biomass production and N<sub>2</sub>O evolution from the mesocosm soils over the course of three crop cuttings. This work revealed that the total harvestable biomass production of *P. pratense* was enhanced by the experimental doubling of the air's CO<sub>2</sub> concentration by 21 percent and 26 percent, respectively, in the low and moderate soil N treatments, while corresponding biomass enhancements for *T. pratense* were 22 percent and 18 percent. In addition, the researchers found that after emergence of the mixed stand and during vegetative growth before the first harvest and N fertilization, N<sub>2</sub>O fluxes were higher under ambient CO<sub>2</sub> in both the low and moderate soil N treatments. In fact, it was not until the water table had been raised and extra fertilization given after the first harvest that the elevated CO<sub>2</sub> seemed to increase N<sub>2</sub>O fluxes. The four Finnish researchers thus concluded that the mixed stand of *P. pratense* and *T. pratense* was “able to utilize the increased supply of atmospheric CO<sub>2</sub> for enhanced biomass production without a simultaneous increase in the N<sub>2</sub>O fluxes,” thereby raising “the possibility of maintaining N<sub>2</sub>O emissions at their current level, while still enhancing the yield production [via the aerial fertilization effect of elevated CO<sub>2</sub>] even under low N fertilizer additions.”

In a similar study, Kettunen *et al.* (2007b) grew timothy (*Phleum pratense*) in monoculture within sandy-soil-filled mesocosms located within greenhouses maintained at atmospheric CO<sub>2</sub> concentrations of either 360 or 720 ppm for a period of 3.5 months at moderate (standard), low (half-standard), and high (1.5 times standard) soil N supply, while they measured the evolution of N<sub>2</sub>O from the mesocosms, vegetative net CO<sub>2</sub> exchange, and final above- and below-ground biomass production over the course of three harvests. In this experiment the elevated CO<sub>2</sub> concentration increased the net CO<sub>2</sub> exchange of the ecosystems (which phenomenon was primarily driven by CO<sub>2</sub>-induced increases in photosynthesis) by about 30 percent, 46 percent and 34 percent at the low, moderate, and high soil N levels, respectively, while it increased the above-ground biomass of the crop by about 8 percent, 14 percent, and 8 percent at the low, moderate and high soil N levels, and its below-ground biomass by 28 percent, 27 percent, and 41 percent at the same respective soil N levels. And once again, Kettunen *et al.* report that “an explicit increase in N<sub>2</sub>O fluxes due

to the elevated atmospheric CO<sub>2</sub> concentration was not found.”

Welzmler *et al.* (2008) measured N<sub>2</sub>O and denitrification emission rates in a C<sub>4</sub> sorghum [*Sorghum bicolor* (L.) Moench] production system with ample and limited flood irrigation rates under Free-Air CO<sub>2</sub> Enrichment (seasonal mean = 579 ppm) and control (seasonal mean = 396 ppm) CO<sub>2</sub> during the 1998 and 1999 summer growing seasons at the experimental FACE site near Maricopa, Arizona (USA). The study found “elevated CO<sub>2</sub> did not result in increased N<sub>2</sub>O or N-gas emissions with either ample or limited irrigation,” which findings they describe as being “consistent with findings for unirrigated western U.S. ecosystems reported by Billings *et al.* (2002) for Mojave Desert soils and by Mosier *et al.* (2002) for Colorado shortgrass steppe.”

In discussing the implications of their findings, Welzmler *et al.* say their results suggest that “as CO<sub>2</sub> concentrations increase, there will not be major increases in denitrification in C<sub>4</sub> cropping environments such as irrigated sorghum in the desert southwestern United States,” which further suggests there will not be an increased impetus for global warming due to this phenomenon.

In a different type of study—driven by the possibility that the climate of the Amazon Basin may gradually become drier due to a warming-induced increase in the frequency and/or intensity of El Niño events that have historically brought severe drought to the region—Davidson *et al.* (2004) devised an experiment to determine the consequences of the drying of the soil of an Amazonian moist tropical forest for the net surface-to-air fluxes of both N<sub>2</sub>O and methane (CH<sub>4</sub>). This they did in the Tapajos National Forest near Santarem, Brazil, by modifying a one-hectare plot of land covered by mature evergreen trees so as to dramatically reduce the amount of rain that reached the forest floor (throughfall), while maintaining an otherwise similar one-hectare plot of land as a control for comparison.

Prior to making this modification, the three researchers measured the gas exchange characteristics of the two plots for a period of 18 months; then, after initiating the throughfall-exclusion treatment, they continued their measurements for an additional three years. This work revealed that the “drier soil conditions caused by throughfall exclusion inhibited N<sub>2</sub>O and CH<sub>4</sub> production and promoted CH<sub>4</sub> consumption.” In fact, they report that “the exclusion manipulation lowered annual N<sub>2</sub>O emissions by >40 percent and increased rates of consumption of

atmospheric CH<sub>4</sub> by a factor of >4,” which results they attributed to the “direct effect of soil aeration on denitrification, methanogenesis, and methanotrophy.”

Consequently, if global warming would indeed increase the frequency and/or intensity of El Niño events as some claim it will, the results of this study suggest that the anticipated drying of the Amazon Basin would initiate a strong negative feedback via (1) large drying-induced reductions in the evolution of both N<sub>2</sub>O and CH<sub>4</sub> from its soils, and (2) a huge drying-induced increase in the consumption of CH<sub>4</sub> by its soils. Although Davidson *et al.* envisage a more extreme second phase response “in which drought-induced plant mortality is followed by increased mineralization of C and N substrates from dead fine roots and by increased foraging of termites on dead coarse roots” (an extreme response that would be expected to increase N<sub>2</sub>O and CH<sub>4</sub> emissions), we note that the projected rise in the air’s CO<sub>2</sub> content would likely prohibit such a thing from ever occurring, due to the documented tendency for atmospheric CO<sub>2</sub> enrichment to greatly increase the water use efficiency of essentially all plants, which would enable the forest to continue to flourish under significantly drier conditions than those of the present.

In summation, it would appear that concerns about additional global warming arising from enhanced N<sub>2</sub>O emissions from agricultural soils in a CO<sub>2</sub>-enriched atmosphere of the future are not well founded.

Additional information on this topic, including reviews of newer publications as they become available, can be found at <http://www.co2science.org/subject/n/nitrousoxide.php>

## 2.6. Methane

What impact do global warming, the ongoing rise in the air’s carbon dioxide (CO<sub>2</sub>) content and a number of other contemporary environmental trends have on the atmosphere’s methane (CH<sub>4</sub>) concentration? The implications of this question are huge because methane is a more powerful greenhouse gas, molecule for molecule, than is carbon dioxide. Its atmospheric concentration is determined by the difference between how much CH<sub>4</sub> goes into the air (emissions) and how much comes out of it (extractions) over the same time period. There are significant forces at play that will likely produce a large negative feedback toward the future warming potential of this powerful greenhouse gas, nearly all of which forces are ignored by the IPCC.

### 2.6.1. Extraction

Early indications that atmospheric CO<sub>2</sub> enrichment might significantly reduce methane emissions associated with the production of rice were provided by Schrope *et al.* (1999), who studied batches of rice growing in large vats filled with topsoil and placed within greenhouse tunnels maintained at atmospheric CO<sub>2</sub> concentrations of 350 and 700 ppm, each of

which tunnels was further subdivided into four sections that provided temperature treatments ranging from ambient to as much as 5°C above ambient. As would be expected, doubling the air's CO<sub>2</sub> content significantly enhanced rice biomass production in this system, increasing it by up to 35 percent above-ground and by up to 83 percent below-ground. However, in a truly unanticipated development, methane emissions from the rice grown at 700 ppm CO<sub>2</sub> were found to be 10 to 45 times less than emissions from the plants grown at 350 ppm. As Schroppe *et al.* describe it, "the results of this study did not support our hypothesis that an effect of both increased carbon dioxide and temperature would be an increase in methane emissions." Indeed, they report that "both increased carbon dioxide and increased temperatures were observed to produce decreased methane emissions," except for the first 2°C increase above ambient, which produced a slight increase in methane evolution from the plant-soil system.

In checking for potential problems with their experiment, Schroppe *et al.* could find none. They thus stated that their results "unequivocally support the conclusion that, during this study, methane emissions from *Oryza sativa* [rice] plants grown under conditions of elevated CO<sub>2</sub> were dramatically reduced relative to plants grown in comparable conditions under ambient levels of CO<sub>2</sub>," and to be doubly sure of this fact, they went on to replicate their experiment in a second year of sampling and obtained essentially the same results. Four years later, however, a study of the same phenomenon by a different set of scientists yielded a different result in a different set of circumstances.

Inubushi *et al.* (2003) grew a different cultivar of rice in 1999 and 2000 in paddy culture at Shizukuishi, Iwate, Japan in a FACE study where the air's CO<sub>2</sub> concentration was increased 200 ppm above ambient. They found that the extra CO<sub>2</sub> "significantly increased the CH<sub>4</sub> [methane] emissions by 38 percent in 1999 and 51 percent in 2000," which phenomenon they attributed to "accelerated CH<sub>4</sub> production as a result of increased root exudates and root autolysis products and to the increased plant-mediated CH<sub>4</sub> emission because of the higher rice tiller numbers under FACE conditions." With such a dramatically different result from that of Schroppe *et al.*, many more studies likely will be required to determine which of these results is the more typical of rice culture around the world.

A somewhat related study was conducted by Kruger and Frenzel (2003), who note that "rice paddies contribute approximately 10-13 percent to the global CH<sub>4</sub> emission (Neue, 1997; Crutzen and Lelieveld, 2001)," and that "during the next 30 years rice production has to be increased by at least 60 percent to meet the demands of the growing human population (Cassman *et al.*, 1998)." Because of these facts they further note that "increasing amounts of fertilizer will have to be applied to maximize yields [and] there is ongoing discussion on the possible effects of fertilization on CH<sub>4</sub> emissions."

To help promote that discussion, Kruger and Frenzel investigated the effects of N-fertilizer (urea) on CH<sub>4</sub> emission, production, and oxidation in rice culture in laboratory, microcosm and field experiments they conducted at the Italian Rice Research Institute in northern Italy. They report that in some prior studies "N-fertilisation stimulated CH<sub>4</sub> emissions (Cicerone and Shetter, 1981; Banik *et al.*, 1996; Singh *et al.*, 1996)," while "methanogenesis and CH<sub>4</sub> emission was found to be inhibited in others (Cai *et al.*, 1997; Schutz *et al.*, 1989; Lindau *et al.*, 1990)," similar to the polarized findings of Schroppe *et al.* and Inubushi *et al.* with respect to the effects of elevated CO<sub>2</sub> on methane emissions. In the mean, therefore, there may well be little to no change in overall CH<sub>4</sub> emissions from rice fields in response to both elevated CO<sub>2</sub> and increased N-fertilization. With respect to their own study, for example, Kruger and Frenzel say that "combining our field, microcosm and laboratory experiments we conclude that any agricultural praxis improving the N-supply to the rice plants will also be favourable for the CH<sub>4</sub> oxidising bacteria," noting that "N-fertilisation had only a transient influence and was counter-balanced in the field by an elevated CH<sub>4</sub> production." The implication of these findings is well articulated in the concluding sentence of their paper: "neither positive nor negative consequences for the overall global warming potential could be found."

Another agricultural source of methane is the fermentation of feed in the rumen of cattle and sheep. Fievez *et al.* (2003) studied the effects of various types and levels of fish-oil feed additives on this process by means of both *in vitro* and *in vivo* experiments with sheep, observing a maximal 80 percent decline in the ruminants' production of methane when using fish-oil additives containing n-3-eicosapentanoic acid. With respect to cattle, Boadi *et al.* (2004) report that existing mitigation strategies for reducing CH<sub>4</sub> emissions from dairy cows include the

addition of ionophores and fats to their food, as well as the use of high-quality forages and grains in their diet, while newer mitigation strategies include “the addition of probiotics, acetogens, bacteriocins, archaeal viruses, organic acids, [and] plant extracts (e.g., essential oils) to the diet, as well as immunization, and genetic selection of cows.” To this end, they provide a table of 20 such strategies, where the average maximum potential CH<sub>4</sub> reduction that may result from the implementation of each strategy is 30 percent or more.

With as many as 20 different mitigation strategies from which to choose, each one of which (on average) has the potential to reduce CH<sub>4</sub> emissions from dairy cows by as much as a third, it would appear there is a tremendous potential to dramatically curtail the amount of CH<sub>4</sub> released to the atmosphere by these ruminants and, by implication, the host of other ruminants that mankind raises and uses for various purposes around the world. Such high-efficiency approaches to reducing the strength of the atmosphere’s greenhouse effect, while not reducing the biological benefits of elevated atmospheric CO<sub>2</sub> concentrations in the process, should be at the top of any program designed to achieve that difficult (but still highly questionable) objective.

In view of these several observations, we can be cautiously optimistic about our agricultural intervention capabilities and their capacity to help stem the tide of earth’s historically rising atmospheric methane concentration, which could take a huge bite out of methane-induced global warming. But do methane emissions from natural vegetation respond in a similar way?

We have already discussed the results of Davidson *et al.* (2004) in our Nitrous Oxide section, which results suggest that a global warming-induced drying of the Amazon Basin would initiate a strong negative feedback to warming via (1) large drying-induced reductions in the evolution of N<sub>2</sub>O and CH<sub>4</sub> from its soils and (2) a huge drying-induced increase in the consumption of CH<sub>4</sub> by its soils. In a contemporaneous study, Strack *et al.* (2004) also reported that climate models predict increases in evapotranspiration that could lead to drying in a warming world and a subsequent lowering of water tables in high northern latitudes. This prediction cries out for an analysis of how lowered water tables will affect peatland emissions of CH<sub>4</sub>.

In a theoretical study of the subject, Roulet *et al.* (1992) calculated that for a decline of 14 cm in the water tables of northern Canadian peatlands, due to

climate-model-derived increases in temperature (3°C) and precipitation (1mm/day) predicted for a doubling of the air’s CO<sub>2</sub> content, CH<sub>4</sub> emissions would decline by 74-81 percent. In an attempt to obtain some experimental data on the subject, at various times over the period 2001-2003 Strack *et al.* measured CH<sub>4</sub> fluxes to the atmosphere at different locations that varied in depth-to-water table within natural portions of a poor fen in central Quebec, Canada, as well as within control portions of the fen that had been drained eight years earlier.

At the conclusion of their study, the Canadian scientists reported that “methane emissions and storage were lower in the drained fen.” The greatest reductions (up to 97 percent) were measured at the higher locations, while at the lower locations there was little change in CH<sub>4</sub> flux. Averaged over all locations, they determined that the “growing season CH<sub>4</sub> emissions at the drained site were 55 percent lower than the control site,” indicative of the fact that the biosphere appears to be organized to resist warming influences that could push it into a thermal regime that might otherwise prove detrimental to its health.

In another experimental study, Garnet *et al.* (2005) grew seedlings of three emergent aquatic macrophytes (*Orontium aquaticum* L., *Peltandra virginica* L., and *Juncus effusus* L.) plus one coniferous tree (*Taxodium distichum* L.), all of which are native to eastern North America, in a five-to-one mixture of well-fertilized mineral soil and peat moss in pots submerged in water in tubs located within controlled environment chambers for a period of eight weeks. Concomitantly, they measured the amount of CH<sub>4</sub> emitted by the plant foliage, along with net CO<sub>2</sub> assimilation rate and stomatal conductance, which were made to vary by changing the CO<sub>2</sub> concentration of the air surrounding the plants and the density of the photosynthetic photon flux impinging on them.

Methane emissions from the four wetland species increased linearly with increases in both stomatal conductance and net CO<sub>2</sub> assimilation rate; but the researchers found that changes in stomatal conductance affected foliage methane flux “three times more than equivalent changes in net CO<sub>2</sub> assimilation,” making stomatal conductance the more significant of the two CH<sub>4</sub> emission-controllers. In addition, they note that evidence of stomatal control of CH<sub>4</sub> emission has also been reported for *Typha latifolia* (Knapp and Yavitt, 1995) and *Carex* (Morrissey *et al.*, 1993), two other important wetland plants. Hence, since atmospheric CO<sub>2</sub> enrichment

leads to approximately equivalent—but oppositely directed—changes in foliar net CO<sub>2</sub> assimilation (which is increased) and stomatal conductance (which is reduced) in most herbaceous plants (which are the type that comprise most wetlands), it can be appreciated that the ongoing rise in the air's CO<sub>2</sub> content should be acting to *reduce* methane emissions from earth's wetland vegetation, because of the three-times-greater negative CH<sub>4</sub> emission impact of the decrease in stomatal conductance compared to the positive CH<sub>4</sub> emission impact of the equivalent increase in net CO<sub>2</sub> assimilation.

According to Prinn *et al.* (1992), one of the major means by which methane is removed from the atmosphere is via oxidation by methanotrophic bacteria in the aerobic zones of soils, the magnitude of which phenomenon is believed to be equivalent to the annual input of methane to the atmosphere (Watson *et al.*, 1992). This soil sink for methane appears to be ubiquitous, as methane uptake has been observed in soils of tundra (Whalen and Reeburgh, 1990), boreal forests (Whalen *et al.*, 1992), temperate forests (Stuedler *et al.*, 1989; Yavitt *et al.*, 1990), grasslands (Mosier *et al.*, 1997), arable lands (Jensen and Olsen, 1998), tropical forests (Keller, 1986; Singh *et al.*, 1997), and deserts (Striegl *et al.*, 1992), with forest soils—especially boreal and temperate forest upland soils (Whalen and Reeburgh, 1996)—appearing to be the most efficient in this regard (Le Mer and Roger, 2001).

In an attempt to learn more about this subject, Tamai *et al.* (2003) studied methane uptake rates by the soils of three Japanese cypress plantations composed of 30- to 40-year-old trees. Through all seasons of the year, they found that methane was absorbed by the soils of all three sites, being positively correlated with temperature, as has also been observed in several other studies (Peterjohn *et al.*, 1994; Dobbie and Smith, 1996; Prieme and Christensen, 1997; Saari *et al.*, 1998). Methane absorption was additionally—and even more strongly—positively correlated with the C/N ratio of the cypress plantations' soil organic matter. Based on these results, it can be appreciated that any global warming, CO<sub>2</sub>-induced or natural, would produce two biologically mediated negative feedbacks to counter the increase in temperature: (1) a warming-induced increase in methane uptake from the atmosphere that is experienced by essentially all soils, and (2) an increase in soil methane uptake from the atmosphere that is produced by the increase in plant-litter C/N

ratio that typically results from atmospheric CO<sub>2</sub> enrichment.

Another study that deals with this topic is that of Menyailo and Hungate (2003), who assessed the influence of six boreal forest species—spruce, birch, Scots pine, aspen, larch, and Arolla pine—on soil CH<sub>4</sub> consumption in the Siberian artificial afforestation experiment, in which the six common boreal tree species had been grown under common garden conditions for the past 30 years under the watchful eye of the staff of the Laboratory of Soil Science of the Institute of Forest, Siberian Branch of the Russian Academy of Sciences (Menyailo *et al.*, 2002). They determined, in their words, that “soils under hardwood species (aspen and birch) consumed CH<sub>4</sub> at higher rates than soils under coniferous species and grassland.” Under low soil moisture conditions, for example, the soils under the two hardwood species consumed 35 percent more CH<sub>4</sub> than the soils under the four conifers; under high soil moisture conditions they consumed 65 percent more. As for the implications of these findings, Pastor and Post (1988) have suggested, in the words of Menyailo and Hungate, that “changes in temperature and precipitation resulting from increasing atmospheric CO<sub>2</sub> concentrations will cause a northward migration of the hardwood-conifer forest border in North America.” Consequently, if such a shifting of species does indeed occur, it will likely lead to an increase in methane consumption by soils and a reduction in methane-induced global warming potential, thereby providing yet another biologically mediated negative feedback factor that has yet to be incorporated into models of global climate change.

Last, we note that increases in the air's CO<sub>2</sub> concentration will likely lead to a net reduction in vegetative isoprene emissions, which, as explained in Section 7.7.1. under the heading of Isoprene, should also lead to a significant removal of methane from the atmosphere. Hence, as the air's CO<sub>2</sub> content—and possibly its temperature—continues to rise, we can expect to see a significant increase in the rate of methane removal from earth's atmosphere, which should help to reduce the potential for further global warming.

Additional information on this topic, including reviews of newer publications as they become available, can be found at <http://www.co2science.org/subject/m/methaneextract.php>, <http://www.co2science.org/subject/m/methaneag.php>, and <http://www.co2science.org/subject/m/methagnatural.php>.

## 2.6.2. Concentrations

In Section 2.6.1, we reported on several real-world phenomena that can act to reduce or extract methane (CH<sub>4</sub>) from the atmosphere, most of which feedbacks are enhanced as the air's CO<sub>2</sub> concentration rises. That those feedbacks may already be operating and having a significant impact on global methane concentrations is illustrated in a discussion of observed atmospheric methane trends.

We begin with Figure 2.6.2.1, the graph of real-world data from Simpson *et al.* (2002), which clearly shows a linear-trend decline in CH<sub>4</sub> growth rates since the mid-1980s. The authors contended it was "premature to believe" the rate of growth was falling, even though their own data bore witness against them.

**Figure 2.6.2.1.** Global tropospheric methane (CH<sub>4</sub>) growth rate vs. time. Adapted from Simpson *et al.* (2002).

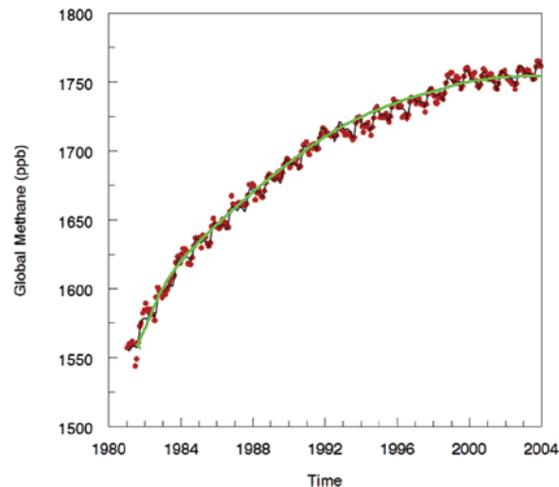

The first of the 1990s' large CH<sub>4</sub> spikes is widely recognized as having been caused by the eruption of Mt. Pinatubo in June 1991 (Bekki *et al.*, 1994;

Dlugokencky *et al.*, 1996; Lowe *et al.*, 1997), while the last and most dramatic of the spikes has been linked to the remarkably strong El Niño of 1997-98 (Dlugokencky *et al.*, 2001). As noted earlier, Dlugokencky *et al.* (1998), Francey *et al.* (1999), and Lassey *et al.* (2000) have all suggested that the annual rate-of-rise of the atmosphere's CH<sub>4</sub> concentration is indeed declining and leading to a cessation of growth in the atmospheric burden of methane.

Dlugokencky *et al.* (2003) revisited the subject with an additional two years' of data. Based on measurements from 43 globally distributed remote boundary-layer sites that were obtained by means of the methods of Dlugokencky *et al.* (1994), they defined an evenly spaced matrix of surface CH<sub>4</sub> mole fractions as a function of time and latitude, from which they calculated global CH<sub>4</sub> concentration averages for the years 1984-2002. We have extracted the results from their graphical presentation and re-plotted them as shown in Figure 2.6.2.2.

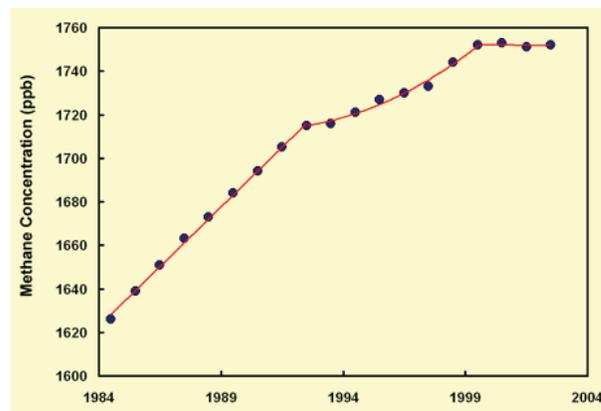

With respect to these data, Dlugokencky *et al.* note that the globally averaged atmospheric methane concentration "was constant at ~1751 ppb from 1999 through 2002," which suggests, in their words, that "during this 4-year period the global methane budget has been at steady state." They caution, however, that "our understanding is still not sufficient to tell if the prolonged pause in CH<sub>4</sub> increase is temporary or permanent." We agree. However, we feel confident in suggesting that if the recent pause in CH<sub>4</sub> increase is indeed temporary, it will likely be followed by a decrease in CH<sub>4</sub> concentration, since that would be the next logical step in the observed progression from significant, to much smaller, to no yearly CH<sub>4</sub> increase.

Khalil *et al.* (2007) essentially "put the nails in the coffin" of the idea that rising atmospheric CH<sub>4</sub> concentrations pose any further global warming threat at all. In their study, the three Oregon (USA) researchers combined two huge atmospheric methane datasets to produce the unified dataset depicted in Figure 2.6.2.3.

**Figure 2.6.2.2.** Global methane (CH<sub>4</sub>) concentration. Adapted from Khalil *et al.* (2007).

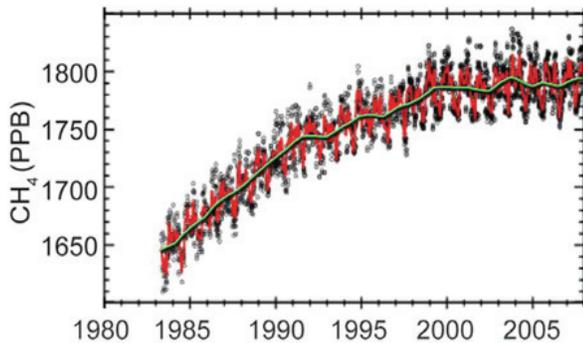

In viewing this graph, to which we have added the smooth line, it is clear that the rate of methane increase in the atmosphere has dropped dramatically over time. As Khalil *et al.* describe it, "the trend has been decreasing for the last two decades until the present when it has reached near zero," and they go on to say that "it is questionable whether human activities can cause methane concentrations to increase greatly in the future."

**Figure 2.6.2.3.** Global tropospheric methane (CH<sub>4</sub>) concentration vs. time. Adapted from Dlugokencky *et al.* (2003).

One year later, Schnell and Dlugokencky (2008) provided an update through 2007 of atmospheric methane concentrations as determined from weekly discrete samples collected on a regular basis since 1983 at the NOAA/ESRL Mauna Loa Observatory.

Our adaptation of the graphical rendition of the data provided by the authors is presented in Figure 2.6.2.4.

**Figure 2.6.2.4.** Trace gas mole fractions of methane ( $\text{CH}_4$ ) as measured at Mauna Loa, Hawaii. Adapted from Schnell and Dlugokencky (2008).

In commenting on the data contained in the figure above, Schnell and Dlugokencky state that “atmospheric  $\text{CH}_4$  has remained nearly constant since the late 1990s.” This is a most important finding, because, as they also note, “methane’s contribution to anthropogenic radiative forcing, including direct and indirect effects, is about  $0.7 \text{ Wm}^{-2}$ , about half that of  $\text{CO}_2$ .” In addition, they say that “the increase in methane since the preindustrial era is responsible for approximately one-half the estimated increase in background tropospheric  $\text{O}_3$  during that time.”

Most recently, Rigby *et al.* (2008) analyzed methane data obtained from the Advanced Global Atmospheric Gases Experiment (AGAGE) and the Australian Commonwealth Scientific and Industrial Research Organization (CSIRO) over the period January 1997 to April 2008. The results of their analysis indicated that methane concentrations “show renewed growth from the end of 2006 or beginning of 2007 until the most recent measurements,” with the record-long range of methane growth rates mostly hovering about zero, but sometimes dropping five parts per billion (ppb) per year into the negative range, while rising near the end of the record to mean positive values of 8 and 12 ppb per year for the two measurement networks.

Although some people might be alarmed by these findings, as well as by the US, UK, and Australian researchers’ concluding statement that the methane growth rate during 2007 “was significantly elevated at all AGAGE and CSIRO sites simultaneously for the first time in almost a decade,” there is also reassurance in the recent findings. We note, for example, that near the end of 1998 and the beginning

of 1999, both networks measured even larger methane growth rate increases of approximately 13 ppb per year, before dropping back to zero at the beginning of the new millennium. And we note that the most current displayed data from the two networks indicate the beginning of what could well be another downward trend.

Additional reassurance in this regard comes from the work of Simpson *et al.* (2002), the findings of whom we reproduced previously in Figure 2.6.2.1. As can be seen there, even greater methane growth rates than those observed by Rigby *et al.* occurred in still earlier years. Hence, these periodic one-year-long upward spikes in methane growth rate must be the result of some normal phenomenon, the identity of which has yet to be determined.

In light of these findings, it can be appreciated that over the past decade there have been essentially no increases in methane emissions to the atmosphere, and that the leveling out of the atmosphere’s methane concentration—the exact causes of which, in the words of Schnell and Dlugokencky, “are still unclear”—has resulted in a one-third reduction in the combined radiative forcing that would otherwise have been produced by a continuation of the prior rates-of-rise of the concentrations of the two atmospheric greenhouse gases.

Additional information on this topic, including reviews of newer publications as they become available, can be found at <http://www.co2science.org/subject/m/methaneatmos.php>.

### 2.7. Dimethyl Sulfide

More than two decades ago, Charlson *et al.* (1987) discussed the plausibility of a multi-stage negative

feedback process, whereby warming-induced increases in the emission of dimethyl sulfide (DMS) from the world's oceans tend to counteract any initial impetus for warming. The basic tenet of their hypothesis was that the global radiation balance is significantly influenced by the albedo of marine stratus clouds (the greater the cloud albedo, the less the input of solar radiation to the earth's surface). The albedo of these clouds, in turn, is known to be a function of cloud droplet concentration (the more and smaller the cloud droplets, the greater the cloud albedo and the reflection of solar radiation), which is dependent upon the availability of cloud condensation nuclei on which the droplets form (the more cloud condensation nuclei, the more and smaller the cloud droplets). And in completing the negative feedback loop, Charlson *et al.* noted that the cloud condensation nuclei concentration often depends upon the flux of biologically produced DMS from the world's oceans (the higher the sea surface temperature, the greater the sea-to-air flux of DMS).

Since the publication of Charlson *et al.*'s initial hypothesis, much empirical evidence has been gathered in support of its several tenets. One review, for example, states that "major links in the feedback chain proposed by Charlson *et al.* (1987) have a sound physical basis," and that there is "compelling observational evidence to suggest that DMS and its atmospheric products participate significantly in processes of climate regulation and reactive atmospheric chemistry in the remote marine boundary layer of the Southern Hemisphere" (Ayers and Gillett, 2000).

But just how strong is the negative feedback phenomenon proposed by Charlson *et al.*? Is it powerful enough to counter the threat of greenhouse gas-induced global warming? According to the findings of Sciare *et al.* (2000), it may well be able to do just that.

In examining 10 years of DMS data from Amsterdam Island in the southern Indian Ocean, these researchers found that a sea surface temperature increase of only 1°C was sufficient to increase the atmospheric DMS concentration by as much as 50 percent. This finding suggests that the degree of warming typically predicted to accompany a doubling of the air's  $\text{CO}_2$  content would increase the atmosphere's DMS concentration by a factor of three or more, providing what they call a "very important" negative feedback that could potentially offset the original impetus for warming.

Other research has shown that this same chain of events can be set in motion by means of phenomena not discussed in Charlson *et al.*'s original hypothesis. Simo and Pedros-Alio (1999), for example, discovered that the depth of the surface mixing-layer has a substantial influence on DMS yield in the short term, via a number of photo-induced (and thereby mixing-depth mediated) influences on several complex physiological phenomena, as do longer-term seasonal variations in vertical mixing, via their influence on seasonal planktonic succession scenarios and food-web structure.

More directly supportive of Charlson *et al.*'s hypothesis was the study of Kouvarakis and Mihalopoulos (2002), who measured seasonal variations of gaseous DMS and its oxidation products—non-sea-salt sulfate ( $\text{nss-SO}_4^{2-}$ ) and methanesulfonic acid (MSA)—at a remote coastal location in the Eastern Mediterranean Sea from May 1997 through October 1999, as well as the diurnal variation of DMS during two intensive measurement campaigns conducted in September 1997. In the seasonal investigation, DMS concentrations tracked sea surface temperature (SST) almost perfectly, going from a low of  $0.87 \text{ nmol m}^{-3}$  in the winter to a high of  $3.74 \text{ nmol m}^{-3}$  in the summer. Such was also the case in the diurnal studies: DMS concentrations were lowest when it was coldest (just before sunrise), rose rapidly as it warmed thereafter to about 1100, after which they dipped slightly and then experienced a further rise to the time of maximum temperature at 2000, whereupon a decline in both temperature and DMS concentration set in that continued until just before sunrise. Consequently, because concentrations of DMS and its oxidation products (MSA and  $\text{nss-SO}_4^{2-}$ ) rise dramatically in response to both diurnal and seasonal increases in SST, there is every reason to believe that the same negative feedback phenomenon would operate in the case of the long-term warming that could arise from increasing greenhouse gas concentrations, and that it could substantially mute the climatic impacts of those gases.

Also of note in this regard, Baboukas *et al.* (2002) report the results of nine years of measurements of methanesulfonate (MS<sup>-</sup>), an exclusive oxidation product of DMS, in rainwater at Amsterdam Island. Their data, too, revealed “a well distinguished seasonal variation with higher values in summer, in line with the seasonal variation of its gaseous precursor (DMS),” which, in their words, “further confirms the findings of Sciare *et al.* (2000).” In addition, the MS<sup>-</sup> anomalies in the rainwater were

found to be closely related to SST anomalies; and Baboukas *et al.* say this observation provides even more support for “the existence of a positive ocean-atmosphere feedback on the biogenic sulfur cycle above the Austral Ocean, one of the most important DMS sources of the world.”

In a newer study of this phenomenon, Toole and Siegel (2004) note that it has been shown to operate as described above in the 15 percent of the world's oceans “consisting primarily of high latitude, continental shelf, and equatorial upwelling regions,” where DMS may be accurately predicted as a function of the ratio of the amount of surface chlorophyll derived from satellite observations to the depth of the climatological mixed layer, which they refer to as the “bloom-forced regime.” For the other 85 percent of the world's marine waters, they demonstrate that modeled surface DMS concentrations are independent of chlorophyll and are a function of the mixed layer depth alone, which they call the “stress-forced regime.” So how does the warming-induced DMS negative feedback cycle operate in these waters?

For oligotrophic regimes, Toole and Siegel find that “DMS biological production rates are negatively or insignificantly correlated with phytoplankton and bacterial indices for abundance and productivity while more than 82 percent of the variability is explained by UVR(325) [ultraviolet radiation at 325 nm].” This relationship, in their words, is “consistent with recent laboratory results (e.g., Sunda *et al.*, 2002),” who demonstrated that intracellular DMS concentration and its biological precursors (particulate and dissolved dimethylsulfoniopropionate) “dramatically increase under conditions of acute oxidative stress such as exposure to high levels of UVR,” which “are a function of mixed layer depth.”

These results—which Toole and Siegel confirmed via an analysis of the Dacey *et al.* (1998) 1992-1994 organic sulfur time-series that was sampled in concert with the U.S. JGOFS Bermuda Atlantic Time-Series Study (Steinberg *et al.*, 2001)—suggest, in their words, “the potential of a global change-DMS-climate feedback.” Specifically, they say that “UVR doses will increase as a result of observed decreases in stratospheric ozone and the shoaling of ocean mixed layers as a result of global warming (e.g., Boyd and Doney, 2002),” and that “in response, open-ocean phytoplankton communities should increase their DMS production and ventilation to the atmosphere, increasing cloud condensing nuclei, and potentially

playing out a coupled global change-DMS-climate feedback.”

This second DMS-induced negative-feedback cycle, which operates over 85 percent of the world's marine waters and complements the first DMS-induced negative-feedback cycle, which operates over the other 15 percent, is another manifestation of the capacity of earth's biosphere to regulate its affairs in such a way as to maintain climatic conditions over the vast majority of the planet's surface within bounds conducive to the continued existence of life, in all its variety and richness. In addition, it has been suggested that a DMS-induced negative climate feedback phenomenon also operates over the terrestrial surface of the globe, where the volatilization of reduced sulfur gases from soils may be just as important as marine DMS emissions in enhancing cloud albedo (Idso, 1990).

On the basis of experiments that showed soil DMS emissions to be positively correlated with soil organic matter content, for example, and noting that additions of organic matter to a soil tend to increase the amount of sulfur gases emitted therefrom, Idso (1990) hypothesized that because atmospheric CO<sub>2</sub> is an effective aerial fertilizer, augmenting its atmospheric concentration and thereby increasing vegetative inputs of organic matter to earth's soils should also produce an impetus for cooling, even in the absence of surface warming.

Nevertheless, and in spite of the overwhelming empirical evidence for both land- and ocean-based DMS-driven negative feedbacks to global warming, the effects of these processes have not been fully incorporated into today's state-of-the-art climate models. Hence, the warming they predict in response to future anthropogenic CO<sub>2</sub> emissions must be considerably larger than what could actually occur in the real world. It is very possible these biologically driven phenomena could entirely compensate for the warming influence of all greenhouse gas emissions experienced to date, as well as all those anticipated to occur in the future.

Additional information on this topic, including reviews of newer publications as they become available, can be found at <http://www.co2science.org/subject/d/dms.php>.

## 2.8. Aerosols

### 2.8.1. Total Aerosol Effect

The IPCC estimates the net effect of all aerosols is to produce a cooling effect, with a total direct radiative forcing of  $-0.5 \text{ Wm}^{-2}$  and an additional indirect cloud albedo forcing of  $-0.7 \text{ Wm}^{-2}$  (IPCC, 2007-I, p. 4). However, the scientific literature indicates these estimates are too low. Many studies suggest the radiative forcing of aerosols may be as large as, or larger than, the radiative forcing due to atmospheric  $\text{CO}_2$ .

Vogelmann *et al.* (2003) report that “mineral aerosols have complex, highly varied optical properties that, for equal loadings, can cause differences in the surface IR flux between 7 and 25  $\text{Wm}^{-2}$  (Sokolik *et al.*, 1998),” and “only a few large-scale climate models currently consider aerosol IR [infrared] effects (e.g., Tegen *et al.*, 1996; Jacobson, 2001) despite their potentially large forcing.” In an attempt to persuade climate modelers to rectify this situation, they used high-resolution spectra to obtain the IR radiative forcing at the earth’s surface for aerosols encountered in the outflow from northeastern Asia, based on measurements made by the Marine-Atmospheric Emitted Radiance Interferometer from the NOAA Ship *Ronald H. Brown* during the Aerosol Characterization Experiment-Asia. As a result of this work, the scientists determined that “daytime surface IR forcings are often a few  $\text{Wm}^{-2}$  and can reach almost 10  $\text{Wm}^{-2}$  for large aerosol loadings.” These values, in their words, “are comparable to or larger than the 1 to 2  $\text{Wm}^{-2}$  change in the globally averaged surface IR forcing caused by greenhouse gas increases since pre-industrial times” and “highlight the importance of aerosol IR forcing which should be included in climate model simulations.”

Chou *et al.* (2002) analyzed aerosol optical properties retrieved from the satellite-mounted Sea-viewing Wide Field-of-view Sensor (SeaWiFS) and used them in conjunction with a radiative transfer model of the planet’s atmosphere to calculate the climatic effects of aerosols over earth’s major oceans. In general, this effort revealed that “aerosols reduce the annual-mean net downward solar flux by 5.4  $\text{Wm}^{-2}$  at the top of the atmosphere, and by 5.9  $\text{Wm}^{-2}$  at the surface.” During the large Indonesian fires of September-December 1997, however, the radiative impetus for cooling at the top of the atmosphere was more than 10  $\text{Wm}^{-2}$ , while it was more than 25  $\text{Wm}^{-2}$  at the surface of the sea in the vicinity of Indonesia.

These latter results are similar to those obtained earlier by Wild (1999), who used a comprehensive set of collocated surface and satellite observations to calculate the amount of solar radiation absorbed in the atmosphere over equatorial Africa and compared the results with the predictions of three general circulation models of the atmosphere. This work revealed that the climate models did not properly account for spatial and temporal variations in atmospheric aerosol concentrations, leading them to predict regional and seasonal values of solar radiation absorption in the atmosphere with underestimation biases of up to 30  $\text{Wm}^{-2}$ . By way of comparison, as noted by Vogelmann *et al.*, the globally averaged surface IR forcing caused by greenhouse gas increases since pre-industrial times is 1 to 2  $\text{Wm}^{-2}$ .

Aerosol uncertainties and the problems they generate figure prominently in a study by Anderson *et al.* (2003), who note there are two different ways by which the aerosol forcing of climate may be computed. The first is forward calculation, which is based, in their words, on “knowledge of the pertinent aerosol physics and chemistry.” The second approach is inverse calculation, based on “the total forcing required to match climate model simulations with observed temperature changes.”

The first approach utilizes known physical and chemical laws and assumes nothing about the outcome of the calculation. The second approach, in considerable contrast, is based on matching residuals, where the aerosol forcing is computed from what is required to match the calculated change in temperature with the observed change over some period of time. Consequently, in the words of Anderson *et al.*, “to the extent that climate models rely on the results of inverse calculations, the possibility of circular reasoning arises.”

So which approach do climate models typically employ? “Unfortunately,” according to Anderson *et al.*, “virtually all climate model studies that have included anthropogenic aerosol forcing as a driver of climate change have used only aerosol forcing values that are consistent with the inverse approach.”

How significant is this choice? Anderson *et al.* report that the negative forcing of anthropogenic aerosols derived by forward calculation is “considerably greater” than that derived by inverse calculation; so much so, in fact, that if forward calculation is employed, the results “differ greatly” and “even the sign of the total forcing is in question,” which implies that “natural variability (that is, variability not forced by anthropogenic emissions) is

much larger than climate models currently indicate.” The bottom line, in the words of Anderson *et al.*, is that “inferences about the causes of surface warming over the industrial period and about climate sensitivity may therefore be in error.”

Schwartz (2004) also addressed the subject of uncertainty as it applies to the role of aerosols in climate models. Noting that the National Research Council (1979) concluded that “climate sensitivity [to CO<sub>2</sub> doubling] is likely to be in the range 1.5-4.5°C” and that “remarkably, despite some two decades of intervening work, neither the central value nor the uncertainty range has changed,” Schwartz opined that this continuing uncertainty “precludes meaningful model evaluation by comparison with observed global temperature change or empirical determination of climate sensitivity,” and that it “raises questions regarding claims of having reproduced observed large-scale changes in surface temperature over the 20th century.”

Schwartz thus contends that climate model predictions of CO<sub>2</sub>-induced global warming “are limited at present by uncertainty in radiative forcing of climate change over the industrial period, which is dominated by uncertainty in forcing by aerosols,” and that if this situation is not improved, “it is likely that in another 20 years it will still not be possible to specify the climate sensitivity with [an] uncertainty range appreciably narrower than it is at present.” Indeed, he says “the need for reducing the uncertainty from its present estimated value by at least a factor of 3 and perhaps a factor of 10 or more seems inescapable if the uncertainty in climate sensitivity is to be reduced to an extent where it becomes useful for formulating policy to deal with global change,” which surely suggests that even the best climate models of the day are wholly inadequate for this purpose.

Coming to much the same conclusion was the study of Jaenicke *et al.* (2007), who reviewed the status of research being conducted on biological materials in the atmosphere, which they denominate primary biological atmospheric particles or PBAPs. Originally, these particles were restricted to culture-forming units, including pollen, bacteria, mold and viruses, but they also include fragments of living and dead organisms and plant debris, human and animal epithelial cells, broken hair filaments, parts of insects, shed feather fractions, etc., which they lump together under the category of “dead biological matter.”

With respect to the meteorological and climatic relevance of these particles, they note that many PBAPs, including “decaying vegetation, marine

plankton and bacteria are excellent ice nuclei,” and “one can easily imagine the [IR] influence on cloud cover, climate forcing and feedback and global precipitation distribution.”

In describing their own measurements and those of others, which they say “have now been carried out at several geographical locations covering all seasons of the year and many characteristic environments,” Jaenicke *et al.* report that “by number and volume, the PBAP fraction is ~20 percent of the total aerosol, and appears rather constant during the year.” In addition, they write that “the impression prevails that the biological material, whether produced directly or shed during the seasons, sits on surfaces, ready to be lifted again in resuspension.”

In a brief summation of their findings, the German researchers say “the overall conclusion can only be that PBAPs are a major fraction of atmospheric aerosols, and are comparable to sea salt over the oceans and mineral particles over the continents,” and, consequently, that “the biosphere must be a major source for directly injected biological particles, and those particles should be taken into account in understanding and modeling atmospheric processes.” However, they note that “the IPCC-Report of 2007 does not even mention these particles,” and that “this disregard of the biological particles requires a new attitude.”

We agree. Over much of the planet’s surface, the radiative cooling influence of atmospheric aerosols (many of which are produced by anthropogenic activities) must prevail, suggesting a probable net anthropogenic-induced climatic signal that must be very close to zero and incapable of producing what the IPCC refers to as the “unprecedented” warming of the twentieth century. Either the air temperature record they rely on is in error or the warming, if real, is due to something other than anthropogenic CO<sub>2</sub> emissions.

Our review of important aerosol studies continues below with a separate discussion of four important aerosol categories: (1) Biological (Aquatic), (2) Biological (Terrestrial), (3) Non-Biological (Anthropogenic), and (4) Non-Biological (Natural). Additional information on this topic, including reviews of aerosols not discussed here, can be found at [http://www.co2science.org/subject/a/subject\\_a.php](http://www.co2science.org/subject/a/subject_a.php) under the heading Aerosols.

- studies, that links biology with climate change. The process begins with an initial impetus for warming that stimulates primary production in marine phytoplankton. This enhanced process leads to the production of more copious quantities of dimethylsulphoniopropionate, which leads in turn to the evolution of greater amounts of dimethyl sulphide, or DMS, in the surface waters of the world's oceans. Larger quantities of DMS diffuse into the atmosphere, where the gas is oxidized, leading to the creation of greater amounts of acidic aerosols that function as cloud condensation nuclei. This phenomenon then leads to the creation of more and brighter clouds that reflect more incoming solar radiation back to space, thereby providing a cooling influence that counters the initial impetus for warming.
- Several recent studies have shed additional light on this complex hypothesis. Simo and Pedros-Alio (1999) used satellite imagery and *in situ* experiments to study the production of DMS by enzymatic cleavage of dimethylsulphoniopropionate in the North Atlantic Ocean about 400 km south of Iceland, finding that the depth of the surface mixing-layer has a substantial influence on DMS yield in the short term, as do seasonal variations in vertical mixing in the longer term, which observations led them to conclude that “climate-controlled mixing controls DMS production over vast regions of the ocean.”
- Hopke *et al.* (1999) analyzed weekly concentrations of 24 different airborne particulates measured at the northernmost manned site in the world—Alert, Northwest Territories, Canada—from 1980 to 1991. They found concentrations of biogenic sulfur, including sulfate and methane sulfonate, were low in winter but high in summer, and that the year-to-year variability in the strength of the biogenic sulfur signal was strongly correlated with the mean temperature of the Northern Hemisphere. “This result,” the authors say, “suggests that as the temperature rises, there is increased biogenic production of the reduced sulfur precursor compounds that are oxidized in the atmosphere to sulfate and methane sulfonate and could be evidence of a negative feedback mechanism in the global climate system.”
- Ayers and Gillett (2000) summarized relevant empirical evidence collected at Cape Grim, Tasmania, along with pertinent evidence reported in many peer-reviewed scientific papers on this subject. They conclude that “major links in the feedback chain proposed by Charlson *et al.* (1987) have a sound

### 2.8.2. Biological (Aquatic)

Charlson *et al.* (1987) described a multi-stage negative feedback phenomenon, several components of which have been verified by subsequent scientific

physical basis.” More specifically, they noted there is “compelling observational evidence to suggest that DMS and its atmospheric products participate significantly in processes of climate regulation and reactive atmospheric chemistry in the remote marine boundary layer of the Southern Hemisphere.”

Sciare *et al.* (2000) made continuous measurements of atmospheric DMS concentration over the 10-year period 1990-1999 at Amsterdam Island in the southern Indian Ocean. Their study revealed “a clear seasonal variation with a factor of 20 in amplitude between its maximum in January (austral summer) and minimum in July-August (austral winter).” In addition, they found DMS anomalies to be “closely related to sea surface temperature anomalies, clearly indicating a link between DMS and climate changes.” They found that a temperature increase of only 1°C was sufficient to increase the atmospheric DMS concentration by as much as 50 percent on a monthly basis, noting that “this is the first time that a direct link between SSTs [sea surface temperatures] and atmospheric DMS is established for a large oceanic area.”

Another pertinent study was conducted by Kouvarakis and Mihalopoulos (2002), who investigated the seasonal variations of gaseous DMS and its oxidation products—non-sea-salt sulfate (nss-SO<sub>4</sub><sup>2-</sup>) and methanesulfonic acid (MSA)—at a remote coastal location in the Eastern Mediterranean Sea from May 1997 through October 1999, as well as the diurnal variation of DMS during two intensive measurement campaigns in September 1997. In the seasonal investigation, DMS concentrations tracked sea surface temperature (SST) almost perfectly, going from a low of 0.87 nmol m<sup>-3</sup> in the winter to a high of 3.74 nmol m<sup>-3</sup> in the summer. Such was also the case in the diurnal study: DMS concentrations were lowest just before sunrise, rose rapidly thereafter to about 1100, were followed by a little dip and then a further rise to 2000, whereupon a decline set in that continued until just before sunrise. MSA concentrations exhibited a similar seasonal variation to that displayed by DMS, ranging from a wintertime low of 0.04 nmol m<sup>-3</sup> to a summertime high of 0.99 nmol m<sup>-3</sup>. The same was also true of aerosol nss-SO<sub>4</sub><sup>2-</sup> which varied from 0.6 to 123.9 nmol m<sup>-3</sup> in going from winter to summer.

A related study of methanesulfonate (MS<sup>-</sup>) in rainwater at Amsterdam Island, by Baboukas *et al.* (2002), in the authors’ words, “further confirms the findings of Sciare *et al.* (2000).” For more about that

study and a newer study by Toole and Siegel (2004), see Section 2.7 of this report.

As time passes, more studies confirm the Charlson *et al.* hypothesis that as marine phytoplankton are exposed to rising temperatures, they give off greater quantities of gases that lead to the production of greater quantities of cloud condensation nuclei, which create more and brighter clouds, that reflect more incoming solar radiation back to space, and thereby either reverse, stop, or slow the warming that initiated this negative feedback phenomenon. The normal hour-to hour, day-to-day, and season-to-season behaviors of the phytoplanktonic inhabitants of earth’s marine ecosystems seem to be effectively combating extreme environmental temperature changes.

### 2.8.3. Biological (Terrestrial)

Just as marine phytoplankton respond to rising temperatures by giving off gases that ultimately lead to less global warming, so too do terrestrial plants. What is more, earth's terrestrial plants have a tendency to operate in this manner more effectively as the air's CO<sub>2</sub> content rises.

A good introduction to this subject is provided by the review paper of Peñuelas and Llusia (2003), who say biogenic volatile organic compounds (BVOCs) constitute "one of nature's biodiversity treasures." Comprised of isoprene, terpenes, alkanes, alkenes, alcohols, esters, carbonyls, and acids, this diverse group of substances is produced by a variety of processes occurring in many plant tissues. Some of the functions of these substances, according to the two scientists, include acting as "deterrents against pathogens and herbivores, or to aid wound sealing after damage (Pichersky and Gershenzon, 2002)." They also say BVOCs provide a means "to attract pollinators and herbivore predators, and to communicate with other plants and organisms (Peñuelas *et al.*, 1995; Shulaev *et al.*, 1997)."

Of particular importance within the context of global climate change, in the opinion of Peñuelas and Llusia, is the growing realization that "isoprene and monoterpenes, which constitute a major fraction of BVOCs, might confer protection against high temperatures" by acting "as scavengers of reactive oxygen species produced [within plants] under high temperatures." If this is indeed the case, it can be appreciated that with respect to the claimed ill effects of CO<sub>2</sub>-induced global warming on earth's vegetation, there are likely to be two strong ameliorative phenomena that act to protect the planet's plants: (1) the aerial fertilization effect of atmospheric CO<sub>2</sub> enrichment, which is typically more strongly expressed at higher temperatures, and (2) the tendency for rising air temperatures and CO<sub>2</sub> concentrations to spur the production of higher concentrations of heat-stress-reducing BVOCs. With respect to temperature, Peñuelas and Llusia calculate

that "global warming over the past 30 years could have increased the BVOC global emissions by approximately 10 percent, and a further 2-3°C rise in the mean global temperature ... could increase BVOC global emissions by an additional 30-45 percent."

There may also be other phenomena that favor earth's plants within this context. Peñuelas and Llusia note that "the increased release of nitrogen into the biosphere by man probably also enhances BVOC emissions by increasing the level of carbon fixation and the activity of the responsible enzymes (Litvak *et al.*, 1996)." The conversion of abandoned agricultural lands to forests and the implementation of planned reforestation projects should help the rest of the biosphere too, since Peñuelas and Llusia report that additional numbers of "*Populus*, *Eucalyptus* or *Pinus*, which are major emitters, might greatly increase BVOC emissions."

Most intriguing of all, perhaps, is how increased BVOC emissions might impact climate change. Peñuelas and Llusia say that "BVOCs generate large quantities of organic aerosols that could affect climate significantly by forming cloud condensation nuclei." As a result, they say "there should be a net cooling of the Earth's surface during the day because of radiation interception," noting that Shallcross and Monks (2000) "have suggested that one of the reasons plants emit the aerosol isoprene might be to cool the surroundings in addition to any physiological or evaporative effects that might cool the plant directly."

Not all experiments have reported increases in plant BVOC emissions with increasing atmospheric CO<sub>2</sub> concentrations, one example being Constable *et al.* (1999), who found no effect of elevated CO<sub>2</sub> on monoterpene emissions from Ponderosa pine and Douglas fir trees. Some studies, in fact, have reported *decreases* in BVOC emissions, such as those of Vuorinen *et al.* (2004), who worked with cabbage plants, and Loreto *et al.* (2001), who studied monoterpene emissions from oak seedlings.

On the other hand, Staudt *et al.* (2001) observed CO<sub>2</sub>-induced *increases* in BVOC emissions in the identical species of oak studied by Vuorinen *et al.* An explanation for this wide range of results comes from Baraldi *et al.* (2004), who—after exposing sections of a southern California chaparral ecosystem to atmospheric CO<sub>2</sub> concentrations ranging from 250 to 750 ppm in 100-ppm increments for a period of four years—concluded that "BVOC emission can remain nearly constant as rising CO<sub>2</sub> reduces emission per unit leaf area while stimulating biomass growth and leaf area per unit ground area." In most of the cases

investigated, however, BVOC emissions tend to increase with atmospheric CO<sub>2</sub> enrichment; and the increases are often large.

Jasoni *et al.* (2003) who grew onions from seed for 30 days in individual cylindrical flow-through growth chambers under controlled environmental conditions at atmospheric CO<sub>2</sub> concentrations of either 400 or 1,000 ppm. At the end of the study, the plants in the CO<sub>2</sub>-enriched chambers had 40 percent more biomass than the plants grown in ambient air, and their photosynthetic rates were 22 percent greater. In addition, the CO<sub>2</sub>-enriched plants exhibited 17-fold and 38-fold increases in emissions of the BVOC hydrocarbons 2-undecanone and 2-tridecanone, respectively, which Jasoni *et al.* make a point of noting, “confer insect resistance against a major agricultural pest, spider mites.” More generally, they conclude that “plants grown under elevated CO<sub>2</sub> will accumulate excess carbon and that at least a portion of this excess carbon is funneled into an increased production of BVOCs,” which have many positive implications in the realms of both biology and climate, as noted above.

Raisanen *et al.* (2008) conducted an experiment designed to see to what extent a doubling of the air’s CO<sub>2</sub> content and a 2°–6°C increase in air temperature might impact the emission of monoterpenes from 20-year-old Scots pine (*Pinus sylvestris* L.) seedlings. They studied the two phenomena (and their interaction) within closed-top chambers built on a naturally seeded stand of the trees in eastern Finland that had been exposed to the four treatments—ambient CO<sub>2</sub> and ambient temperature, ambient temperature and elevated CO<sub>2</sub>, ambient CO<sub>2</sub> and elevated temperature, elevated temperature and elevated CO<sub>2</sub>—for the prior five years.

Over the five-month growing season of May–September, the three Finnish researchers found that total monoterpene emissions in the elevated-CO<sub>2</sub>-only treatment were 5 percent greater than those in the ambient CO<sub>2</sub>, ambient temperature treatment, and that emissions in the elevated-temperature-only treatment were 9 percent less than those in ambient air. In the presence of both elevated CO<sub>2</sub> and elevated temperature, however, there was an increase of fully 126 percent in the total amount of monoterpenes emitted over the growing season, which led the authors to conclude, “the amount of monoterpenes released by Scots pines into the atmosphere during a growing season will increase substantially in the predicted future climate.”

A number of studies suggest that the phenomena discussed in the preceding paragraphs do indeed operate in the real world. Kavouras *et al.* (1998), for example, measured a number of atmospheric gases and particles in a eucalyptus forest in Portugal and analyzed their observations to see if there was any evidence of biologically produced gases being converted to particles that could function as cloud condensation nuclei. Their work demonstrated that certain hydrocarbons emitted by vegetation (isoprene and terpenes, in particular) do indeed experience gas-to-particle transformations. In fact, aerosols (or biosols) produced from two of these organic acids (*cis*- and *trans*-pinonic acid) comprised as much as 40 percent of the fine particle atmospheric mass during daytime hours.

A similar study was conducted by O’Dowd *et al.* (2002), who measured aerosol electrical-mobility size-distributions before and during the initial stage of an atmospheric nucleation event over a boreal forest in Finland. Simultaneously, organic vapor growth rate measurements were made of particles that nucleated into organic cloud-droplets in the flow-tube cloud chamber of a modified condensation-particle counter. This work demonstrated, in their words, that newly formed aerosol particles over forested areas “are composed primarily of organic species, such as *cis*-pinonic acid and pinonic acid, produced by oxidation of terpenes in organic vapours released from the canopy.”

Commenting on this finding, O’Dowd *et al.* note that “aerosol particles produced over forested areas may affect climate by acting as nuclei for cloud condensation,” but they say there remain numerous uncertainties involving complex feedback processes “that must be determined if we are to predict future changes in global climate.”

Shifting from trees to a much smaller plant, Kuhn and Kesselmeier (2000) collected lichens from an open oak woodland in central California, USA, and studied their uptake of carbonyl sulfide (OCS) in a dynamic cuvette system under controlled conditions in the laboratory. When optimally hydrated, OCS was absorbed from the atmosphere by the lichens at a rate that gradually doubled as air temperature rose from approximately 3° to 25°C, whereupon the rate of OCS absorption dropped precipitously, reaching a value of zero at 35°C. Why is this significant?

OCS is the most stable and abundant reduced sulfur gas in the atmosphere and is thus a major player in determining earth’s radiation budget. After making its way into the stratosphere, it can be photo-

dissociated, as well as oxidized, to form SO<sub>2</sub>, which is typically converted to sulfate aerosol particles that are highly reflective of incoming solar radiation and, therefore, have the capacity to significantly cool the earth as more and more of them collect above the tropopause. This being the case, biologically modulated COS concentrations may play a role in keeping earth's surface air temperature within bounds conducive to the continued existence of life, exactly what is implied by the observations of Kuhn and Kesselmeier.

Once air temperature rises above 25°C, the rate of removal of OCS from the air by this particular species of lichen declines dramatically. When this happens, more OCS remains in the air, which increases the potential for more OCS to make its way into the stratosphere, where it can be converted into sulfate aerosol particles that can reflect more incoming solar radiation back to space and thereby cool the earth. Since the consumption of OCS by lichens is under the physiological control of carbonic anhydrase—which is the key enzyme for OCS uptake in all higher plants, algae, and soil organisms—we could expect this phenomenon to be generally operative throughout much of the plant kingdom. This biological “thermostat” may well be powerful enough to define an upper limit above which the surface air temperature of the planet may be restricted from rising, even when changes in other forcing factors, such as greenhouse gases, produce an impetus for it to do so. For more about OCS, see Section 2.2 of this report.

Although BVOCs emitted from terrestrial plants both small and large are important to earth's climate, trees tend to dominate in this regard. Recent research suggests yet another way in which their response to atmospheric CO<sub>2</sub> enrichment may provide an effective counterbalance to the greenhouse properties of CO<sub>2</sub>. The phenomenon begins with the propensity for CO<sub>2</sub>-induced increases in BVOCs, together with the cloud particles they spawn, to enhance the amount of diffuse solar radiation reaching the earth's surface (Suraqui *et al.*, 1974; Abakumova *et al.*, 1996), which is followed by the ability of enhanced diffuse lighting to reduce the volume of shade within vegetative canopies (Roderick *et al.*, 2001), which is followed by the tendency for less internal canopy shading to enhance whole-canopy photosynthesis (Healey *et al.*, 1998), which finally produces the end result: a greater photosynthetic extraction of CO<sub>2</sub> from the air and the subsequent reduction of the strength of the atmosphere's greenhouse effect.

The significance of this process is described and documented at some length in Section 2.3 of this report. For example, Roderick *et al.* concluded that the Mt. Pinatubo eruption—a unique natural experiment to evaluate the overall climatic sensitivity of the planet—may well have resulted in the removal of an extra 2.5 Gt of carbon from the atmosphere due to its diffuse-light-enhancing stimulation of terrestrial photosynthesis in the year following the eruption. Additional real-world evidence for the existence of this phenomenon was provided by Gu *et al.* (2003), Law *et al.* (2002), Farquhar and Roderick (2003), Reichenau and Esser (2003), and Niyogi *et al.* (2004).

One final beneficial effect of CO<sub>2</sub>-induced increases in BVOC emissions is the propensity of BVOCs to destroy tropospheric ozone, as documented by Goldstein *et al.* (2004). Earth's vegetation is responsible for the production of vast amounts of ozone (O<sub>3</sub>) (Chameides *et al.*, 1988; Harley *et al.*, 1999), but it is also responsible for *destroying* a lot of O<sub>3</sub>. With respect to the latter phenomenon, Goldstein *et al.* mention three major routes by which O<sub>3</sub> exits the air near the earth's surface: leaf stomatal uptake, surface deposition, and within-canopy gas-phase chemical reactions with BVOCs.

The first of these exit routes, according to Goldstein *et al.*, accounts for 30 percent to 90 percent of total ecosystem O<sub>3</sub> uptake from the atmosphere (that is, O<sub>3</sub> destruction), while the remainder has typically been attributed to deposition on non-stomatal surfaces. However, they note that “Kurpius and Goldstein (2003) recently showed that the non-stomatal flux [from the atmosphere to oblivion] increased exponentially as a function of temperature at a coniferous forest site,” and that “the exponential increase with temperature was consistent with the temperature dependence of monoterpene emissions from the same ecosystem, suggesting O<sub>3</sub> was lost via gas phase reactions with biogenically emitted terpenes before they could escape the forest canopy.”

In a study designed to take the next step towards turning the implication of this observation into something stronger than a mere suggestion, Schade and Goldstein (2003) demonstrated that forest thinning dramatically enhances monoterpene emissions. In the current study, Goldstein *et al.* take another important step towards clarifying the issue by measuring the effect of forest thinning on O<sub>3</sub> destruction in an attempt to see if it is enhanced in parallel fashion to the thinning-induced increase in monoterpene emissions.

In a ponderosa pine plantation in the Sierra Nevada Mountains of California, USA, a management procedure to improve forest health and optimize tree growth was initiated on May 11, 2000 and continued through June 15, 2000. This procedure involved the use of a *masticator* to mechanically “chew up” smaller unwanted trees and leave their debris on site, which reduced plantation green leaf biomass by just over half. Simultaneously, monoterpene mixing ratios and fluxes were measured hourly within the plantation canopy, while total ecosystem O<sub>3</sub> destruction was “partitioned to differentiate loss due to gas-phase chemistry from stomatal uptake and deposition.”

Goldstein *et al.* report that both the destruction of ozone due to gas-phase chemistry and emissions of monoterpenes increased dramatically with the onset of thinning, and that these phenomena continued in phase with each other thereafter. Hence, they “infer that the massive increase of O<sub>3</sub> flux [from the atmosphere to oblivion] during and following mastication is driven by loss of O<sub>3</sub> through chemical reactions with unmeasured terpenes or closely related BVOCs whose emissions were enhanced due to wounding [by the masticator].” Indeed, they say that “considered together, these observations provide a conclusive picture that the chemical loss of O<sub>3</sub> is due to reactions with BVOCs emitted in a similar manner as terpenes,” and that “we can conceive no other possible explanation for this behavior other than chemical O<sub>3</sub> destruction in and above the forest canopy by reactions with BVOCs.”

Goldstein *et al.* say their results “suggest that total reactive terpene emissions might be roughly a factor of 10 higher than the typically measured and modeled monoterpene emissions, making them larger than isoprene emissions on a global scale.” If this proves to be the case, it will be a most important finding, for it would mean that vegetative emissions of terpenes, which lead to the destruction of ozone, are significantly greater than vegetative emissions of isoprene, which lead to the creation of ozone (Poisson *et al.*, 2000). In addition, there is substantial evidence to suggest that the ongoing rise in the air’s CO<sub>2</sub> content may well lead to an overall reduction in vegetative isoprene emissions, while at the same time enhancing vegetative productivity, which may well lead to an overall increase in vegetative terpene emissions. As a result, there is reason to believe that the ongoing rise in the air’s CO<sub>2</sub> content will help to reduce the ongoing rise in the air’s O<sub>3</sub> concentration, which should be a boon to the entire biosphere.

In conclusion, a wealth of real-world evidence is beginning to suggest that both rising air temperatures and CO<sub>2</sub> concentrations significantly increase desirable vegetative BVOC emissions, particularly from trees, which constitute the most prominent photosynthetic force on the planet, and that this phenomenon has a large number of extremely important and highly beneficial biospheric consequences.

These findings further demonstrate that the biology of the earth influences the climate of the earth. Specifically, they reveal a direct connection between the metabolic activity of trees and the propensity for the atmosphere to produce clouds, the metabolic activity of lichens and the presence of sulfate aerosol particles in the atmosphere that reflect incoming solar radiation, and the increased presence of BVOCs caused by rising CO<sub>2</sub> and an increase in diffuse solar radiation, which leads to increased photosynthetic extraction of CO<sub>2</sub> from the air. In each case, the relationship is one that is self-protecting of the biosphere. This being the case, we wonder how anyone can presume to decide what should or should not be done about anthropogenic CO<sub>2</sub> emissions.

Additional information on this topic, including reviews of newer publications as they become available, can be found at <http://www.co2science.org/subject/a/aerosolsterr.php>.

### 2.8.4. Non-Biological (Anthropogenic)

There are several ways the activities of humanity lead to the creation of aerosols that have the potential to alter earth's radiation balance and affect its climate.

Contrails created in the wake of emissions from jet aircraft are one example. Minnis *et al.* (2004) have calculated that nearly all of the surface warming observed over the United States between 1975 and 1994 (0.54°C) may well be explained by aircraft-induced increases in cirrus cloud coverage over that period. If true, this result would imply that little to none of the observed U.S. warming over that period could be attributed to the concomitant increase in the air's CO<sub>2</sub> content.

Ship tracks, or bright streaks that form in layers of marine stratus clouds, are another example. They are created by emissions from ocean-going vessels; these persistent and highly reflective linear patches of low-level clouds generally tend to cool the planet (Ferek *et al.*, 1998; Schreier *et al.*, 2006). Averaged over the surface of the earth both day and night and over the year, Capaldo *et al.* (1999) calculated that this phenomenon creates a mean negative radiative forcing of -0.16 Wm<sup>-2</sup> in the Northern Hemisphere and -0.06 Wm<sup>-2</sup> in the Southern Hemisphere, which values are to be compared to the much larger positive radiative forcing of approximately 4 Wm<sup>-2</sup> due to a 300 ppm increase in the atmosphere's CO<sub>2</sub> concentration.

In some cases, the atmosphere over the sea also carries a considerable burden of anthropogenically produced aerosols from terrestrial sites. In recent years, attention to this topic has centered on highly polluted air from south and southeast Asia that makes its way over the northern Indian Ocean during the dry monsoon season. There has been much discussion about the impact of this phenomenon on regional climates. Norris (2001) looked at cloud cover as the ultimate arbiter of the various competing hypotheses, finding that daytime low-level oceanic cloud cover increased substantially over the last half of the past century in both the Northern and Southern Hemispheres at essentially all hours of the day. This finding is indicative of a pervasive net cooling effect.

Aerosol-generating human activities also have a significant impact on local, as well as more wide-ranging, climatic phenomena over land. Sahai (1998) found that although suburban areas of Nagpur, India had warmed over recent decades, the central part of the city had cooled, especially during the day, because of "increasing concentrations of suspended particulate matter." Likewise, outside of, but adjacent to, industrial complexes in the Po Valley of Italy, Facchini *et al.* (1999) found that water vapor was more likely to form on aerosols that had been altered by human-produced organic solutes, and that this

phenomenon led to the creation of more numerous and more highly reflective cloud droplets that had a tendency to cool the surface below them.

In a similar vein, Rosenfeld (2000) studied pollution tracks downwind of urban/industrial complexes in Turkey, Canada and Australia. His findings indicated that the clouds comprising these pollution tracks were composed of small droplets that suppressed precipitation by inhibiting further coalescence and ice precipitation formation. In commenting on this research, Toon (2000) pointed out that when clouds are composed of smaller droplets, they will not “rain out” as quickly and will therefore last longer and cover more of the earth, both of which effects tend to cool the globe.

In reviewing these and other advances in the field of anthropogenic aerosol impacts on clouds, Charlson *et al.* (2001) note that droplet clouds “are the most important factor controlling the albedo (reflectivity) and hence the temperature of our planet.” They say man-made aerosols “have a strong influence on cloud albedo, with a global mean forcing estimated to be of the same order (but opposite in sign) as that of greenhouse gases,” and “both the forcing [of this man-induced impetus for cooling] and its magnitude may be even larger than anticipated.” They rightly warn that lack of inclusion of the consequences of these important phenomena in climate change deliberations “poses additional uncertainty beyond that already recognized by the Intergovernmental Panel on Climate Change, making the largest uncertainty in estimating climate forcing even larger.”

Another assessment of the issue was provided by Ghan *et al.* (2001), who studied both the positive radiative forcings of greenhouse gases and the negative radiative forcings of anthropogenic aerosols and reported that current best estimates of “the total global mean present-day anthropogenic forcing range from  $3 \text{ Wm}^{-2}$  to  $-1 \text{ Wm}^{-2}$ ,” which represents everything from a modest warming to a slight cooling. After performing their own analysis of the problem, they reduced the magnitude of this range somewhat but the end result still stretched from a small cooling influence to a modest impetus for warming. “Clearly,” they concluded, “the great uncertainty in the radiative forcing must be reduced if the observed climate record is to be reconciled with model predictions and if estimates of future climate change are to be useful in formulating emission policies.”

Another pertinent observation comes from Stanhill and Cohen (2001), who reviewed numerous

solar radiation measurement programs around the world to see if there had been any trend in the mean amount of solar radiation falling on the surface of the earth over the past half-century. They determined there was a significant 50-year downward trend in this parameter that “has globally averaged  $0.51 \pm 0.05 \text{ Wm}^{-2}$  per year, equivalent to a reduction of 2.7 percent per decade, [which] now totals  $20 \text{ Wm}^{-2}$ .” They also concluded that the most probable explanation for this observation “is that increases in man-made aerosols and other air pollutants have changed the optical properties of the atmosphere, in particular those of clouds.”

Although this surface-cooling influence is huge, it falls right in the mid-range of a similar solar radiative perturbation documented by Satheesh and Ramanathan (2000) in their study of the effects of human-induced pollution over the tropical northern Indian Ocean, where they determined that “mean clear-sky solar radiative heating for the winters of 1998 and 1999 decreased at the ocean surface by 12 to  $30 \text{ Wm}^{-2}$ .” Hence, the decline in solar radiation reception discovered by Stanhill and Cohen could well be real. And if it is, it represents a *tremendous* counter-influence to the enhanced greenhouse effect produced by the contemporaneous increase in atmospheric  $\text{CO}_2$  concentration.

In a more recent study, Ruckstuhl *et al.* (2008) presented “observational evidence of a strong decline in aerosol optical depth over mainland Europe during the last two decades of rapid warming”—when air temperatures rose by about  $1^\circ\text{C}$  after 1980—via analyses of “aerosol optical depth measurements from six specific locations and surface irradiance measurements from a large number of radiation sites in Northern Germany and Switzerland.”

In consequence of the observed decline in aerosol concentration of up to 60 percent, the authors state there was “a statistically significant increase of solar irradiance under cloud-free skies since the 1980s.” The value of the direct aerosol effect of this radiative forcing was approximately  $0.84 \text{ Wm}^{-2}$ ; and when combined with the concomitant cloud-induced radiative forcing of about  $0.16 \text{ Wm}^{-2}$ , it led to a total radiative surface climate forcing over mainland Europe of about  $1 \text{ Wm}^{-2}$  that “most probably strongly contributed to the recent rapid warming in Europe.” Cleaning up significantly polluted skies, it seems, can provide an even greater impetus for climate warming than does the carbon dioxide that is concurrently emitted to them, as has apparently been the case over mainland Europe for the past quarter-century.

Anthropogenic aerosols plainly have a major effect on climate. The evidence is clear: contrails created by emissions from jet aircraft, ship tracks created by ocean-going vessels, and air pollution from terrestrial sources all have effects on temperatures that rival or exceed the likely effect of rising CO<sub>2</sub> levels. With the progress that has been made in recent years in reducing air pollution in developed countries, it is possible the lion's share of the warming has likely been produced by the removal from the atmosphere of *true* air pollutants.

### 2.8.5. Non-Biological (Natural)

We conclude our section on aerosols with a brief discussion of a non-biological, naturally produced aerosol—dust. Dust is about as natural and ubiquitous a substance as there is. One might think we would have a pretty good handle on what it does to earth's climate as it is moved about by the planet's ever-active atmosphere. But such is not the case, as was made strikingly clear by Sokolik (1999), who with the help of nine colleagues summarized the sentiments of a number of scientists who have devoted their lives to studying the subject.

Sokolik notes state-of-the-art climate models “rely heavily on oversimplified parameterizations” of many important dust-related phenomena, “while ignoring others.” As a result, the group concludes, “the magnitude and even the sign of dust net direct radiative forcing of climate remains unclear.”

According to Sokolik, there are a number of unanswered questions about airborne dust, including: (1) How does one quantify dust emission rates from both natural and anthropogenic (disturbed) sources with required levels of temporal and spatial resolution? (2) How does one accurately determine the composition, size, and shape of dust particles from ground-based and aircraft measurements? (3) How does one adequately measure and model light absorption by mineral particles? (4) How does one

link the ever-evolving optical, chemical, and physical properties of dust to its life cycle in the air? (5) How does one model complex multi-layered aerosol stratification in the dust-laden atmosphere? (6) How does one quantify airborne dust properties from satellite observations?

In discussing these questions, Sokolik makes some interesting observations, noting that: (1) what is currently known (or believed to be known) about dust emissions “is largely from micro-scale experiments and theoretical studies,” (2) new global data sets are needed to provide “missing information” on input parameters (such as soil type, surface roughness, and soil moisture) required to model dust emission rates, (3) improvements in methods used to determine some of these parameters are also “sorely needed,” (4) how to adequately measure light absorption by mineral particles is still an “outstanding problem,” and (5) it “remains unknown how well these measurements represent the light absorption by aerosol particles suspended in the atmosphere.”

It is easy to understand why Sokolik says “a challenge remains in relating dust climatology and the processes controlling the evolution of dust at all relevant spatial/temporal scales needed for chemistry and climate models,” for until this challenge is met, we will but “see through a glass, darkly,” especially when it comes to trying to discern the effects of airborne dust on earth’s climate.

Vogelmann *et al.* (2003) reiterate that “mineral aerosols have complex, highly varied optical properties that, for equal loadings, can cause differences in the surface IR flux [of] between 7 and 25  $\text{Wm}^{-2}$  (Sokolik *et al.*, 1998),” while at the same time acknowledging that “only a few large-scale climate models currently consider aerosol IR effects (e.g., Tegen *et al.*, 1996; Jacobson, 2001) despite their potentially large forcing.”

Vogelmann *et al.* “use[d] high-resolution spectra to obtain the IR radiative forcing at the surface for aerosols encountered in the outflow from northeastern Asia,” based on measurements made by the Marine-Atmospheric Emitted Radiance Interferometer aboard the NOAA Ship *Ronald H. Brown* during the Aerosol Characterization Experiment-Asia. This work led them to conclude that “daytime surface IR forcings are often a few  $\text{Wm}^{-2}$  and can reach almost 10  $\text{Wm}^{-2}$  for large aerosol loadings,” which values, in their words, “are comparable to or larger than the 1 to 2  $\text{Wm}^{-2}$  change in the globally averaged surface IR forcing caused by greenhouse gas increases since pre-industrial times.” And in a massive understatement of

fact, Vogelmann *et al.* say that these results “highlight the importance of aerosol IR forcing which should be included in climate model simulations.”

Another aspect of the dust-climate connection centers on the African Sahel, which has figured prominently in discussions of climate change ever since it began to experience extended drought conditions in the late 1960s and early ‘70s. Initial studies of the drought attributed it to anthropogenic factors such as overgrazing of the region’s fragile grasses, which tends to increase surface albedo, which was envisioned to reduce precipitation, resulting in a further reduction in the region’s vegetative cover, and so on (Otterman, 1974; Charney, 1975). This scenario, however, was challenged by Jackson and Idso (1975) and Idso (1977) on the basis of empirical observations; while Lamb (1978) and Folland *et al.* (1986) attributed the drought to large-scale atmospheric circulation changes triggered by multidecadal variations in sea surface temperature.

Building on the insights provided by these latter investigations, Giannini *et al.* (2003) presented evidence based on an ensemble of integrations with a general circulation model of the atmosphere—forced only by the observed record of sea surface temperature—which suggested that the “variability of rainfall in the Sahel results from the response of the African summer monsoon to oceanic forcing amplified by land-atmosphere interaction.” The success of this analysis led them to conclude that “the recent drying trend in the semi-arid Sahel is attributed to warmer-than-average low-latitude waters around Africa, which, by favoring the establishment of deep convection over the ocean, weaken the continental convergence associated with the monsoon and engender widespread drought from Senegal to Ethiopia.” They further concluded that “the secular change in Sahel rainfall during the past century was not a direct consequence of regional environmental change, anthropogenic in nature or otherwise.”

In a companion article, Prospero and Lamb (2003) report that measurements made from 1965 to 1998 in the Barbados trade winds show large interannual changes in the concentration of dust of African origin that are highly anticorrelated with the prior year’s rainfall in the Soudano-Sahel. They say the 2001 IPCC report “assumes that natural dust sources have been effectively constant over the past several hundred years and that all variability is attributable to human land-use impacts.” But “there is little firm evidence to support either of these

assumptions,” they say, and their findings demonstrate why: The IPCC assumptions are wrong.

Clearly, much remains to be learned about the climatic impacts of dust before anyone can place any confidence in the climatic projections of the IPCC. Additional information on this topic, including reviews of newer publications as they become available, can be found at [http://www.co2science.org/subject/a/aerononbio nat.php](http://www.co2science.org/subject/a/aerononbio%20nat.php).

## Observations: Temperature Records

---

### 3. Observations: Temperature Records

- 3.1. Paeloclimatic Data
- 3.2. Past 1,000 Years
- 3.3. Urban Heat Island
- 3.4. Fingerprints
- 3.5. Satellite Data
- 3.6. Arctic
- 3.7. Antarctic

#### Introduction

The Intergovernmental Panel on Climate Change (IPCC) claims to have found evidence in paeloclimatic data that higher levels of atmospheric CO<sub>2</sub> can cause or amplify an increase in global temperatures (IPCC, 2007-I, Chapter 6). The IPCC further claims to have evidence of an anthropogenic effect on climate in the earth's temperature history during the past century (Chapters 3, 9), in the pattern (or "fingerprint") of more recent warming (Chapter 9, Section 9.4.1.4), in data from land-based temperature stations and satellites (Chapter 3), and in the temperature records of the Arctic region and Antarctica where models predict anthropogenic global warming should be detected first (Chapter 11, Section 8). In this chapter, we critically examine the data used to support each of these claims, starting with the relationship between CO<sub>2</sub> and temperature in ancient climates.

#### 3.1. Paeloclimatic Data

Rothman (2002) derived a 500-million-year history of the air's CO<sub>2</sub> content based on considerations related to the chemical weathering of rocks, volcanic and metamorphic degassing, and the burial of organic carbon, along with considerations related to the isotopic content of organic carbon and strontium in marine sedimentary rocks. The results of this analysis suggest that over the majority of the half-billion-year record, earth's atmospheric CO<sub>2</sub> concentration fluctuated between values that were two to four times greater than those of today at a dominant period on the order of 100 million years. Over the last 175 million years, however, the data depict a long-term decline in the air's CO<sub>2</sub> content.

Rothman reports that the CO<sub>2</sub> history "exhibits no systematic correspondence with the geologic record of climatic variations at tectonic time scales." A visual examination of Rothman's plot of CO<sub>2</sub> and concomitant major cold and warm periods indicates the three most striking peaks in the air's CO<sub>2</sub> concentration occur either totally or partially within periods of time when earth's climate was relatively cool.

A more detailed look at the most recent 50 million years of earth's thermal and CO<sub>2</sub> history was prepared by Pagani *et al.* (2005). They found about 43 million years ago, the atmosphere's CO<sub>2</sub> concentration was approximately 1400 ppm and the oxygen isotope ratio (a proxy for temperature) was

## Climate Change Reconsidered

**Figure 3.1.** Temperature history derived by Petit *et al.* (1999) from an ice core extracted from the Russian Vostok drilling station in East Antarctica.

about 1.0 per mil. Then, over the next ten million years, the air's CO<sub>2</sub> concentration experienced three huge oscillations on the order of 1000 ppm from peak to valley. In the first two oscillations, temperature did not appear to respond at all to the change in CO<sub>2</sub>, exhibiting an uninterrupted slow decline. Following the third rise in CO<sub>2</sub>, however, temperatures seemed to respond, but in the direction opposite to what the greenhouse theory of global warming predicts, as the rise in CO<sub>2</sub> was followed by the sharpest drop in temperature of the entire record.

Following this large drop in temperature between 34 and 33 million years before present (Ma BP), the oxygen isotope ratio hovered around a value of 2.7 per mil from about 33 to 26 Ma BP, indicating little change in temperature over that period. The corresponding CO<sub>2</sub> concentration, on the other hand, experienced about a 500 ppm increase around 32 Ma BP, after which it dropped 1,000 ppm over the next two million years, only to rise again by a few hundred ppm, refuting – three times – the CO<sub>2</sub>-induced global warming hypothesis. Next, around 26 Ma BP, the oxygen isotope ratio dropped to about 1.4 per mil (implying a significant *rise* in temperature), during which time the air's CO<sub>2</sub> content declined. From 24 Ma BP to the end of the record at 5 Ma BP, there were relatively small variations in atmospheric CO<sub>2</sub> content but relatively large variations in oxygen isotope values, both up and down. All of these many observations, according to Pagani *et al.* (2005), “argue for a decoupling between global climate and CO<sub>2</sub>.”

Moving closer to the modern era, Fischer *et al.* (1999) examined trends of atmospheric CO<sub>2</sub> and air temperature derived from Antarctic ice core data that extended back in time a quarter of a million years.

Over this period, the three most dramatic warming events experienced on earth were the terminations of the last three ice ages; and for each of these climatic transitions, earth's air temperature always rose well in advance of the increase in atmospheric CO<sub>2</sub>. In fact, the air's CO<sub>2</sub> content did not begin to rise until 400 to 1,000 years after the planet began to warm.

Another research team, Petit *et al.* (1999), studied the beginnings rather than the ends of glacial ages. They discovered that during all glacial inceptions of the past half million years, temperature always dropped well before the decline in the air's CO<sub>2</sub> concentration. They said their data indicate that “the CO<sub>2</sub> decrease lags the temperature decrease by several thousand years.” Petit *et al.* also found the current interglacial is the coolest of the five most recent such periods. In fact, the peak temperatures of the four interglacials that preceded it were, on average, more than 2°C warmer than that of the one in which we currently live. (See Figure 3.1.)

Figure 3.1 tells us three things about the current warm period. First, temperatures of the last decades of the twentieth century were “unprecedented” or “unusual” only because they were *cooler* than during past interglacial peaks. Second, the current temperature of the globe cannot be taken as evidence of an anthropogenic effect since it was warmer during parts of all preceding interglacials for which we have good proxy temperature data. And third, the higher temperatures of the past four interglacials cannot be attributed to higher CO<sub>2</sub> concentrations caused by some non-human influence because atmospheric CO<sub>2</sub> concentrations during all four prior interglacials never rose above approximately 290 ppm, whereas the air's CO<sub>2</sub> concentration today stands at nearly 380 ppm.

Likewise, Mudelsee (2001) determined that

variations in atmospheric CO<sub>2</sub> concentration lagged behind variations in air temperature by 1,300 to 5,000 years over the past 420,000 years. During certain climatic transitions characterized by rapid warmings of several degrees Centigrade, which were followed by slower coolings that returned the climate to essentially full glacial conditions, Staufer *et al.* (1998) observed the atmospheric CO<sub>2</sub> concentration derived from ice core records typically varied by less than 10 ppm. They, too, considered the CO<sub>2</sub> perturbations to have been caused by the changes in climate, rather than vice versa.

Other studies have also demonstrated this reverse coupling of atmospheric CO<sub>2</sub> and temperature (e.g., Cheddadi *et al.*, 1998; Gagan *et al.*, 1998; Raymo *et al.*, 1998), where temperature is the independent variable that appears to induce changes in CO<sub>2</sub>. Steig (1999) noted cases between 7,000 and 5,000 years ago when atmospheric CO<sub>2</sub> concentrations increased by just over 10 ppm at a time when temperatures in both hemispheres cooled.

Caillon *et al.* (2003) measured the isotopic composition of argon – specifically, δ<sup>40</sup>Ar, which they argue “can be taken as a climate proxy, thus providing constraints about the timing of CO<sub>2</sub> and climate change” – in air bubbles in the Vostok ice core over the period that comprises what is called Glacial Termination III, which occurred about 240,000 years ago. The results of their tedious but meticulous analysis led them to conclude that “the CO<sub>2</sub> increase lagged Antarctic deglacial warming by 800 ± 200 years.” This finding, in their words, “confirms that CO<sub>2</sub> is not the forcing that initially drives the climatic system during a deglaciation.”

Indermuhle *et al.* (1999) determined that after the termination of the last great ice age, the CO<sub>2</sub> content of the air gradually rose by approximately 25 ppm in almost linear fashion between 8,200 and 1,200 years ago, over a period of time that saw a slow but steady *decline* in global air temperature. On the other hand, when working with a high-resolution temperature and atmospheric CO<sub>2</sub> record spanning the period 60 to 20 thousand years ago, Indermuhle *et al.* (2000) discovered four distinct periods when temperatures rose by approximately 2°C and CO<sub>2</sub> rose by about 20 ppm. However, one of the statistical tests they performed on the data suggested that the shifts in the air’s CO<sub>2</sub> content during these intervals *followed* the shifts in air temperature by approximately 900 years; while a second statistical test yielded a mean CO<sub>2</sub> lag time of 1,200 years.

Another pertinent study is that of Siegenthaler *et*

*al.* (2005), who analyzed CO<sub>2</sub> and proxy temperature (δD, the ratio of deuterium to hydrogen) data derived from an ice core in Antarctica. Results of their analysis revealed a coupling of Antarctic temperature and CO<sub>2</sub> in which they obtained the best correlation between CO<sub>2</sub> and temperature “for a lag of CO<sub>2</sub> of 1900 years.” Specifically, over the course of glacial terminations V to VII, they indicate that “the highest correlation of CO<sub>2</sub> and deuterium, with use of a 20-ky window for each termination, yields a lag of CO<sub>2</sub> to deuterium of 800, 1600, and 2800 years, respectively.” In addition, they note that “this value is consistent with estimates based on data from the past four glacial cycles,” citing in this regard the work of Fischer *et al.* (1999), Monnin *et al.* (2001) and Caillon *et al.* (2003).

These observations seem to undermine the IPCC’s claims that the CO<sub>2</sub> produced by the burning of fossil fuels will lead to catastrophic global warming. Nevertheless, Siegenthaler *et al.* stubbornly state that the new findings “do not cast doubt ... on the importance of CO<sub>2</sub> as a key amplification factor of the large observed temperature variations of glacial cycles.” The previously cited Caillon *et al.* also avoid the seemingly clear implication of their own findings, that CO<sub>2</sub> doesn’t *cause* global warming. We find such disclaimers disingenuous.

When temperature is found to lead CO<sub>2</sub> by thousands of years, during both glacial terminations and inceptions (Genthon *et al.*, 1987; Fischer *et al.*, 1999; Petit *et al.*, 1999; Indermuhle *et al.*, 2000; Monnin *et al.*, 2001; Mudelsee, 2001; Caillon *et al.*, 2003), it is extremely likely that CO<sub>2</sub> plays only a minor role in enhancing temperature changes that are induced by something else. Compared with the mean conditions of the preceding four interglacials, there is currently 90 ppm more CO<sub>2</sub> in the air and yet it is currently more than 2°C colder than it was then. There is no way these real-world observations can be construed to suggest that a significant increase in atmospheric CO<sub>2</sub> would necessarily lead to *any* global warming, much less the catastrophic type that is predicted by the IPCC.

### 3.2. Past 1,000 Years

The IPCC claims “average Northern Hemisphere temperatures during the second half of the 20<sup>th</sup> century were *very likely* higher than during any other 50-year period in the past 500 years and *likely* the highest in at least the past 1,300 years [italics in the original]” (IPCC, 2007-I, p. 9). Later in that report, the IPCC says “the warming observed after 1980 is unprecedented compared to the levels measured in the previous 280 years” (p. 466) and “it is likely that the 20<sup>th</sup> century was the warmest in at least the past 1.3 kyr. Considering the recent instrumental and longer proxy evidence together, it is very likely that average NH [Northern Hemisphere] temperatures during the second half of the 20<sup>th</sup> century were higher than for any other 50-year period in the last 500 years” (p. 474).

The notions that the warming of the second half of the twentieth century was “unprecedented” and that temperatures during the twentieth century were “the warmest in at least the past 1.3 kyr” will be questioned and tested again and again in the present report. We start here with an examination of the work of Mann *et al.* (1998, 1999, 2004) and Mann and Jones (2003), which captured the attention of the world in the early years of the twenty-first century and upon which the IPCC still relies heavily for its conclusions. We then present a thorough examination of temperature records around the world to test the IPCC’s claim that there was no Medieval Warm Period during which temperatures exceeded those of the twentieth century, starting with data from Africa and then from Antarctica, the Arctic, Asia, Europe, North America, and finally South America. We return to Antarctica and the Arctic at the end of this chapter to discuss more recent temperature trends.

### 3.2.1. The Hockey Stick

One of the most famous pieces of “evidence” for anthropogenic global warming (AGW) brought forth in recent years was the “hockey stick” diagram of Michael Mann and colleagues (Mann *et al.*, 1998; Mann *et al.*, 1999; Mann and Jones, 2003). (See Figure 3.2.1.) Because the graph played such a big role in mobilizing concern over global warming in the years since it was first released, and since the IPCC continues to rely upon and defend it in its latest report (see IPCC, 2007-I, pp. 466-471), we devote some space here to explaining its unusual origins and subsequent rejection by much of the scientific community.

The hockey stick graph first appeared in a 1998 study led by Michael Mann, a young Ph.D. from the University of Massachusetts (Mann *et al.*, 1998). Mann and his colleagues used several temperature proxies (but primarily tree rings) as a basis for assessing past temperature changes from 1000 to 1980. They then grafted the surface temperature record of the twentieth century onto the pre-1980 proxy record. The effect was visually dramatic. (See Figure 3.2.1.) Gone were the difficult-to-explain Medieval Warming and the awkward Little Ice Age. Mann gave us nine hundred years of stable global temperatures—until about 1910. Then the twentieth century’s temperatures seem to rocket upward out of control.

The Mann study gave the Clinton administration the quick answer it wanted to the argument that natural climate variations exceed whatever effect human activity might have had in the twentieth century by claiming, quite simply, that even the very biggest past historic changes in temperatures *simply never happened*. The Clinton administration featured it as the first visual in the *U.S. National Assessment of the Potential Consequences of Climate Variability and Change* (later published as *Climate Change Impacts on the United States: The Potential Consequences of Climate Variability and Change* (National Assessment Synthesis Team, 2001)). Mann was named an IPCC lead author and his graph was prominently displayed in the IPCC’s Third Assessment Report (IPCC-TAR, 2001), and it subsequently appeared in Al Gore’s movie, “An Inconvenient Truth.” Mann was named an editor of *The Journal of Climate*, a major professional journal, signaling the new order of things to the rest of his profession.

**Figure 3.2.1.** The ‘hockey stick’ temperature graph was used by the IPCC to argue that the twentieth century was unusually warm (IPCC-TAR 2001, p. 3).

The “hockey stick” graph was severely critiqued by two Canadian nonscientists who were well trained in statistics—metals expert Stephen McIntyre of Toronto and economist Ross McKittrick from Canada’s University of Guelph (McIntyre and McKittrick, 2003, 2005). McIntyre and McKittrick requested the original study data from Mann. It was provided—haltingly and incompletely—indicating that no one else had previously requested the data for a peer review in connection with the original publication in *Nature*. They found the data did not produce the claimed results “due to collation errors, unjustifiable truncation or extrapolation of source data, obsolete data, geographical location errors, incorrect calculation of principal components and other quality control defects.”

In their exchanges with the Mann research team, McIntyre and McKittrick learned that the Mann studies give by far the heaviest weight to tree-ring data from 14 sites in California’s Sierra Nevada Mountains. At those sites, ancient, slow-growing, high-elevation bristlecone pine trees (which can live 5,000 years) showed a strong twentieth century growth spurt. The growth ring data from those trees were collected and presented in a 1993 paper by Donald Graybill and Sherwood Idso. Significantly, that paper was titled “Detecting the Aerial

Fertilization Effect of Atmospheric CO<sub>2</sub> Enrichment in Tree Ring Chronologies” (Graybill and Idso, 1993). Graybill and Idso specifically pointed out in their study that neither local nor regional temperature changes could account for the twentieth century growth spurt in those already-mature trees. But CO<sub>2</sub> acts like fertilizer for trees and plants and also increases their water-use efficiency. All trees with more CO<sub>2</sub> in their atmosphere are very likely to grow more rapidly. Trees like the high-altitude bristlecone pines, on the margins of both moisture and fertility, are likely to exhibit very strong responses to CO<sub>2</sub> enrichment—which was the point of the Graybill and Idso study.

McIntyre and McKittrick demonstrated that removing the bristlecone pine tree data eliminates the distinctive rise at the end of the “hockey stick.” Mann and his coauthors could hardly have escaped knowing the CO<sub>2</sub> reality, since it was clearly presented in the title of the study from which they derived their most heavily weighted data sites. Using corrected and updated source data, McIntyre and McKittrick recalculated the Northern Hemisphere temperature index for the period 1400–1980 using Mann’s own methodology. This was published in *Energy & Environment*, with the data refereed by the World Data Center for Paleoclimatology (McIntyre and

McKittrick, 2003). “The major finding is that the [warming] in the early 15th century exceed[s] any [warming] in the 20th century,” report McIntyre and McKittrick. In other words, the Mann study was fundamentally wrong.

Mann and his team were forced to publish a correction in *Science* admitting to errors in their published proxy data, but they still claimed that “none of these errors affect our previously published results” (Mann *et al.*, 2004). That claim, too, was contradicted by later work by McIntyre and McKittrick (2005), by statistics expert Edward Wegman (Wegman *et al.*, 2006), and by a National Academy of Sciences report (NAS, 2006). The NAS skipped lightly over the errors of the hockey-stick analysis and concluded it showed only that the twentieth century was the warmest in 400 years, but this conclusion is hardly surprising, since the Little Ice Age was near its nadir 400 years ago, with temperatures at their lowest. It was the claim that temperatures in the second half of the twentieth century were the highest in the last millennium that properly generated the most attention.

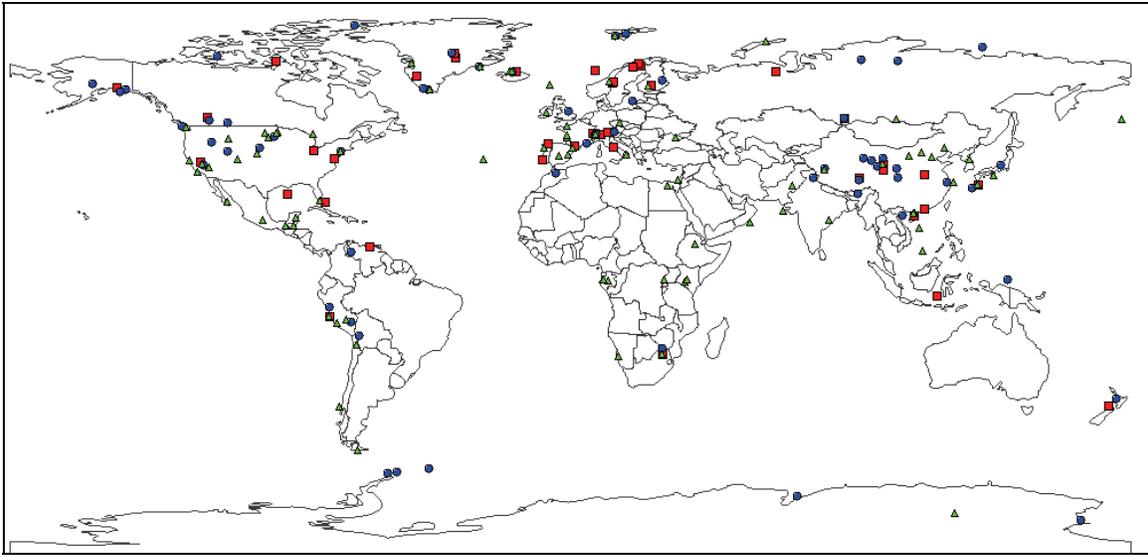

Where does the IPCC stand today regarding the “hockey stick”? Surprisingly, it still defends and relies on it. It appears in a series of graphs on page 467. Critiques by Soon and Baliunas (2003) and McIntyre and McKittrick are reported briefly but both are dismissed, the first because “their qualitative approach precluded any quantitative summary of the evidence at precise times,” and the latter by citing a defense of Mann by Wahl and Ammann (2006) “who show the impact on the amplitude of the final reconstruction is very small ( $\sim 0.05^{\circ}\text{C}$ )” (IPCC, 2007-I, p. 466). The Medieval Warm Period appears only in quotes in the index and body of the IPCC 2007-I report. In the glossary (Annex I), it is defined as “an interval between AD 1000 and 1300 in which some Northern Hemisphere regions were warmer than during the Little Ice Age that followed” (p. 949). In the text it is referred to as “the so-called ‘Medieval Warm Period.’” In a boxed discussion of “Hemispheric Temperatures in the ‘Medieval Warm Period,’” it says “medieval warmth was heterogeneous in terms of its precise timing and regional expression” and “the warmest period prior to the 20th century very likely occurred between 950 and 1100, but temperatures were probably between  $0.1^{\circ}\text{C}$  and  $0.2^{\circ}\text{C}$  below the 1961 to 1990 mean and significantly below the level shown by instrumental data after 1980” (p. 469).

One can disprove the IPCC’s claim by demonstrating that about 1,000 years ago, there was a world-wide Medieval Warm Period (MWP) when global temperatures were equally as high as or higher than they were over the latter part of the twentieth century, despite there being approximately 25 percent less  $\text{CO}_2$  in the atmosphere than there is today. This real-world fact conclusively demonstrates there is nothing unnatural about the planet’s current temperature, and that whatever warming occurred during the twentieth century was likely caused by the recurrence of whatever cyclical phenomena created the equal or even greater warmth of the MWP.

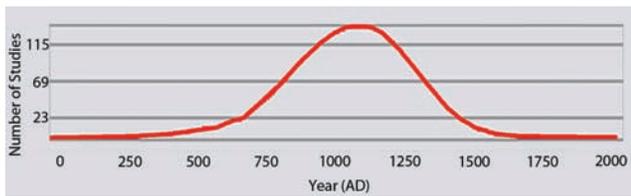

The degree of warming and climatic influence during the MWP varied from region to region and, hence, its consequences were manifested in several ways. But that it occurred and was a global phenomenon is certain; there are literally hundreds of peer-reviewed scientific articles that bear witness to this truth.

The Center for the Study of Carbon Dioxide and Global Change has analyzed more than 200 peer-reviewed research papers produced by more than 660 individual scientists working in 385 separate institutions from 40 different countries that comment on the MWP. Figure 3.2.2 illustrates the spatial distribution of these studies. Squares denote studies where the scientists who conducted the work provided quantitative data that enable one to determine the degree by which the peak temperature of the MWP differed from the peak temperature of the Current Warm Period (CWP). Circles denote studies where the scientists who conducted the work provided qualitative data that enable one to determine which of the two periods was warmer, but not by how much. Triangles denote studies where the MWP was evident in the study’s data, but the data did not provide a means by which the warmth of the MWP could be compared with that of the CWP. The third category includes studies that are based on data related to parameters other than temperature, such as precipitation. As can be seen from the figure, evidence of the MWP has been uncovered at locations throughout the world, revealing the truly global nature of this phenomenon.

A second question often posed with respect to the MWP is: When did it occur? A histogram of the timeframe (start year to end year) associated with the MWP of the studies plotted in Figure 3.2.2 is shown in Figure 3.2.3. The peak timeframe of all studies occurs around 1050 AD, within a more generalized 800 to 1300 AD warm era.

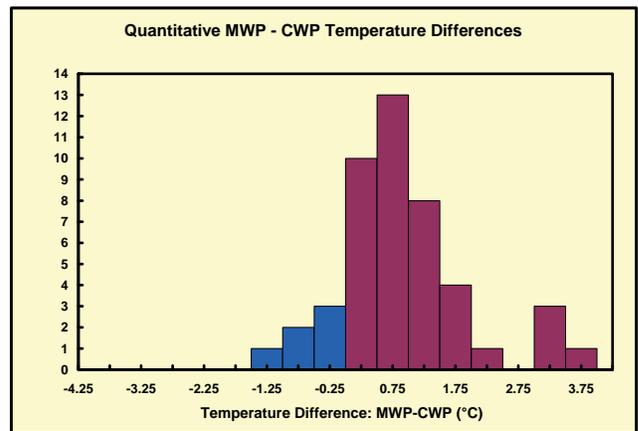

**Figure 3.2.2.** Plot of the locations of proxy climate studies for which (a) quantitative determinations of the temperature difference between the MWP and CWP can be made (squares), (b) qualitative determinations of the temperature difference between the MWP and CWP can be made (circles), and (c) neither quantitative nor qualitative determinations can be made, with the studies simply indicating that the Medieval Warm Period did indeed occur in the studied region (triangles).

**Figure 3.2.3.** Histogram showing the timeframe associated with all MWP studies plotted in Figure 3.2.2.

With respect to how warm it was during this period, we have plotted the frequency distribution of all MWP-CWP temperature differentials from all quantitative studies (squares) shown in Figure 3.2.2 to create Figure 3.2.4. This figure reveals there are a few studies in which the MWP was determined to have been cooler than the CWP, but the vast majority of the temperature differentials are positive, indicating the MWP was warmer than the CWP. The average of all such differentials is  $1.01^{\circ}\text{C}$ , while the median is  $0.90^{\circ}\text{C}$ .

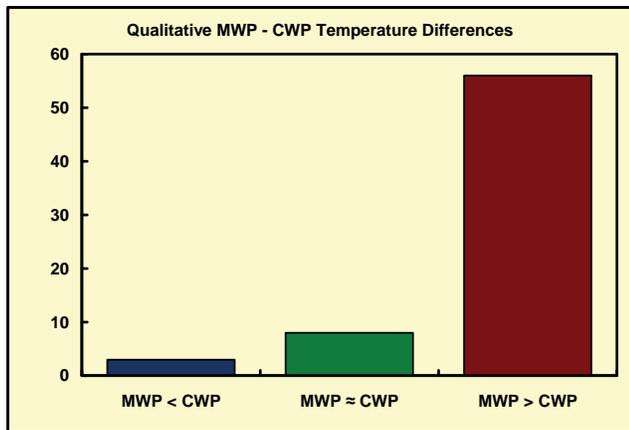

We can further generalize the superior warmth of the MWP by analyzing the qualitative studies in Figure 3.2.2, which we have done in Figure 3.2.5. Here we have plotted the number of studies in Figure 3.2.2 in which the MWP was warmer than, cooler than, or about the same as, the CWP, based upon data

**Figure 3.2.4.** The distribution, in  $0.5^{\circ}\text{C}$  increments, of studies that allow one to identify the degree by which peak Medieval Warm Period temperatures either exceeded or fell short of peak Current Warm Period temperatures.

presented by the authors of the original works. The vast majority of studies indicates the MWP was warmer than the CWP.

It is often claimed that temperatures over the latter part of the twentieth century were higher than those experienced at any other time over the past one to two millennia. Based upon the synthesis of real-world data presented here (and hereafter), however, that claim is seen to be false.

**Figure 3.2.5.** The distribution of studies that allow one to determine whether peak Medieval Warm Period temperatures were warmer than, equivalent to, or cooler than peak Current Warm Period temperatures.

In the rest of this section, we highlight the results of studies from regions across the globe that show the existence of a Medieval Warm Period. Additional information on this topic, including reviews on the Medieval Warm Period not discussed here, can be found at [http://www.co2science.org/subject/m/subject\\_m.php](http://www.co2science.org/subject/m/subject_m.php) under the heading Medieval Warm Period.

### 3.2.2. Africa

Based on the temperature and water needs of the crops that were cultivated by the first agropastoralists of southern Africa, Huffman (1996) constructed a climate history of the region based on archaeological evidence acquired from various Iron Age settlements. In the course of completing this project, dated relic evidence of the presence of cultivated sorghum and millets was considered by Huffman to be so strong as to essentially prove that the climate of the subcontinent-wide region must have been warmer and

wetter than it is today from approximately AD 900-1300, for these crops cannot be grown in this part of southern Africa under current climatic conditions, which are much too cool and dry.

Other evidence for this conclusion comes from Tyson *et al.* (2000), who obtained a quasi-decadal record of oxygen and carbon-stable isotope data from a well-dated stalagmite of Cold Air Cave in the Makapansgat Valley (30 km southwest of Pietersburg, South Africa), which they augmented with five-year-resolution temperature data that they reconstructed from color variations in banded growth-layer laminations of the stalagmite that were derived from a relationship calibrated against actual air temperatures obtained from a surrounding 49-station climatological network over the period 1981-1995, which had a correlation of +0.78 that was significant at the 99 percent confidence level. This record revealed the existence of a significantly warmer-than-present period that began prior to AD 1000 and lasted to about AD 1300. Tyson *et al.* report that the “maximum warming at Makapansgat at around 1250 produced conditions up to 3-4°C hotter than those of the present.”

In a similar study, Holmgren *et al.* (2001) derived a 3,000-year temperature record for South Africa that revealed several multi-century warm and cold periods. They found a dramatic warming at approximately AD 900, when temperatures reached a level that was 2.5°C higher than that prevailing at the time of their analysis of the data.

Lamb *et al.* (2003) provided strong evidence for the hydrologic fingerprint of the Medieval Warm Period in Central Kenya in a study of pollen data obtained from a sediment core taken from Crescent Island Crater, which is a sub-basin of Lake Naivasha. Of particular interest in this regard is the strong similarity between their results and those of Verschuren *et al.* (2000). The most striking of these correspondences occurred over the period AD 980 to 1200, when lake-level was at an 1,100-year low and woody taxa were significantly underrepresented in the pollen assemblage.

Holmgren *et al.* (2003) developed a 25,000-year temperature history from a stalagmite retrieved from Makapansgat Valley’s Cold Air Cave based on  $\delta^{18}\text{O}$  and  $\delta^{13}\text{C}$  measurements dated by  $^{14}\text{C}$  and high-precision thermal ionization mass spectrometry using the  $^{230}\text{Th}/^{234}\text{U}$  method. This work revealed, in the words of the nine researchers (together with our interspersed notes), that “cooling is evident from ~6 to 2.5ka [thousand years before present, during the

long interval of coolness that preceded the Roman Warm Period], followed by warming between 1.5 and 2.5 ka [the Roman Warm Period] and briefly at ~AD 1200 [the Medieval Warm Period, which followed the Dark Ages Cold Period],” after which “maximum Holocene cooling occurred at AD 1700 [the depth of the Little Ice Age].” They also note that “the Little Ice Age covered the four centuries between AD 1500 and 1800 and at its maximum at AD 1700 represents the most pronounced negative  $\delta^{18}\text{O}$  deviation in the entire record.” This new temperature record from far below the equator (24°S) reveals the existence of all of the major millennial-scale oscillations of climate that are evident in data collected from regions surrounding the North Atlantic Ocean.

Two years later, Kondrashov *et al.* (2005) applied advanced spectral methods to fill data gaps and locate interannual and interdecadal periodicities in historical records of annual low- and high-water levels on the Nile River over the 1,300-year period AD 622-1922. In doing so, several statistically significant periodicities were noted, including cycles at 256, 64, 19, 12, 7, 4.2 and 2.2 years. With respect to the causes of these cycles, the three researchers say that the 4.2- and 2.2-year oscillations are likely due to El Niño-Southern Oscillation variations, that the 7-year cycle may be related to North Atlantic influences, and that the longer-period oscillations could be due to astronomical forcings. They also note that the annual-scale resolution of their results provides a “sharper and more reliable determination of climatic-regime transitions” in tropical east Africa, including the documentation of fairly abrupt shifts in river flow at the beginning and end of the Medieval Warm Period.

Ngomanda *et al.* (2007) derived high-resolution (<40 years) paleoenvironmental reconstructions for the past 1,500 years based on pollen and carbon isotope data obtained from sediment cores retrieved from Lakes Kamalete and Nguene in the lowland rainforest of Gabon. The nine researchers state that after a sharp rise at ~1200 cal yr BP, “A/H [aquatic/hygrophytic] pollen ratios showed intermediate values and varied strongly from 1150 to 870 cal yr BP, suggesting decadal-scale fluctuations in the water balance during the ‘Medieval Warm Period.’” Thereafter, lower A/H pollen ratios “characterized the interval from ~500 to 300 cal yr BP, indicating lower water levels during the ‘Little Ice Age.’” In addition, they report that “all inferred lake-level low stands, notably between 500 and 300 cal yr BP, are associated with decreases in the score of the TRFO [Tropical Rainforest] biome.”

In discussing their findings, Ngomanda *et al.* state that “the positive co-variation between lake level and rainforest cover changes may indicate a direct vegetational response to regional precipitation variability,” noting that “evergreen rainforest expansion occurs during wet intervals, with contraction during periods of drought.” It appears that in this part of Western Equatorial Africa, the Little Ice Age was a time of low precipitation, low lake levels, and low evergreen rainforest presence, while much the opposite was the case during the Medieval Warm Period, when fluctuating wet-dry conditions led to fluctuating lake levels and a greater evergreen rainforest presence.

Placing these findings within a broader temporal context, Ngomanda *et al.* additionally note that “rainforest environments during the late Holocene in western equatorial Africa are characterized by successive millennial-scale changes according to pollen (Elenga *et al.*, 1994, 1996; Reynaud-Farrera *et al.*, 1996; Maley and Brenac, 1998; Vincens *et al.*, 1998), diatom (Nguetsop *et al.*, 2004), geochemical (Delegue *et al.*, 2001; Giresse *et al.*, 1994), and sedimentological data (Giresse *et al.*, 2005; Wirmann *et al.*, 2001),” and that “these changes were essentially driven by natural climatic variability (Vincens *et al.*, 1999; Elenga *et al.*, 2004).”

Esper *et al.* (2007) used *Cedrus atlantica* ring-width data “to reconstruct long-term changes in the Palmer Drought Severity Index (PDSI) over the past 953 years in Morocco, Northwest Africa.” They report “the long-term PDSI reconstruction indicates generally drier conditions before ~1350, a transition period until ~1450, and generally wetter conditions until the 1970s,” after which there were “dry conditions since the 1980s.” In addition, they determined that “the driest 20-year period reconstructed is 1237-1256 (PDSI = -4.2),” adding that “1981-2000 conditions are in line with this historical extreme (-3.9).” Also of significance, the six researchers note that “millennium-long temperature reconstructions from Europe (Buntgen *et al.*, 2006) and the Northern Hemisphere (Esper *et al.*, 2002) indicate that Moroccan drought changes are broadly coherent with well-documented temperature fluctuations including warmth during medieval times, cold in the Little Ice Age, and recent anthropogenic warming,” which latter coherency would tend to suggest that the peak warmth of the Medieval Warm Period was at least as great as that of the last two decades of the twentieth century throughout the entire Northern Hemisphere; and, if the coherency is strictly

interpreted, it suggests that the warmth of the MWP was likely even greater than that of the late twentieth century.

In light of these research findings, it appears that (1) the Medieval Warm Period did occur over wide reaches of Africa, and (2) the Medieval Warm Period was probably more extreme in Africa than has been the Current Warm Period to this point in time.

### 3.2.3. Antarctica

Hemer and Harris (2003) extracted a sediment core from beneath the Amery Ice Shelf, East Antarctica, at a point that is currently about 80 km landward of the location of its present edge. In analyzing the core's characteristics over the past 5,700 <sup>14</sup>C years, the two scientists observed a peak in absolute diatom abundance in general, and the abundance of *Fragilariopsis curta* in particular—which parameters, in their words, “are associated with increased proximity to an area of primary production, such as the sea-ice zone”—at about 750 <sup>14</sup>C yr B.P., which puts the time of maximum Ice Shelf retreat in close proximity to the historical time frame of the Medieval Warm Period.

Khim *et al.* (2002) likewise analyzed a sediment core removed from the eastern Bransfield Basin just off the northern tip of the Antarctic Peninsula, including grain size, total organic carbon content, magnetic susceptibility, biogenic silica content, <sup>210</sup>Pb geochronology, and radiocarbon (<sup>14</sup>C) age, all of which data clearly depicted, in their words, the presence of the “Little Ice Age and Medieval Warm period, together with preceding climatic events of similar intensity and duration.”

Hall and Denton (2002) mapped the distribution and elevation of surficial deposits along the southern Scott Coast of Antarctica in the vicinity of the Wilson Piedmont Glacier, which runs parallel to the coast of the western Ross Sea from McMurdo Sound north to

Granite Harbor. The chronology of the raised beaches they studied was determined from more than 60  $^{14}\text{C}$  dates of incorporated organic materials they had previously collected from hand-dug excavations (Hall and Denton, 1999); the record the dates helped define demonstrated that near the end of the Medieval Warm Period, “as late as 890  $^{14}\text{C}$  yr BP,” as Hall and Denton describe it, “the Wilson Piedmont Glacier was still less extensive than it is now,” demonstrating that the climate of that period was in all likelihood considerably warmer than it is currently.

Noon *et al.* (2003) used oxygen isotopes preserved in authigenic carbonate retrieved from freshwater sediments of Sombre Lake on Signy Island ( $60^{\circ}43'\text{S}$ ,  $45^{\circ}38'\text{W}$ ) in the Southern Ocean to construct a 7,000-year history of that region’s climate. This work revealed that the general trend of temperature at the study site has been downward. Of most interest to us, however, is the millennial-scale oscillation of climate that is apparent in much of the record. This climate cycle is such that approximately 2,000 years ago, after a thousand-year gap in the data, Signy Island experienced the relative warmth of the last vestiges of the Roman Warm Period, as delineated by McDermott *et al.* (2001) on the basis of a high-resolution speleothem  $\delta^{18}\text{O}$  record from southwest Ireland. Then comes the Dark Ages Cold period, which is also contemporaneous with what McDermott *et al.* observe in the Northern Hemisphere, after which the Medieval Warm Period appears at the same point in time and persists for the same length of time that it does in the vicinity of Ireland, whereupon the Little Ice Age sets in just as it does in the Northern Hemisphere. Finally, there is an indication of late twentieth century warming, but with still a long way to go before conditions comparable to those of the Medieval Warm Period are achieved.

Two years later, Castellano *et al.* (2005) derived a detailed history of Holocene volcanism from the sulfate record of the first 360 meters of the Dome Concordia ice core that covered the period 0-11.5 kyr BP, after which they compared their results for the past millennium with similar results obtained from eight other Antarctic ice cores. Before doing so, however, they normalized the results at each site by dividing its several volcanic-induced sulfate deposition values by the value produced at that site by the AD 1816 Tambora eruption, in order to reduce deposition differences among sites that might have been induced by differences in local site characteristics. This work revealed that most volcanic events in the early last millennium (AD 1000-1500)

exhibited greater among-site variability in normalized sulphate deposition than was observed thereafter.

Citing Budner and Cole-Dai (2003) in noting that “the Antarctic polar vortex is involved in the distribution of stratospheric volcanic aerosols over the continent,” Castellano *et al.* say that assuming the intensity and persistence of the polar vortex in both the troposphere and stratosphere “affect the penetration of air masses to inland Antarctica, isolating the continental area during cold periods and facilitating the advection of peripheral air masses during warm periods (Krinner and Genthon, 1998), we support the hypothesis that the pattern of volcanic deposition intensity and geographical variability [higher values at coastal sites] could reflect a warmer climate of Antarctica in the early last millennium,” and that “the re-establishment of colder conditions, starting in about AD 1500, reduced the variability of volcanic depositions.”

Describing this phenomenon in terms of what it implies, Castellano *et al.* say “this warm/cold step could be like a Medieval Climate Optimum-like to Little Ice Age-like transition.” They additionally cite Goosse *et al.* (2004) as reporting evidence from Antarctic ice-core  $\delta\text{D}$  and  $\delta^{18}\text{O}$  data “in support of a Medieval Warming-like period in the Southern Hemisphere, delayed by about 150 years with respect to Northern Hemisphere Medieval Warming.” The researchers conclude by postulating that “changes in the extent and intra-Antarctic variability of volcanic depositional fluxes may have been consequences of the establishment of a Medieval Warming-like period that lasted until about AD 1500.”

A year later, Hall *et al.* (2006) collected skin and hair (and even some whole-body mummified remains) from Holocene raised-beach excavations at various locations along Antarctica’s Victoria Land Coast, which they identified by both visual inspection and DNA analysis as coming from southern elephant seals, and which they analyzed for age by radiocarbon dating. By these means they obtained data from 14 different locations within their study region—which they describe as being “well south” of the seals’ current “core sub-Antarctic breeding and molting grounds”—that indicate that the period of time they denominate the Seal Optimum began about 600 BC and ended about AD1400, the latter of which dates they describe as being “broadly contemporaneous with the onset of Little Ice Age climatic conditions in the Northern Hemisphere and with glacier advance near [Victoria Land’s] Terra Nova Bay.”

In describing the significance of their findings, the US, British, and Italian researchers say they are indicative of “warmer-than-present climate conditions” at the times and locations of the identified presence of the southern elephant seal, and that “if, as proposed in the literature, the [Ross] ice shelf survived this period, it would have been exposed to environments substantially warmer than present,” which would have included both the Roman Warm Period and Medieval Warm Period.

More recently, Williams *et al.* (2007) presented methyl chloride (CH<sub>3</sub>Cl) measurements of air extracted from a 300-m ice core that was obtained at the South Pole, Antarctica, covering the time period 160 BC to AD 1860. In describing what they found, the researchers say “CH<sub>3</sub>Cl levels were elevated from 900-1300 AD by about 50 ppt relative to the previous 1000 years, coincident with the warm Medieval Climate Anomaly (MCA),” and that they “decreased to a minimum during the Little Ice Age cooling (1650-1800 AD), before rising again to the modern atmospheric level of 550 ppt.” Noting that “today, more than 90% of the CH<sub>3</sub>Cl sources and the majority of CH<sub>3</sub>Cl sinks lie between 30°N and 30°S (Khalil and Rasmussen, 1999; Yoshida *et al.*, 2004),” they say “it is likely that climate-controlled variability in CH<sub>3</sub>Cl reflects changes in tropical and subtropical conditions.” They go on to say that “ice core CH<sub>3</sub>Cl variability over the last two millennia suggests a positive relationship between atmospheric CH<sub>3</sub>Cl and *global* [our italics] mean temperature.”

As best we can determine from the graphical representation of their data, the peak CH<sub>3</sub>Cl concentration measured by Williams *et al.* during the MCA is approximately 533 ppt, which is within 3 percent of its current mean value of 550 ppt and well within the range of 520 to 580 ppt that characterizes methyl chloride’s current variability. Hence, we may validly conclude that the mean peak temperature of the MCA (which we refer to as the Medieval Warm Period) over the latitude range 30°N to 30°S—and possibly over the entire globe—may not have been materially different from the mean peak temperature so far attained during the Current Warm Period.

This conclusion, along with the findings of the other studies we have reviewed of the climate of Antarctica, suggests there is nothing unusual, unnatural, or unprecedented about the current level of earth’s warmth.

### 3.2.4. Arctic

Dahl-Jensen *et al.* (1998) used temperature measurements from two Greenland Ice Sheet boreholes to reconstruct the temperature history of this portion of the earth over the past 50,000 years. Their data indicate that after the termination of the glacial period, temperatures steadily rose to a maximum of 2.5°C warmer than at present during the Holocene Climatic Optimum (4,000 to 7,000 years ago). The Medieval Warm Period and Little Ice Age were also documented in the record, with temperatures 1°C warmer and 0.5-0.7°C cooler than at present, respectively. After the Little Ice Age, they report that temperatures once again rose, but that they “have decreased during the last decades.” These results thus clearly indicate that the Medieval Warm Period in this part of the Arctic was significantly warmer than current temperatures.

Wagner and Melles (2001) also worked on Greenland, where they extracted a 3.5-m-long sediment core from a lake (Raffels So) on an island (Raffles O) located just off Liverpool Land on the east coast of Greenland, which they analyzed for a number of properties related to the past presence of seabirds there, obtaining a 10,000-year record that tells us much about the region’s climatic history. Key to the study were biogeochemical data that, in the words of the researchers, reflect “variations in seabird breeding colonies in the catchment which influence nutrient and cadmium supply to the lake.”

Wagner and Melles’ data reveal sharp increases in the values of the parameters they measured between about 1100 and 700 years before present (BP), indicative of the summer presence of significant

numbers of seabirds during that “medieval warm period,” as they describe it, which had been preceded by a several-hundred-year period (Dark Ages Cold Period) of little to no bird presence. Thereafter, their data suggest another absence of birds during what they call “a subsequent Little Ice Age,” which they note was “the coldest period since the early Holocene in East Greenland.”

The Raffels So data also show signs of a “resettlement of seabirds during the last 100 years, indicated by an increase of organic matter in the lake sediment and confirmed by bird observations.” However, values of the most recent measurements are not as great as those obtained from the earlier Medieval Warm Period, which indicates that higher temperatures prevailed during the period from 1,100 to 700 years BP than what has been observed over the most recent hundred years.

A third relevant Greenland study was conducted by Kaplan *et al.* (2002), who derived a climatic history of the Holocene by analyzing the physical-chemical properties of sediments obtained from a small lake in southern Greenland. They determined that the interval from 6,000 to 3,000 years BP was marked by warmth and stability, but that the climate cooled thereafter until its culmination in the Little Ice Age. From 1,300-900 years BP, however, there was a partial amelioration during the Medieval Warm Period, which was associated with an approximate 1.5°C rise in temperature.

In a non-Greenland Arctic study, Jiang *et al.* (2002) analyzed diatom assemblages from a high-resolution core extracted from the seabed of the north Icelandic shelf to reconstruct a 4,600-year history of mean summer sea surface temperature at that location. Starting from a maximum value of about 8.1°C at 4,400 years BP, the climate was found to have cooled fitfully for about 1,700 years and then more consistently over the final 2,700 years of the record. The most dramatic departure from this long-term decline was centered on about 850 years BP, during the Medieval Warm Period, when the temperature rose by more than 1°C above the line describing the long-term downward trend to effect an almost complete recovery from the colder temperatures of the Dark Ages Cold Period, after which temperatures continued their descent into the Little Ice Age, ending with a final most recent value of approximately 6.3°C. These data also clearly indicate that the Medieval Warm Period in this part of the Arctic was significantly warmer than it is there now.

Moore *et al.* (2001) analyzed sediment cores from Donard Lake, Baffin Island, Canada, producing a 1,240-year record of average summer temperatures for this Arctic region. Over the entire period from AD 750-1990, temperatures averaged 2.9°C. However, anomalously warm decades with summer temperatures as high as 4°C occurred around AD 1000 and 1100, while at the beginning of the thirteenth century, Donard Lake witnessed “one of the largest climatic transitions in over a millennium,” as “average summer temperatures rose rapidly by nearly 2°C from 1195-1220 AD, ending in the warmest decade in the record” with temperatures near 4.5°C.

This rapid warming of the thirteenth century was followed by a period of extended warmth that lasted until an abrupt cooling event occurred around 1375 and made the following decade one of the coldest in the record. This event signaled the onset of the Little Ice Age, which lasted for 400 years, until a gradual warming trend began about 1800, which was followed by a dramatic cooling event in 1900 that brought temperatures back to levels similar to those of the Little Ice Age. This cold regime lasted until about 1950, whereupon temperatures warmed for about two decades but then tended downwards again all the way to the end of the record in 1990. Hence, in this part of the Arctic the Medieval Warm Period was also warmer than it is there currently.

Grudd *et al.* (2002) assembled tree-ring widths from 880 living, dead, and subfossil northern Swedish pines into a continuous and precisely dated chronology covering the period 5407 BC to AD 1997. The strong association between these data and summer (June-August) mean temperatures of the last 129 years of the period then enabled them to produce a 7,400-year history of summer mean temperature for northern Swedish Lapland.

The most dependable portion of this record, based upon the number of trees that were sampled, consisted of the last two millennia, which the authors say “display features of century-timescale climatic variation known from other proxy and historical sources, including a warm ‘Roman’ period in the first centuries AD and a generally cold ‘Dark Ages’ climate from about AD 500 to about AD 900.” They also note that “the warm period around AD 1000 may correspond to a so-called ‘Mediaeval Warm Period,’ known from a variety of historical sources and other proxy records.” Lastly, they say “the climatic deterioration in the twelfth century can be regarded as the starting point of a prolonged cold period that continued to the first decade of the twentieth

century,” which “Little Ice Age,” in their words, is also “known from instrumental, historical and proxy records.” Going back further in time, the tree-ring record displays several more of these relatively warmer and colder periods. They report that “the relatively warm conditions of the late twentieth century do not exceed those reconstructed for several earlier time intervals.”

Seppa and Birks (2002) used a recently developed pollen-climate reconstruction model and a new pollen stratigraphy from Toskaljarvi—a tree-line lake in the continental sector of northern Fennoscandia (located just above 69°N latitude)—to derive quantitative estimates of annual precipitation and July mean temperature. As they describe it, their reconstructions “agree with the traditional concept of a ‘Medieval Warm Period’ (MWP) and ‘Little Ice Age’ in the North Atlantic region (Dansgaard *et al.*, 1975) and in northern Fennoscandia (Korhola *et al.*, 2000).” In addition, they report there is “a clear correlation between [their] MWP reconstruction and several records from Greenland ice cores,” and that “comparisons of a smoothed July temperature record from Toskaljarvi with measured borehole temperatures of the GRIP and Dye 3 ice cores (Dahl-Jensen *et al.*, 1998) and the  $\delta^{18}\text{O}$  record from the Crete ice core (Dansgaard *et al.*, 1975) show the strong similarity in timing of the MWP between the records.” Finally, they note that “July temperature values during the Medieval Warm Period (ca. 1400-1000 cal yr B.P.) were ca. 0.8°C higher than at present,” where present means the last six decades of the twentieth century.

Noting that temperature changes in high latitudes are (1) sensitive indicators of *global* temperature changes, and that they can (2) serve as a basis for verifying climate model calculations, Naurzbaev *et al.* (2002) developed a 2,427-year proxy temperature history for the part of the Taimyr Peninsula of northern Russia that lies between 70°30' and 72°28' North latitude, based on a study of ring-widths of living and preserved larch trees, noting further that “it has been established that the main driver of tree-ring variability at the polar timber-line [where they worked] is temperature (Vaganov *et al.*, 1996; Briffa *et al.*, 1998; Schweingruber and Briffa, 1996).” In doing so, they found that “the warmest periods over the last two millennia in this region were clearly in the third [Roman Warm Period], tenth to twelfth [Medieval Warm Period] and during the twentieth [Current Warm Period] centuries.”

With respect to the second of these periods, they emphasize that “the warmth of the two centuries AD 1058-1157 and 950-1049 attests to the reality of relative mediaeval warmth in this region.” Their data also reveal three other important pieces of information: (1) the Roman and Medieval Warm Periods were both warmer than the Current Warm Period has been to date, (2) the “beginning of the end” of the Little Ice Age was somewhere in the vicinity of 1830, and (3) the Current Warm Period peaked somewhere in the vicinity of 1940. All of these observations are at odds with what is portrayed in the thousand-year Northern Hemispheric “hockey stick” temperature history of Mann *et al.* (1998, 1999) and its thousand-year global extension developed by Mann and Jones (2003).

Knudsen *et al.* (2004) documented climatic changes over the past 1,200 years by means of high-resolution multi-proxy studies of benthic and planktonic foraminiferal assemblages, stable isotopes, and ice-rafted debris found in three sediment cores retrieved from the North Icelandic shelf. This work revealed that “the time period between 1200 and around 7,800 cal. years BP, including the Medieval Warm Period, was characterized by relatively high bottom and surface water temperatures,” after which “a general temperature decrease in the area marks the transition to ... the Little Ice Age.” They also note that “minimum sea-surface temperatures were reached at around 350 cal. BP, when very cold conditions were indicated by several proxies.” Thereafter, they say “a modern warming of surface waters ... is *not* [our italics] registered in the proxy data,” and that “there is no clear indication of warming of water masses in the area during the last decades,” even in sea surface temperatures measured over the period 1948-2002.

Grinsted *et al.* (2006) developed “a model of chemical fractionation in ice based on differing elution rates for pairs of ions ... as a proxy for summer melt (1130-1990),” based on data obtained from a 121-meter-long ice core they extracted from the highest ice field in Svalbard (Lomonosovfonna: 78°51'53"N, 17°25'30"E), which was “validated against twentieth-century instrumental records and longer historical climate proxies.” This history indicated that “in the oldest part of the core (1130-1200), the washout indices [were] more than 4 times as high as those seen during the last century, indicating a high degree of runoff.” In addition, they report they have performed regular snow pit studies near the ice core site since 1997 (Virkkunen, 2004) and that “the very warm 2001 summer resulted in

similar loss of ions and washout ratios as the earliest part of the core.” They then state that “this suggests that the Medieval Warm Period in Svalbard summer conditions [was] as warm (or warmer) as present-day, consistent with the Northern Hemisphere temperature reconstruction of Moberg *et al.* (2005).” In addition, they conclude that “the degree of summer melt was significantly larger during the period 1130-1300 than in the 1990s,” which likewise suggests that a large portion of the Medieval Warm Period was significantly warmer than the peak warmth (1990s) of the Current Warm Period.

Besonen *et al.* (2008) derived thousand-year histories of varve thickness and sedimentation accumulation rate for Canada’s Lower Murray Lake (81°20'N, 69°30'W), which is typically covered for about 11 months of each year by ice that reaches a thickness of 1.5 to 2 meters at the end of each winter. With respect to these parameters, they say—citing seven other studies—that “field-work on other High Arctic lakes clearly indicates that sediment transport and varve thickness are related to temperatures during the short summer season that prevails in this region, and we have no reason to think that this is not the case for Lower Murray Lake.”

They found “the twelfth and thirteenth centuries were relatively warm,” with their data indicating that Lower Murray Lake and its environs were often much warmer during this time period (AD 1080-1320) than they were at any point in the twentieth century, which has also been shown to be the case for Donard Lake (66.25°N, 62°W) by Moore *et al.* (2001).

The studies reviewed above indicate that the Arctic—which climate models suggest should be sensitive to greenhouse-gas-induced warming—is still not as warm as it was many centuries ago during portions of the Medieval Warm Period, when there was much less CO<sub>2</sub> and methane in the air than there is today. This further suggests the planet’s more modest current warmth need not be the result of historical increases in these two greenhouse gases.

### 3.2.5. Asia

#### 3.2.5.1. China

Using a variety of climate records derived from peat, lake sediment, ice core, tree-ring and other proxy sources, Yang *et al.* (2002) identified a period of exceptional warmth throughout China between AD 800 and 1100. Yafeng *et al.* (1999) also observed a warm period between AD 970 and 1510 in  $\delta^{18}\text{O}$  data obtained from the Guliya ice cap of the Qinghai-Tibet Plateau. Similarly, Hong *et al.* (2000) developed a 6,000-year  $\delta^{18}\text{O}$  record from plant cellulose deposited in a peat bog in the Jilin Province (42° 20' N, 126° 22' E), within which they found evidence of “an obvious warm period represented by the high  $\delta^{18}\text{O}$

from around AD 1100 to 1200 which may correspond to the Medieval Warm Epoch of Europe.”

Shortly thereafter, Xu *et al.* (2002) determined from a study of plant cellulose  $\delta^{18}\text{O}$  variations in cores retrieved from peat deposits at the northeastern edge of the Qinghai-Tibet Plateau that from AD 1100-1300 “the  $\delta^{18}\text{O}$  of Hongyuan peat cellulose increased, consistent with that of Jinchuan peat cellulose and corresponding to the ‘Medieval Warm Period’.” In addition, Qian and Zhu (2002) analyzed the thickness of laminae in a stalagmite found in Shihua Cave, Beijing, from whence they inferred the existence of a relatively wet period running from approximately AD 940 to 1200.

Hong *et al.* (2000) also report that at the time of the MWP “the northern boundary of the cultivation of citrus tree (*Citrus reticulata* Blanco) and *Boehmeria nivea* (a perennial herb), both subtropical and thermophilous plants, moved gradually into the northern part of China, and it has been estimated that the annual mean temperature was 0.9-1.0°C higher than at present.” Considering the climatic conditions required to successfully grow these plants, they further note that annual mean temperatures in that part of the country during the Medieval Warm Period must have been about 1.0°C higher than at present, with extreme January minimum temperatures fully 3.5°C warmer than they are today, citing De’er (1994).

Chu *et al.* (2002) studied the geochemistry of 1,400 years of dated sediments recovered from seven cores taken from three locations in Lake Huguangyan (21°9’N, 110°17’E) on the low-lying Leizhou Peninsula in the tropical region of South China, together with information about the presence of snow, sleet, frost, and frozen rivers over the past 1,000 years obtained from historical documents. They report that “recent publications based on the phenological phenomena, distribution patterns of subtropical plants and cold events (Wang and Gong, 2000; Man, 1998; Wu and Dang, 1998; Zhang, 1994) argue for a warm period from the beginning of the tenth century AD to the late thirteenth century AD,” as their own data also suggest. In addition, they note there was a major dry period from AD 880-1260, and that “local historical chronicles support these data, suggesting that the climate of tropical South China was dry during the ‘Mediaeval Warm Period’.”

Paulsen *et al.* (2003) used high-resolution  $\delta^{13}\text{C}$  and  $\delta^{18}\text{O}$  data derived from a stalagmite found in Buddha Cave [33°40’N, 109°05’E] to infer changes in climate in central China for the past 1,270 years.

Among the climatic episodes evident in their data were “those corresponding to the Medieval Warm Period, Little Ice Age and 20th-century warming, lending support to the global extent of these events.” In terms of timing, the dry-then-wet-then-dry-again MWP began about AD 965 and continued to approximately AD 1475.

Also working with a stalagmite, this one from Jingdong Cave about 90 km northeast of Beijing, Ma *et al.* (2003) assessed the climatic history of the past 3,000 years at 100-year intervals on the basis of  $\delta^{18}\text{O}$  data, the Mg/Sr ratio, and the solid-liquid distribution coefficient of Mg. They found that between 200 and 500 years ago, “air temperature was about 1.2°C lower than that of the present,” but that between 1,000 and 1,300 years ago, there was an equally aberrant but warm period that “corresponded to the Medieval Warm Period in Europe.”

Based on 200 sets of phenological and meteorological records extracted from a number of historical sources, many of which are described by Gong and Chen (1980), Man (1990, 2004), Sheng (1990), and Wen and Wen (1996), Ge *et al.* (2003) produced a 2,000-year history of winter half-year temperature (October to April, when CO<sub>2</sub>-induced global warming is projected to be most evident) for the region of China bounded by latitudes 27° and 40°N and longitudes 107° and 120°E. Their work revealed a significant warm epoch that lasted from the AD 570s to the 1310s, the peak warmth of which was “about 0.3-0.6°C higher than present for 30-year periods, but over 0.9°C warmer on a 10-year basis.”

Bao *et al.* (2003) utilized proxy climate records (ice-core  $\delta^{18}\text{O}$ , peat-cellulose  $\delta^{18}\text{O}$ , tree-ring widths, tree-ring stable carbon isotopes, total organic carbon, lake water temperatures, glacier fluctuations, ice-core CH<sub>4</sub>, magnetic parameters, pollen assemblages, and sedimentary pigments) obtained from 20 prior studies to derive a 2,000-year temperature history of the northeastern, southern and western sections of the Tibetan Plateau. In each case, there was more than one prior 50-year period of time when the mean temperature of each region was warmer than it was over the most recent 50-year period. In the case of the northeastern sector of the plateau, all of the maximum-warmth intervals occurred during the Medieval Warm Period; in the case of the western sector, they occurred near the end of the Roman Warm Period, and in the case of the southern sector they occurred during both warm periods.

From these several studies, it is evident that for a considerable amount of time during the Medieval

Warm Period, many parts of China exhibited warmer conditions than those of modern times. Since those earlier high temperatures were caused by something other than high atmospheric CO<sub>2</sub> concentrations, whatever was responsible for them could be responsible for the warmth of today.

### 3.2.5.2. Russia

Demezhko and Shchapov (2001) studied a borehole extending to more than 5 km depth, reconstructing an 80,000-year history of ground surface temperature in the Middle Urals within the western rim of the Tagil subsidence (58°24' N, 59°44'E). The reconstructed temperature history revealed the existence of a number of climatic excursions, including, in their words, the "Medieval Warm Period with a culmination about 1000 years ago."

Further north, Hiller *et al.* (2001) analyzed subfossil wood samples from the Khibiny mountains

on the Kola Peninsula of Russia (67-68°N, 33-34°E) in an effort to reconstruct the region's climate history over the past 1,500 years. They determined that between AD 1000 and 1300 the tree-line was located at least 100-140 m above its current elevation. This observation, in their words, suggests that mean summer temperatures during this "Medieval climatic optimum" were "at least 0.8°C higher than today," and that "the Medieval optimum was the most pronounced warm climate phase on the Kola Peninsula during the last 1500 years."

Additional evidence for the Medieval Warm Period in Russia comes from Naurzbaev and Vaganov (2000), who developed a 2,200-year proxy temperature record (212 BC to 1996 AD) using tree-ring data obtained from 118 trees near the upper timberline in Siberia. Based on their results, they concluded that the warming experienced in the twentieth century was "not extraordinary," and that "the warming at the border of the first and second millennia was longer in time and similar in amplitude."

Krenke and Chernavskaya (2002) present an impressive overview of what is known about the MWP within Russia, as well as throughout the world, based on historical evidence, glaciological evidence, hydrologic evidence, dendrological data, archaeological data, and palynological data. Concentrating on data wholly from within Russia, they report large differences in a number of variables between the Little Ice Age (LIA) and MWP. With respect to the annual mean temperature of northern Eurasia, they report an MWP to LIA drop on the order of 1.5°C. They also say that "the frequency of severe winters reported was increased from once in 33 years in the early period of time, which corresponds to the MWP, to once in 20 years in the LIA," additionally noting that "the abnormally severe winters [of the LIA] were associated with the spread of Arctic air masses over the entire Russian Plain." Finally, they note that the data they used to draw these conclusions were "not used in the reconstructions performed by Mann *et al.*," which perhaps explains why the Mann *et al.* temperature history of the past millennium does not depict the coolness of the LIA or the warmth of the MWP nearly as well as the more appropriately derived temperature history of Esper *et al.* (2002).

In discussing their approach to the subject of global warming detection and attribution, the Russians state that "an analysis of climate variations over 1000 years should help ... reveal natural

multicentennial variations possible at present but not detectable in available 100-200-year series of instrumental records." In this endeavor, they were highly successful, stating unequivocally that "the Medieval Warm Period and the Little Ice Age existed globally."

Additional information on this topic, including reviews of newer publications as they become available, can be found at <http://www.co2science.org/subject/m/mwprussia.php>.

### 3.2.5.3. Other Asia Locations

In addition to China and Russia, the Medieval Warm Period (MWP) has been identified in several other parts of Asia.

Schilman *et al.* (2001) analyzed foraminiferal oxygen and carbon isotopes, together with the physical and geochemical properties of sediments, contained in two cores extracted from the bed of the southeastern Mediterranean Sea off the coast of Israel, where they found evidence for the MWP centered on AD 1200. In discussing their findings, they note there is an abundance of other evidence for the existence of the MWP in the Eastern Mediterranean as well, including, in their words, “high Saharan lake levels (Schoell, 1978; Nicholson, 1980), high Dead Sea levels (Issar *et al.*, 1989, 1991; Issar, 1990, 1998; Issar and Makover-Levin, 1996), and high levels of the Sea of Galilee (Frumkin *et al.*, 1991; Issar and Makover-Levin, 1996),” in addition to “a precipitation maximum at the Nile headwaters (Bell and Menzel, 1972; Hassan, 1981; Ambrose and DeNiro, 1989) and in the northeastern Arabian Sea (von Rad *et al.*, 1999).”

Further to the east, Kar *et al.* (2002) explored the nature of climate change preserved in the sediment profile of an outwash plain two to three km from the snout of the Gangotri Glacier in the Uttarkashi district of Utranchal, Western Himalaya. Between 2,000 and 1,700 years ago, their data reveal the existence of a relatively cool climate. Then, from 1,700 to 850 years ago, there was what they call an “amelioration of climate,” during the transition from the depth of the Dark Ages Cold Period to the midst of the Medieval Warm Period. Subsequent to that time, Kar *et al.*’s data indicate the climate “became much cooler,” indicative of its transition to Little Ice Age conditions, while during the last 200 years there has been a rather steady warming, as shown by Esper *et al.* (2002a) to have been characteristic of the entire Northern Hemisphere.

At a pair of other Asian locations, Esper *et al.* (2002b) used more than 200,000 ring-width measurements obtained from 384 trees at 20 individual sites ranging from the lower to upper timberline in the Northwest Karakorum of Pakistan (35-37°N, 74-76°E) and the Southern Tien Shan of Kirghizia (40°10’N, 72°35’E) to reconstruct regional patterns of climatic variations in Western Central Asia since AD 618. According to their analysis, the Medieval Warm Period was already firmly established and growing even warmer by the early seventh century; and between AD 900 and 1000, tree growth was exceptionally rapid, at rates they say “cannot be observed during any other period of the last millennium.”

Between AD 1000 and 1200, however, growing conditions deteriorated; and at about 1500, minimum tree ring-widths were reached that persisted well into the seventeenth century. Towards the end of the twentieth century, ring-widths increased once again; but Esper *et al.* (2002b) report that “the twentieth-century trend does not approach the AD 1000 maximum.” In fact, there is almost no comparison between the two periods, with the Medieval Warm Period being much more conducive to good tree growth than the Current Warm Period. As the authors describe the situation, “growing conditions in the twentieth century exceed the long-term average, but the amplitude of this trend is not comparable to the conditions around AD 1000.”

The latest contribution to Asian temperature reconstruction is the study of Esper *et al.* (2003), who processed several extremely long juniper ring-width chronologies for the Alai Range of the western Tien Shan in Kirghizia in such a way as to preserve multi-centennial growth trends that are typically “lost during the processes of tree ring data standardization and chronology building (Cook and Kairiukstis, 1990; Fritts, 1976).” In doing so, they used two techniques that maintain low frequency signals: long-term mean standardization (LTM) and regional curve standardization (RCS), as well as the more conventional spline standardization (SPL) technique that obscures (actually *removes*) long-term trends.

Carried back in time a full thousand years, the SPL chronologies depict significant inter-decadal variations but no longer-term trends. The LTM and RCS chronologies, on the other hand, show long-term decreasing trends from the start of the record until about AD 1600, broad minima from 1600 to 1800, and long-term increasing trends from about 1800 to the present. As a result, in the words of Esper *et al.* (2003), “the main feature of the LTM and RCS Alai Range chronologies is a multi-centennial wave with high values towards both ends.”

This grand result has essentially the same form as the Northern Hemisphere extratropical temperature history of Esper *et al.* (2002a), which is vastly different from the hockey stick temperature history of Mann *et al.* (1998, 1999) and Mann and Jones (2003), in that it depicts the existence of both the Little Ice Age and preceding Medieval Warm Period, which are nowhere to be found in the Mann reconstructions. In addition, the new result—especially the LTM chronology, which has a much smaller variance than the RCS chronology—depicts several periods in the first half of the last millennium that were warmer than

any part of the last century. These periods include much of the latter half of the Medieval Warm Period and a good part of the first half of the fifteenth century, which has also been found to have been warmer than it is currently by McIntyre and McKittrick (2003) and by Loehle (2004).

In commenting on their important findings, Esper *et al.* (2003) remark that “if the tree ring reconstruction had been developed using ‘standard’ detrending procedures only, it would have been limited to inter-decadal scale variation and would have missed some of the common low frequency signal.” We would also remark, with respect to the upward trend of their data since 1800, that a good portion of that trend may have been due to the aerial fertilization effect of the concomitantly increasing atmospheric CO<sub>2</sub> content, which is known to greatly stimulate the growth of trees. Properly accounting for this very real effect would make the warmer-than-present temperatures of the first half of the past millennium even warmer, relative to those of the past century, than they appear to be in Esper *et al.*’s LTM and RCS reconstructions.

### 3.2.6. Europe

Based on analyses of subfossil wood samples from the Khibiny mountains on the Kola Peninsula of Russia, Hiller *et al.* (2001) were able to reconstruct a 1,500-year history of alpine tree-line elevation. This record indicates that between AD 1000 and 1300, the tree-line there was located at least 100 to 140 meters above its current location. The researchers state that this fact implies a mean summer temperature that was “at least 0.8°C higher than today.”

Moving from land to water, in a study of a well-dated sediment core from the Bornholm Basin in the southwestern Baltic Sea, Andren *et al.* (2000) found evidence for a period of high primary production at approximately AD 1050. Many of the diatoms of that period were warm water species that the scientists say “cannot be found in the present Baltic Sea.” This balmy period, they report, “corresponds to the time when the Vikings succeeded in colonizing Iceland and Greenland.” The warmth ended rather abruptly, however, at about AD 1200, when they note there was “a major decrease in warm water taxa in the diatom assemblage and an increase in cold water taxa,” which latter diatoms are characteristic of what they

call the Recent Baltic Sea Stage that prevails to this day.

In another marine study, Voronina *et al.* (2001) analyzed dinoflagellate cyst assemblages in two sediment cores retrieved from the southeastern Barents Sea, one spanning a period of 8,300 years and one spanning a period of 4,400 years. The longer of the two cores indicated a warm interval from about 8,000 to 3,000 years before present, followed by cooling pulses coincident with lowered salinity and extended ice cover in the vicinity of 5,000, 3,500, and 2,500 years ago. The shorter core additionally revealed cooling pulses at tentative dates of 1,400, 300, and 100 years before present. For the bulk of the past 4,400 years, however, ice cover lasted only two to three months per year, as opposed to the modern mean of 4.3 months per year. In addition, August temperatures ranged between 6° and 8°C, significantly warmer than the present mean of 4.6°C.

Moving back towards land, Mikalsen *et al.* (2001) made detailed measurements of a number of properties of sedimentary material extracted from the bottom of a fjord on the west coast of Norway, deriving a relative temperature history of the region that spanned the last five millennia. This record revealed the existence of a period stretching from A.D. 1330 to 1600 that, in their words, “had the highest bottom-water temperatures in Sulafjorden during the last 5000 years.”

In eastern Norway, Nesje *et al.* (2001) analyzed a sediment core obtained from Lake Atnsjoen, deriving a 4,500-year record of river flooding. They observed “a period of little flood activity around the Medieval period (AD 1000-1400),” which was followed by “a period of the most extensive flood activity in the Atnsjoen catchment.” This flooding, in their words, resulted from the “post-Medieval climate deterioration characterized by lower air temperature, thicker and more long-lasting snow cover, and more frequent storms associated with the ‘Little Ice Age.’”

Working in both Norway and Scotland, Brooks and Birks (2001) studied midges, the larval-stage head capsules of which are well preserved in lake sediments and are, in their words, “widely recognized as powerful biological proxies for inferring past climate change.” Applying this technique to sediments derived from a lake in the Cairngorms region of the Scottish Highlands, they determined that temperatures there peaked at about 11°C during what they refer to as the “Little Climatic Optimum”—which we typically call the Medieval Warm Period—

“before cooling by about 1.5°C which may coincide with the ‘Little Ice Age’.”

These results, according to Brooks and Birks, “are in good agreement with a chironomid stratigraphy from Finse, western Norway (Velle, 1998),” where summer temperatures were “about 0.4°C warmer than the present day” during the Medieval Warm Period. This latter observation also appears to hold for the Scottish site, since the upper sample of the lake sediment core from that region, which was collected in 1993, “reconstructs the modern temperature at about 10.5°C,” which is 0.5°C less than the 11°C value the authors found for the Medieval Warm Period.

Moving to Switzerland, Filippi *et al.* (1999) analyzed a sediment core extracted from Lake Neuchatel in the western Swiss Lowlands. During this same transition from the Medieval Warm Period (MWP) to the Little Ice Age (LIA), they detected a drop of approximately 1.5°C in mean annual air temperature. To give some context to this finding, they say that “the warming during the 20th century does not seem to have fully compensated the cooling at the MWP-LIA transition.” And to make the message even more clear, they add that during the Medieval Warm Period, the mean annual air temperature was “on average higher than at present.”

In Ireland, in a cave in the southwestern part of the country, McDermott *et al.* (2001) derived a  $\delta^{18}\text{O}$  record from a stalagmite that provided evidence for climatic variations that are “broadly consistent with a Medieval Warm Period at  $\sim 1000 \pm 200$  years ago and a two-stage Little Ice Age.” Also evident in the data were the  $\delta^{18}\text{O}$  signatures of the earlier Roman Warm Period and Dark Ages Cold Period that comprised the preceding millennial-scale cycle of climate in that region.

In another study of three stalagmites found in a cave in northwest Germany, Niggemann *et al.* (2003) discovered that the climate records they contained “resemble records from an Irish stalagmite (McDermott *et al.*, 1999),” specifically noting that their own records provide evidence for the existence of the Little Ice Age, the Medieval Warm Period and the Roman Warm Period, which evidence also implies the existence of what McDermott *et al.* (2001) call the Dark Ages Cold Period that separated the Medieval and Roman Warm Periods, as well as the existence of the unnamed cold period that preceded the Roman Warm Period.

Bodri and Cermak (1999) derived individual ground surface temperature histories from the

temperature-depth logs of 98 separate boreholes drilled in the Czech Republic. From these data they detected “the existence of a medieval warm epoch lasting from A.D. 1100-1300,” which they describe as “one of the warmest postglacial times. Noting that this spectacular warm period was followed by the Little Ice Age, they went on to suggest that “the observed recent warming may thus be easily a natural return of climate from the previous colder conditions back to a ‘normal’.”

Filippi *et al.* (1999) share similar views, as is demonstrated by their citing of Keigwin (1996) to the effect that “sea surface temperature (SST) reconstructions show that SST was ca. 1°C cooler than today about 400 years ago and ca. 1°C warmer than today during the MWP.” Citing Bond *et al.* (1997), they further note that the MWP and LIA are merely the most recent manifestations of “a pervasive millennial-scale coupled atmosphere-ocean climate oscillation,” which, we might add, has absolutely nothing to do with variations in the air’s CO<sub>2</sub> content.

Lastly, we report the findings of Berglund (2003), who identified several periods of expansion and decline of human cultures in northwest Europe and compared them with a history of reconstructed climate “based on insolation, glacier activity, lake and sea levels, bog growth, tree line, and tree growth.” In doing so, he determined there was a positive correlation between human impact/land-use and climate change. Specifically, in the latter part of the record, where both cultural and climate changes were best defined, there was, in his words, a great “retreat of agriculture” centered on about AD 500, which led to “reforestation in large areas of central Europe and Scandinavia.” He additionally notes that “this period was one of rapid cooling indicated from tree-ring data (Eronen *et al.*, 1999) as well as sea surface temperatures based on diatom stratigraphy in [the] Norwegian Sea (Jansen and Koc, 2000), which can be correlated with Bond’s event 1 in the North Atlantic sediments (Bond *et al.*, 1997).”

Next came what Berglund calls a “boom period” that covered “several centuries from AD 700 to 1100.” This interval of time proved to be “a favourable period for agriculture in marginal areas of Northwest Europe, leading into the so-called Medieval Warm Epoch,” when “the climate was warm and dry, with high treelines, glacier retreat, and reduced lake catchment erosion.” This period “lasted until around AD 1200, when there was a gradual change to cool/moist climate, the beginning of the

Little Ice Age ... with severe consequences for the agrarian society.”

The story from Europe seems quite clear. There was a several-hundred-year period in the first part of the last millennium that was significantly warmer than it is currently. In addition, there is reason to believe the planet may be on a natural climate trajectory that is taking it back to a state reminiscent of the Medieval Warm Period. There is nothing we can do about this natural cycle except, as is implied by the study of Berglund (2003), reap the benefits.

### 3.2.7. North America

Arseneault and Payette (1997) analyzed tree-ring and growth-form sequences obtained from more than 300 spruce remains buried in a presently treeless peatland in northern Quebec to produce a proxy record of climate for this region of the continent between 690 and 1591 AD. Perhaps the most outstanding feature of this history was the warm period it revealed between 860 and 1000 AD. Based on the fact that the northernmost twentieth century location of the forest

tree-line is presently 130 km south of their study site, the scientists concluded that the “Medieval Warm Period was approximately 1°C warmer than the 20th century.”

Shifting to the other side of the continent, Calkin *et al.* (2001) carefully reviewed what they termed “the most current and comprehensive research of Holocene glaciation” along the northernmost Gulf of Alaska between the Kenai Peninsula and Yakutat Bay, where they too detected a Medieval Warm Period that lasted for “at least a few centuries prior to A.D. 1200.” Also identifying the Medieval Warm Period, as well as other major warm and cold periods of the millennial-scale climatic oscillation that is responsible for them, was Campbell (2002), who analyzed the grain sizes of sediment cores obtained from Pine Lake, Alberta, Canada (52°N, 113.5°W) to provide a non-vegetation-based high-resolution record of climate variability for this part of North America over the past 4,000 years. Periods of both increasing and decreasing grain size (related to moisture availability) were noted throughout the 4,000-year record at decadal, centennial, and millennial time scales. The most predominant departures were several-centuries-long epochs that corresponded to the Little Ice Age (about AD 1500-1900), the Medieval Warm Period (about AD 700-1300), the Dark Ages Cold Period (about BC 100 to AD 700), and the Roman Warm Period (about BC 900-100).

Laird *et al.* (2003) studied diatom assemblages in sediment cores taken from three Canadian and three United States lakes situated within the northern prairies of North America, finding that “shifts in drought conditions on decadal through multacentennial scales have prevailed in this region for at least the last two millennia.” In Canada, major shifts occurred near the beginning of the Medieval Warm Period, while in the United States they occurred near its end. In giving some context to these findings, the authors state that “distinct patterns of abrupt change in the Northern Hemisphere are common at or near the termination of the Medieval Warm Period (*ca.* A.D. 800-1300) and the onset of the Little Ice Age (*ca.* A.D. 1300-1850).” They also note that “millennial-scale shifts over at least the past 5,500 years, between sustained periods of wetter and drier conditions, occurring approximately every 1,220 years, have been reported from western Canada (Cumming *et al.*, 2002),” and that “the striking correspondence of these shifts to large changes in fire frequencies, inferred from two sites several hundreds

of kilometers to the southwest in the mountain hemlock zone of southern British Columbia (Hallett *et al.*, 2003), suggests that these millennial-scale dynamics are linked and operate over wide spatial scales.”

In an effort to determine whether these climate-driven millennial-scale cycles are present in the terrestrial pollen record of North America, Viau *et al.* (2002) analyzed a set of 3,076 <sup>14</sup>C dates from the North American Pollen Database used to date sequences in more than 700 pollen diagrams across North America. Results of their statistical analyses indicated there were nine millennial-scale oscillations during the past 14,000 years in which continent-wide synchronous vegetation changes with a periodicity of roughly 1,650 years were recorded in the pollen records. The most recent of the vegetation transitions was centered at approximately 600 years BP (before present). This event, in the words of the authors, “culminat[ed] in the Little Ice Age, with maximum cooling 300 years ago.” Prior to that event, a major transition that began approximately 1,600 years BP represents the climatic amelioration that “culminat[ed] in the maximum warming of the Medieval Warm Period 1000 years ago.”

And so it goes, on back through the Holocene and into the preceding late glacial period, with the times of all major pollen transitions being “consistent,” in the words of the authors of the study, “with ice and marine records.” Viau *et al.* additionally note that “the large-scale nature of these transitions and the fact that they are found in different proxies confirms the hypothesis that Holocene and late glacial climate variations of millennial-scale were abrupt transitions between climatic regimes as the atmosphere-ocean system reorganized in response to some forcing.” They go on to say that “although several mechanisms for such *natural* [our italics] forcing have been advanced, recent evidence points to a potential solar forcing (Bond *et al.*, 2001) associated with ocean-atmosphere feedbacks acting as global teleconnections agents.” Furthermore, they note that “these transitions are identifiable across North America and presumably the world.”

Additional evidence for the solar forcing of these millennial-scale climate changes is provided by Shindell *et al.* (2001), who used a version of the Goddard Institute for Space Studies GCM to estimate climatic differences between the period of the Maunder Minimum in solar irradiance (mid-1600s to early 1700s) and a century later, when solar output was relatively high for several decades. Their results

compared so well with historical and proxy climate data that they concluded, in their words, that “colder winter temperatures over the Northern Hemispheric continents during portions of the 15th through the 17th centuries (sometimes called the Little Ice Age) and warmer temperatures during the 12th through 14th centuries (the putative Medieval Warm Period) may have been influenced by long-term solar variations.”

Rounding out our mini-review of the Medieval Warm Period in North America are two papers dealing with the climatic history of the Chesapeake Bay region of the United States. The first, by Brush (2001), consists of an analysis of sediment cores obtained from the Bay’s tributaries, marshes and main stem that covers the past millennium, in which it is reported that “the Medieval Climatic Anomaly and the Little Ice Age are recorded in Chesapeake sediments by terrestrial indicators of dry conditions for 200 years, beginning about 1000 years ago, followed by increases in wet indicators from about 800 to 400 years ago.”

Willard *et al.* (2003) studied the same region for the period 2,300 years BP to the present, via an investigation of fossil dinoflagellate cysts and pollen from sediment cores. Their efforts revealed that “several dry periods ranging from decades to centuries in duration are evident in Chesapeake Bay records.” The first of these periods of lower-than-average precipitation, which spanned the period 200 BC-AD 300, occurred during the latter part of the Roman Warm Period, as delineated by McDermott *et al.* (2001) on the basis of a high-resolution speleothem  $\delta^{18}\text{O}$  record from southwest Ireland. The next such dry period (~AD 800-1200), in the words of the authors, “corresponds to the ‘Medieval Warm Period’, which has been documented as drier than average by tree-ring (Stahle and Cleaveland, 1994) and pollen (Willard *et al.*, 2001) records from the southeastern USA.”

Willard *et al.* go on to say that “mid-Atlantic dry periods generally correspond to central and southwestern USA ‘megadroughts’, described by Woodhouse and Overpeck (1998) as major droughts of decadal or more duration that probably exceeded twentieth-century droughts in severity.” They further indicate that “droughts in the late sixteenth century that lasted several decades, and those in the ‘Medieval Warm Period’ and between ~AD 50 and AD 350 spanning a century or more have been indicated by Great Plains tree-ring (Stahle *et al.*, 1985; Stahle and Cleaveland, 1994), lacustrine diatom and ostracode

(Fritz *et al.*, 2000; Laird *et al.*, 1996a, 1996b) and detrital clastic records (Dean, 1997).”

It is evident that the Medieval Warm Period has left its mark throughout North America in the form of either warm temperature anomalies or periods of relative dryness.

Additional information on this topic, including reviews of newer publications as they become available, can be found at <http://www.co2science.org/subject/n/northamericamp.php>.

### 3.2.8. South America

In Argentina, Cioccale (1999) assembled what was known at the time about the climatic history of the central region of that country over the past 1,400 years, highlighting a climatic “improvement” that

began some 400 years before the start of the last millennium, which ultimately came to be characterized by “a marked increase of environmental suitability, under a relatively homogeneous climate.” As a result of this climatic amelioration that marked the transition of the region from the Dark Ages Cold Period to the Medieval Warm Period, Cioccale says “the population located in the lower valleys ascended to higher areas in the Andes,” where they remained until around AD 1320, when the transition to the stressful and extreme climate of the Little Ice Age began.

Down at the southern tip of the country in Tierra del Fuego, Mauquoy *et al.* (2004) inferred similar changes in temperature and/or precipitation from plant macrofossils, pollen, fungal spores, testate amoebae, and humification associated with peat monoliths collected from the Valle de Andorra. These new chronologies were compared with other chronologies of pertinent data from both the Southern and Northern Hemispheres in an analysis that indicated there was evidence for a period of warming-induced drier conditions from AD 960-1020, which, in their words, “seems to correspond to the Medieval Warm Period (MWP, as derived in the Northern Hemisphere).” They note that “this interval compares well to the date range of AD 950-1045 based on Northern Hemisphere extratropical tree-ring data (Esper *et al.*, 2002),” and they conclude that this correspondence “shows that the MWP was possibly synchronous in both hemispheres, as suggested by Villalba (1994).”

In Chile, Jenny *et al.* (2002) studied geochemical, sedimentological, and diatom-assemblage data derived from sediment cores extracted from one of the largest natural lakes (Laguna Aculeo) in the central part of the country. From 200 BC, when the record began, until AD 200, conditions there were primarily dry, during the latter stages of the Roman Warm Period. Subsequently, from AD 200-700, with a slight respite in the central hundred years of that period, there was a high frequency of flood events, during the Dark Ages Cold Period. Then came a several-hundred-year period of less flooding that was coeval with the Medieval Warm Period. This more benign period was then followed by another period of frequent flooding from 1300-1700 that was coincident with the Little Ice Age, after which flooding picked up again after 1850.

In Peru, Chepstow-Lusty *et al.* (1998) derived a 4,000-year climate history from a study of pollen in sediment cores obtained from a recently in-filled lake

in the Patacancha Valley near Marcacocha. Their data indicated a several-century decline in pollen content after AD 100, as the Roman Warm Period gave way to the Dark Ages Cold Period. However, a “more optimum climate,” as they describe it, with warmer temperatures and drier conditions, came into being and prevailed for several centuries after about AD 900, which was, of course, the Medieval Warm Period, which was followed by the Little Ice Age, all of which climatic periods are in nearly perfect temporal agreement with the climatic history derived by McDermott *et al.* (2001) from a study of a stalagmite recovered from a cave nearly half the world away in Ireland.

Subsequent work in this area was conducted by Chepstow-Lusty and Winfield (2000) and Chepstow-Lusty *et al.* (2003). Centered on approximately 1,000 years ago, Chepstow-Lusty and Winfield researchers identified what they describe as “the warm global climatic interval frequently referred to as the Medieval Warm Epoch.” This extremely *arid* interval in this part of South America, in their opinion, may have played a significant role in the collapse of the Tiwanaku civilization further south, where a contemporaneous prolonged drought occurred in and around the area of Lake Titicaca (Binford *et al.*, 1997; Abbott *et al.*, 1997).

Near the start of this extended dry period, which had gradually established itself between about AD 700 and 1000, Chepstow-Lusty and Winfield report that “temperatures were beginning to increase after a sustained cold period that had precluded agricultural activity at these altitudes.” This earlier colder and wetter interval was coeval with the Dark Ages Cold Period of the North Atlantic region, which in the Peruvian Andes had held sway for a good portion of the millennium preceding AD 1000, as revealed by a series of climatic records developed from sediment cores extracted from yet other lakes in the Central Peruvian Andes (Hansen *et al.*, 1994) and by proxy evidence of concomitant Peruvian glacial expansion (Wright, 1984; Seltzer and Hastorf, 1990).

Preceding the Dark Ages Cold Period in both parts of the world was what in the North Atlantic region is called the Roman Warm Period. This well-defined climatic epoch is also strikingly evident in the pollen records of Chepstow-Lusty *et al.* (2003), straddling the BC/AD calendar break with one to two hundred years of relative warmth and significant aridity on both sides of it.

Returning to the Medieval Warm Period and proceeding towards the present, the data of

Chepstow-Lusty *et al.* (2003) reveal the occurrence of the Little Ice Age, which in the Central Peruvian Andes was characterized by relative coolness and wetness. These characteristics of that climatic interval are also evident in ice cores retrieved from the Quelccaya ice cap in southern Peru, the summit of which extends 5,670 meters above mean sea level (Thompson *et al.*, 1986, 1988). Finally, both the Quelccaya ice core data and the Marcacocha pollen data reveal the transition to the drier Current Warm Period that occurred over the past 100-plus years.

In harmony with these several findings are the related observations of Rein *et al.* (2004), who derived a high-resolution flood record of the entire Holocene from an analysis of the sediments in a 20-meter core retrieved from a sheltered basin situated on the edge of the Peruvian shelf about 80 km west of Lima. These investigators found a major Holocene anomaly in the flux of lithic components from the continent onto the Peruvian shelf during the Medieval period. Specifically, they report that “lithic concentrations were very low for about 450 years during the Medieval climatic anomaly from A.D. 800 to 1250.” In fact, they state that “all known terrestrial deposits of El Niño mega-floods (Magillan and Goldstein, 2001; Wells, 1990) precede or follow the medieval anomaly in our marine records and none of the El Niño mega-floods known from the continent date within the marine anomaly.” In addition, they report that “this precipitation anomaly also occurred in other high-resolution records throughout the ENSO domain,” citing 11 other references in support of this statement.

Consequently, because heavy winter rainfalls along and off coastal Peru occur only during times of maximum El Niño strength, and because El Niños are typically more prevalent and stronger during cooler as opposed to warmer periods (see El Niño (Relationship to Global Warming) in Chapter 5), the lack of strong El Niños from A.D. 800 to 1250 suggests that this period was truly a Medieval Warm Period; and the significance of this observation was not lost on Rein *et al.* In the introduction to their paper, they note that “discrepancies exist between the Mann curve and alternative time series for the Medieval period.” Most notably, to use their words, “the global Mann curve has no temperature optimum, whereas the Esper *et al.* (2002) reconstruction shows northern hemisphere temperatures almost as high as those of the 20th century” during the Medieval period. As a result, in the final sentence of their paper they suggest that “the occurrence of a Medieval climatic anomaly (A.D.

800-1250) with persistently weak El Niños may therefore assist the interpretation of some of the regional discrepancies in thermal reconstructions of Medieval times,” which is a polite way of suggesting that the Mann *et al.* (1998, 1999) hockey stick temperature history is deficient in not depicting the presence of a true Medieval Warm Period.

In Venezuela, Haug *et al.* (2001) found a temperature/precipitation relationship that was different from that of the rest of the continent. In examining the titanium and iron concentrations of an ocean sediment core taken from the Cariaco Basin on the country’s northern shelf, they determined that the concentrations of these elements were lower during the Younger Dryas cold period between 12.6 and 11.5 thousand years ago, corresponding to a weakened hydrologic cycle with less precipitation and runoff, while during the warmth of the Holocene Optimum of 10.5 to 5.4 thousand years ago, titanium and iron concentrations remained at or near their highest values, suggesting wet conditions and an enhanced hydrologic cycle. Closer to the present, higher precipitation was also noted during the Medieval Warm Period from 1.05 to 0.7 thousand years ago, followed by drier conditions associated with the Little Ice Age between 550 and 200 years ago.

In an update of this study, Haug *et al.* (2003) developed a hydrologic history of pertinent portions of the record that yielded “roughly bi-monthly resolution and clear resolution of the annual signal.” This record revealed that “before about 150 A.D.,” which according to the climate history of McDermott *et al.* corresponds to the latter portion of the Roman Warm Period (RWP), Mayan civilization had flourished. However, during the transition to the Dark Ages Cold Period (DACP), which was accompanied by a slow but long decline in precipitation, Haug *et al.* report that “the first documented historical crisis hit the lowlands, which led to the ‘Pre-Classic abandonment’ (Webster, 2002) of major cities.”

This crisis occurred during the first intense multi-year drought of the RWP-to-DACP transition, which was centered on about the year 250 A.D. Although the drought was devastating to the Maya, Haug *et al.* report that when it was over, “populations recovered, cities were reoccupied, and Maya culture blossomed in the following centuries during the so-called Classic period.” Ultimately, however, there came a time of reckoning, between about 750 and 950 A.D., during what Haug *et al.* determined was the driest interval of the entire Dark Ages Cold Period, when they report that “the Maya experienced a demographic disaster as

profound as any other in human history,” in response to a number of other intense multi-year droughts. During this Terminal Classic Collapse, as it is called, Haug *et al.* say that “many of the densely populated urban centers were abandoned permanently, and Classic Maya civilization came to an end.”

In assessing the significance of these several observations near the end of their paper, Haug *et al.* conclude that the latter droughts “were the most severe to affect this region in the first millennium A.D.” Although some of these spectacular droughts were “brief,” lasting “only” between three and nine years, Haug *et al.* report “they occurred during an extended period of reduced overall precipitation that may have already pushed the Maya system to the verge of collapse.”

Although the Mayan civilization thus faded away, Haug *et al.*’s data soon thereafter depict the development of the Medieval Warm Period, when the Vikings established their historic settlement on Greenland. Then comes the Little Ice Age, which just as quickly led to the Vikings’ demise in that part of the world. This distinctive cold interval of the planet’s millennial-scale climatic oscillation also must have led to hard times for the people of Mesoamerica and northern tropical South America; according to the data of Haug *et al.*, the Little Ice Age produced the lowest precipitation regime (of several hundred years’ duration) of the last two millennia in that part of the world.

In conclusion, it is difficult to believe that the strong synchronicity of the century-long Northern Hemispheric and South American warm and cold periods described above was coincidental. It is much more realistic to believe it was the result of a millennial-scale oscillation of climate that is global in scope and driven by some regularly varying forcing factor. Although one can argue about the identity of that forcing factor and the means by which it exerts its influence, one thing should be clear: It is not the atmosphere’s CO<sub>2</sub> concentration, which has exhibited a significant in-phase variation with global temperature change only over the Little Ice Age to Current Warm Period transition. This being the case, it should be clear that the climatic amelioration of the past century or more has had little or nothing to do with the concomitant rise in the air’s CO<sub>2</sub> content but *everything* to do with the influential forcing factor that has governed the millennial-scale oscillation of earth’s climate as far back in time as we have been able to detect it.

### 3.3. Urban Heat Islands

How accurate are the surface temperature records cited by the IPCC as showing unprecedented millennial warmth over the past couple decades? The IPCC considers them very accurate and nearly free of any contaminating influence, yielding a 1905-2005 increase of  $0.74^{\circ}\text{C} \pm 0.18^{\circ}\text{C}$  (IPCC, 2007-I, p. 237). Warming in many growing cities, on the other hand, may have been a full order of magnitude greater. Since nearly all near-surface air temperature records of this period have been obtained from sensors located in population centers that have experienced significant growth, it is essential that urban heat island (UHI) effects be removed from all original temperature records when attempting to accurately assess what has truly happened in the natural non-urban environment.

The IPCC dismisses this concern, saying the UHI is “an order of magnitude smaller than decadal and longer time-scale trends” (p. 244) and “UHI effects are real but local, and have a negligible influence (less than  $0.006^{\circ}\text{C}$  per decade over land and zero over the oceans) on these [observed temperature] values” (p. 5). On this extremely important matter, the IPCC is simply wrong, as the rest of this section demonstrates.

#### 3.3.1. Global

Hegerl *et al.* (2001) describe UHI-induced temperature perversions as one of three types of systematic error in the surface air temperature record whose magnitude “cannot be assessed at present.” Nevertheless, they go on to do just that, claiming “it has been estimated that temperature trends over rural stations only are very similar to trends using all station data, suggesting that the effect of urbanization on estimates of global-scale signals should be small.” This statement is patently false.

De Laat and Maurellis (2004) used a global dataset developed by Van Aardenne *et al.* (2001), which reveals the spatial distribution of various levels of industrial activity over the planet as quantified by the intensity of anthropogenic  $\text{CO}_2$  emissions to divide the surface of the earth into non-industrial and industrial sectors of various intensity levels, after which they plotted the 1979-2001 temperature trends ( $^{\circ}\text{C}/\text{decade}$ ) of the different sectors using data from both the surface and the lower and middle troposphere.

The two scientists report that “measurements of surface and lower tropospheric temperature change give a very different picture from climate model predictions and show strong observational evidence that the degree of industrialization is correlated with surface temperature increases as well as lower tropospheric temperature changes.” Specifically, they find that the surface and lower tropospheric warming trends of all industrial regions are greater than the mean warming trend of the earth’s non-industrial regions, and that the difference in warming rate between the two types of land use grows ever larger as the degree of industrialization increases.

In discussing the implications of their findings, De Laat and Maurellis say “areas with larger temperature trends (corresponding to higher  $\text{CO}_2$  emissions) cover a considerable part of the globe,” which implies that “the ‘real’ global mean surface temperature trend is very likely to be considerably smaller than the temperature trend in the CRU [Hadley Center/Climate Research Unit] data,” since the temperature measurements that comprise that data base “are often conducted in the vicinity of human (industrial) activity.” These observations, in their words, “suggest a hitherto-overlooked driver of local surface temperature increases, which is linked to the degree of industrialization” and “lends strong support to other indications that surface processes (possibly changes in land-use or the urban heat effect) are crucial players in observed surface temperature changes (Kalnay and Cai, 2003; Gallo *et al.*, 1996, 1999).” They conclude that “the observed surface temperature changes might be a result of local surface heating processes and not related to radiative greenhouse gas forcing.”

A similar study was conducted by McKittrick and Michaels (2004), who calculated 1979-2000 linear trends of monthly mean near-surface air temperature for 218 stations in 93 countries, based upon data they obtained from the Goddard Institute of Space Studies (GISS), after which they regressed the results against

indicators of local economic activity—such as income, gross domestic product growth rates, and coal use—to see if there was any evidence of these socioeconomic factors affecting the supposedly “pristine as possible” temperature data. Then, they repeated the process using the gridded surface air temperature data of the IPCC.

The two scientists report that the spatial pattern of trends they derived from the GISS data was “significantly correlated with non-climatic factors, including economic activity and sociopolitical characteristics.” Likewise, with respect to the IPCC data, they say “very similar correlations appear, despite previous attempts to remove non-climatic effects.” These “socioeconomic effects,” in the words of McKittrick and Michaels, “add up to a net warming bias,” although they say “precise estimation of its magnitude will require further work.”

We can get a good feel for the magnitude of the “socioeconomic effect” in some *past* work, such as that of Oke (1973), who measured the urban heat island strength of 10 settlements in the St. Lawrence Lowlands of Canada that had populations ranging from approximately 1,000 to 2,000,000 people, after which he compared his results with those obtained for a number of other cities in North America, as well as some in Europe. Over the population range studied, Oke found that the magnitude of the urban heat island was linearly correlated with the logarithm of population; this relationship indicated that at the lowest population value encountered, i.e., 1,000 inhabitants, there was an urban heat island effect of 2° to 2.5°C, which warming is more than twice as great as the increase in mean global air temperature believed to have occurred since the end of the Little Ice Age. It should be abundantly clear there is ample opportunity for large errors to occur in thermometer-derived surface air temperature histories of the twentieth century, and that error is probably best described as a large and growing warming bias.

That this urban heat island-induced error has indeed corrupted data bases that are claimed to be immune from it is suggested by the work of Hegerl and Wallace (2000), who attempted to determine if trends in recognizable atmospheric modes of variability could account for all or part of the observed trend in surface-troposphere temperature differential, i.e., lapse rate, which has been driven by the upward-inclined trend in surface-derived temperatures and the nearly level trend in satellite-derived tropospheric temperatures over the last two decades of the twentieth century. After doing

everything they could conceive of doing, they had to conclude that “modes of variability that affect surface temperature cannot explain trends in the observed lapse rate,” and that “no mechanism with clear spatial or time structure can be found that accounts for that trend.” In addition, they had to acknowledge that “all attempts to explain all or a significant part of the observed lapse rate trend by modes of climate variability with structured patterns from observations have failed,” and that “an approach applying model data to isolate such a pattern has also failed.” Nor could they find any evidence “that interdecadal variations in radiative forcing, such as might be caused by volcanic eruptions, variations in solar output, or stratospheric ozone depletion alone, offer a compelling explanation.” Hence, the two scientists ultimately concluded that “there remains a gap in our fundamental understanding of the processes that cause the lapse rate to vary on interdecadal timescales.”

On the other hand, the reason why no meteorological or climatic explanation could be found for the ever-increasing difference between the surface- and satellite-derived temperature trends of the past 20-plus years may be that one of the temperature records is incorrect. Faced with this possibility, one would logically want to determine which of the records is likely to be erroneous and then assess the consequences of that determination. Although this task may seem daunting, it is really not that difficult. One reason why is the good correspondence Hegerl and Wallace found to exist between the satellite and radiosonde temperature trends, which leaves little reason for doubting the veracity of the satellite results, since this comparison essentially amounts to an *in situ* validation of the satellite record. A second important reason comes from the realization that it would be extremely easy for a spurious warming of 0.12°C per decade to be introduced into the surface air temperature trend as a consequence of the worldwide intensification of the urban heat island effect that was likely driven by the world population increase that occurred in most of the places where surface air temperature measurements were made over the last two decades of the twentieth century.

It appears almost certain that surface-based temperature histories of the globe contain a significant warming bias introduced by insufficient corrections for the *non*-greenhouse-gas-induced urban heat island effect. Furthermore, it may well be next to impossible to make proper corrections for this

deficiency, as the urban heat island of even small towns *dwarfs* any concomitant augmented greenhouse effect that may be present.

### 3.3.2. North America

In studying the urban heat island (UHI) of Houston, Texas, Streutker (2003) analyzed 82 sets of nighttime radiation data obtained from the split-window

infrared channels of the Advanced Very High Resolution Radiometer on board the NOAA-9 satellite during March 1985 through February 1987 and from 125 sets of similar data obtained from the NOAA-14 satellite during July 1999 through June 2001. Between these two periods, it was found that the mean nighttime surface temperature of Houston rose by  $0.82 \pm 0.10$  °C. In addition, Streutker notes that the growth of the Houston UHI, both in magnitude and spatial extent, “scales roughly with the increase in population,” and that the mean rural temperature measured during the second interval was “virtually identical to the earlier interval.”

This informative study demonstrates that the UHI phenomenon can sometimes be very powerful, for in just 12 years the UHI of Houston grew by more than the IPCC contends the mean surface air temperature of the planet rose over the entire past century, during which period earth’s population rose by approximately 280 percent, or nearly an order of magnitude more than the 30 percent population growth experienced by Houston over the 12 years of Streutker’s study.

A very different type of study was conducted by Maul and Davis (2001), who analyzed air and seawater temperature data obtained over the past century at the sites of several primary tide gauges maintained by the U.S. Coast and Geodetic Survey. Noting that each of these sites “experienced significant population growth in the last 100 years,” and that “with the increase in maritime traffic and discharge of wastewater one would expect water temperatures to rise” (due to a maritime analogue of the urban heat island effect), they calculated trends for the 14 longest records and derived a mean century-long seawater warming of 0.74°C, with Boston registering a 100-year warming of 3.6°C. In addition, they report that air temperature trends at the tide gauge sites, which represent the standard urban heat island effect, were “much larger” than the seawater temperature trends.

In another different type of study, Dow and DeWalle (2000) analyzed trends in annual evaporation and Bowen ratio measurements on 51 eastern U.S. watersheds that had experienced various degrees of urbanization between 1920 and 1990. In doing so, they determined that as residential development progressively occurred on what originally were rural watersheds, watershed evaporation decreased and sensible heating of the atmosphere increased. And from relationships derived from the suite of watersheds investigated, they

calculated that complete transformation from 100 percent rural to 100 percent urban characteristics resulted in a 31 percent decrease in watershed evaporation and a 13 W/m<sup>2</sup> increase in sensible heating of the atmosphere.

Climate modeling exercises suggest that a doubling of the air's CO<sub>2</sub> concentration will result in a nominal 4 W/m<sup>2</sup> increase in the radiative forcing of earth's surface-troposphere system, which has often been predicted to produce an approximate 4°C increase in the mean near-surface air temperature of the globe, indicative of an order-of-magnitude climate sensitivity of 1°C per W/m<sup>2</sup> change in radiative forcing. Thus, to a first approximation, the 13 W/m<sup>2</sup> increase in the sensible heating of the near-surface atmosphere produced by the total urbanization of a pristine rural watershed in the eastern United States could be expected to produce an increase of about 13°C in near-surface air temperature over the central portion of the watershed, which is consistent with maximum urban heat island effects observed in large and densely populated cities. Hence, a 10 percent rural-to-urban transformation could well produce a warming on the order of 1.3°C, and a mere 2 percent transformation could increase the near-surface air temperature by as much as a quarter of a degree Centigrade.

This powerful anthropogenic but non-greenhouse-gas-induced effect of urbanization on the energy balance of watersheds and the temperature of the boundary-layer air above them begins to express itself with the very first hint of urbanization and, hence, may be readily overlooked in studies seeking to identify a greenhouse-gas-induced global warming signal. In fact, the fledgling urban heat island effect may already be present in many temperature records that have routinely been considered "rural enough" to be devoid of all human influence.

A case in point is provided by the study of Changnon (1999), who used a series of measurements of soil temperatures obtained in a totally rural setting in central Illinois between 1889 and 1952 and a contemporary set of air temperature measurements made in an adjacent growing community (as well as similar data obtained from other nearby small towns), to evaluate the magnitude of unsuspected heat island effects that may be present in small towns and cities that are typically assumed to be free of urban-induced warming. This work revealed that soil temperature in the totally rural setting experienced an increase from the decade of 1901-1910 to the decade of 1941-1950 that amounted to 0.4°C.

This warming is 0.2°C *less* than the 0.6°C warming determined for the same time period from the entire dataset of the U.S. Historical Climatology Network, which is supposedly corrected for urban heating effects. It is also 0.2°C less than the 0.6°C warming determined for this time period by 11 benchmark stations in Illinois with the highest quality long-term temperature data, all of which are located in communities that had populations of less than 6,000 people as of 1990. And it is 0.17°C less than the 0.57°C warming derived from data obtained at the three benchmark stations closest to the site of the soil temperature measurements and with populations of less than 2,000 people.

Changnon says his findings suggest that "both sets of surface air temperature data for Illinois believed to have the best data quality with little or no urban effects may contain urban influences causing increases of 0.2°C from 1901 to 1950." He further notes—in a grand understatement—that "this could be significant because the IPCC (1995) indicated that the global mean temperature increased 0.3°C from 1890 to 1950."

DeGaetano and Allen (2002b) used data from the U.S. Historical Climatology Network to calculate trends in the occurrence of maximum and minimum temperatures greater than the 90th, 95th, and 99th percentile across the United States over the period 1960-1996. In the case of daily warm minimum temperatures, the slope of the regression line fit to the data of a plot of the annual number of 95th percentile exceedences vs. year was found to be 0.09 exceedences per year for rural stations, 0.16 for suburban stations, and 0.26 for urban stations, making the rate of increase in extreme warm minimum temperatures at urban stations nearly three times greater than the rate of increase at rural stations less affected by growing urban heat islands. Likewise, the rate of increase in the annual number of daily maximum temperature 95th percentile exceedences per year over the same time period was found to be 50 percent greater at urban stations than it was at rural stations.

Working on the Arctic Coastal Plain near the Chuckchi Sea at Barrow, Alaska—which is described by Hinkel *et al.* (2003) as "the northernmost settlement in the USA and the largest native community in the Arctic," the population of which "has grown from about 300 residents in 1900 to more than 4600 in 2000"—the four researchers installed 54 temperature-recording instruments in mid-June of 2001, half of them within the urban area and the other

## Observations: Temperature Records

half distributed across approximately 150 km<sup>2</sup> of surrounding land, all of which provided air temperature data at hourly intervals approximately two meters above the surface of the ground. In this paper, they describe the results they obtained for the following winter. Based on urban-rural spatial averages for the entire winter period (December 2001-March 2002), they determined the urban area to be 2.2°C warmer than the rural area. During this period, the mean daily urban-rural temperature difference increased with decreasing temperature, “reaching a peak value of around 6°C in January-February.” It was also determined that the daily urban-rural temperature difference increased with decreasing wind speed, such that under calm conditions ( $< 2 \text{ m s}^{-1}$ ) the daily urban-rural temperature difference was 3.2°C in the winter. Last of all, under simultaneous calm and cold conditions, the urban-rural temperature difference was observed to achieve hourly magnitudes exceeding 9°C.

Four years later, Hinkel and Nelson (2007) reported that for the period 1 December to 31 March of four consecutive winters, the spatially averaged temperature of the urban area of Barrow was about 2°C warmer than that of the rural area, and that it was not uncommon for the daily magnitude of the urban heat island to exceed 4°C. In fact, they say that on some days the magnitude of the urban heat island exceeded 6°C, and that values in excess of 8°C were sometimes recorded, while noting that the warmest individual site temperatures were “consistently observed in the urban core area.”

These results indicate just how difficult it is to measure a background global temperature increase that is believed to have been less than 1°C over the past century (representing a warming of less than 0.1°C per decade), when the presence of a mere 4,500 people can create a winter heat island that may be two orders of magnitude greater than the signal being sought. Clearly, there is no way that temperature measurements made within the range of influence of even a small village can be adjusted to the degree of accuracy that is required to reveal the true magnitude of the pristine rural temperature change.

Moving south, we find Ziska *et al.* (2004) working within and around Baltimore, Maryland, where they characterized the gradual changes that occur in a number of environmental variables as one moves from a rural location (a farm approximately 50 km from the city center) to a suburban location (a park approximately 10 km from the city center) to an urban location (the Baltimore Science Center

approximately 0.5 km from the city center). At each of these locations, four 2 x 2 m plots were excavated to a depth of about 1.1 m, after which they were filled with identical soils, the top layers of which contained seeds of naturally occurring plants of the area. These seeds sprouted in the spring of the year, and the plants they produced were allowed to grow until they senesced in the fall, after which all of them were cut at ground level, removed, dried and weighed.

Ziska *et al.* report that along the rural-to-suburban-to-urban transect, the only consistent differences in the environmental variables they measured were a rural-to-urban increase of 21 percent in average daytime atmospheric CO<sub>2</sub> concentration and increases of 1.6 and 3.3°C in maximum (daytime) and minimum (nighttime) daily temperatures, respectively, which changes, in their words, are “consistent with most short-term (~50 year) global change scenarios regarding CO<sub>2</sub> concentration and air temperature.” In addition, they determined that “productivity, determined as final above-ground biomass, and maximum plant height were positively affected by daytime and soil temperatures as well as enhanced CO<sub>2</sub>, increasing 60 and 115% for the suburban and urban sites, respectively, relative to the rural site.”

The three researchers say their results suggest that “urban environments may act as a reasonable surrogate for investigating future climatic change in vegetative communities,” and those results indicate that rising air temperatures and CO<sub>2</sub> concentrations tend to produce dramatic increases in the productivity of the natural ecosystems typical of the greater Baltimore area and, by inference, probably those of many other areas as well.

Three years later, George *et al.* (2007) reported on five years of work at the same three transect locations, stating that “atmospheric CO<sub>2</sub> was consistently and significantly increased on average by 66 ppm from the rural to the urban site over the five years of the study,” and that “air temperature was also consistently and significantly higher at the urban site (14.8°C) compared to the suburban (13.6°C) and rural (12.7°C) sites.” And they again noted that the increases in atmospheric CO<sub>2</sub> and air temperature they observed “are similar to changes predicted in the short term with global climate change, therefore providing an environment suitable for studying future effects of climate change on terrestrial ecosystems,” specifically noting that “urban areas are currently experiencing elevated atmospheric CO<sub>2</sub> and

temperature levels that can significantly affect plant growth compared to rural areas.”

Working further south still, LaDochy *et al.* (2007) report that “when speculating on how global warming would impact the state [of California], climate change models and assessments often assume that the influence would be uniform (Hansen *et al.*, 1998; Hayhoe *et al.*, 2004; Leung *et al.*, 2004).” Feeling a need to assess the validity of this assumption, they calculated temperature trends over the 50-year period 1950-2000 to explore the extent of warming in various sub-regions of the state, after which they attempted to evaluate the influence of human-induced changes to the landscape on the observed temperature trends and determine their significance compared to those caused by changes in atmospheric composition, such as the air’s CO<sub>2</sub> concentration.

In pursuing this protocol, the three researchers found that “most regions showed a stronger increase in minimum temperatures than with mean and maximum temperatures,” and that “areas of intensive urbanization showed the largest positive trends, while rural, non-agricultural regions showed the least warming.” In fact, they report that the Northeast Interior Basins of the state actually experienced *cooling*. Large urban sites, on the other hand, exhibited rates of warming “over twice those for the state, for the mean maximum temperature, and over five times the state’s mean rate for the minimum temperature.” Consequently, they concluded that “if we assume that global warming affects all regions of the state, then the small increases seen in rural stations can be an estimate of this general warming pattern over land,” which implies that “larger increases,” such as those they observed in areas of intensive urbanization, “must then be due to local or regional surface changes.”

Noting that “breezy cities on small tropical islands ... may not be exempt from the same local climate change effects and urban heat island effects seen in large continental cities,” Gonzalez *et al.* (2005) describe the results of their research into this topic, which they conducted in and about San Juan, Puerto Rico. In this particular study, a NASA Learjet—carrying the Airborne Thermal and Land Applications Sensor (ATLAS) that operates in visual and infrared wavebands—flew several flight lines, both day and night, over the San Juan metropolitan area, the El Yunque National Forest east of San Juan, plus other nearby areas, obtaining surface temperatures, while strategically placed ground instruments recorded local air temperatures. This

work revealed that surface temperature differences between urbanized areas and limited vegetated areas were higher than 3°C during daytime, creating an urban heat island with “the peak of the high temperature dome exactly over the commercial area of downtown,” where noontime air temperatures were as much as 3°C greater than those of surrounding rural areas. In addition, the eleven researchers report that “a recent climatological analysis of the surface [air] temperature of the city has revealed that the local temperature has been increasing over the neighboring vegetated areas at a rate of 0.06°C per year for the past 30 years.”

In discussing their findings, Gonzalez *et al.* state that “the urban heat island dominates the sea breeze effects in downtown areas,” and they say that “trends similar to those reported in [their] article may be expected in the future as coastal cities become more populated.” Indeed, it is probable that this phenomenon has long been operative in coastal cities around the world, helping to erroneously inflate the surface air temperature record of the planet and contributing to the infamous “hockey stick” representation of this parameter that has been so highly touted by the Intergovernmental Panel on Climate Change.

One year later, Velazquez-Lozada *et al.* (2006) evaluated the thermal impacts of historical land cover and land use (LCLU) changes in San Juan, Puerto Rico over the last four decades of the twentieth century via an analysis of air temperatures measured at a height of approximately two meters above ground level within four different LCLU types (urban-coastal, rural-inland, rural-coastal and urban-inland), after which they estimated what the strength of the urban heat island might be in the year 2050, based on anticipated LCLU changes and a model predicated upon their data of the past 40 years. In doing so, their work revealed “the existence of an urban heat island in the tropical coastal city of San Juan, Puerto Rico that has been increasing at a rate of 0.06°C per year for the last 40 years.” In addition, they report that predicted LCLU changes between now and 2050 will lead to an urban heat island effect “as high as 8°C for the year 2050.”

Noting that a mass population migration from rural Mexico into medium- and large-sized cities took place throughout the second half of the twentieth century, Jáuregui (2005) examined the effect of this rapid urbanization on city air temperatures, analyzing the 1950-1990 minimum air temperature series of seven large cities with populations in excess of a

million people and seven medium-sized cities with populations ranging from 125,000 to 700,000 people. This work indicated that temperature trends were positive at all locations, ranging from 0.02°C per decade to 0.74°C per decade. Grouped by population, the average trend for the seven large cities was 0.57°C per decade, while the average trend for the seven mid-sized cities was 0.37°C per decade. In discussing these results, Jáuregui says they “suggest that the accelerated urbanization process in recent decades may have substantially contributed to the warming of the urban air observed in large cities in Mexico.”

One additional question that may arise in relation to this topic is the direct heating of near-surface air in towns and cities by the urban CO<sub>2</sub> dome that occurs above them. Does it contribute significantly to the urban heat island?

In a study designed to answer this question, Balling *et al.* (2002) obtained vertical profiles of atmospheric CO<sub>2</sub> concentration, temperature, and humidity over Phoenix, Arizona from measurements made in association with once-daily aircraft flights conducted over a 14-day period in January 2000 that extended through, and far above, the top of the city’s urban CO<sub>2</sub> dome during the times of its maximum manifestation. They then employed a one-dimensional infrared radiation simulation model to determine the thermal impact of the urban CO<sub>2</sub> dome on the near-surface temperature of the city. These exercises revealed that the CO<sub>2</sub> concentration of the air over Phoenix dropped off rapidly with altitude, returning from a central-city surface value on the order of 600 ppm to a normal non-urban background value of approximately 378 ppm at an air pressure of 800 hPa, creating a calculated surface warming of only 0.12°C at the time of maximum CO<sub>2</sub>-induced warming potential, which is about an order of magnitude less than the urban heat island effect of cities the size of Phoenix. In fact, the authors concluded that the warming induced by the urban CO<sub>2</sub> dome of Phoenix is possibly two orders of magnitude smaller than that produced by other sources of the city’s urban heat island. Although the doings of man are indeed responsible for high urban air temperatures (which can sometimes rise 10°C or more above those of surrounding rural areas), these high values are not the result of a local CO<sub>2</sub>-enhanced greenhouse effect.

Meteorologist Anthony Watts (2009), in research too new to have appeared yet in a peer-reviewed journal, discovered compelling evidence that the temperature stations used to reconstruct the U.S.

surface temperature are unreliable and systemically biased toward recording more warming over time. Watts recruited a team of more than 650 volunteers to visually inspect the temperature stations used by the National Oceanic and Atmospheric Administration (NOAA) and the National Aeronautics and Space Administration (NASA) to measure changes in temperatures in the U.S. In the researcher’s words, “using the same quality standards established by NOAA, they found that 89 percent of the stations – nearly 9 of every 10 – fail to meet NOAA’s own siting requirements for stations with an expected reporting error of less than 1° C. Many of them fall *far* short of that standard [*italics in the original*].”

Watts goes on to report finding stations “located next to the exhaust fans of air conditioning units, causing them to report much- higher-than-actual temperatures. We found stations surrounded by asphalt parking lots and located near roads, sidewalks, and buildings that absorb and radiate heat. We found 68 stations located at wastewater treatment plants, where the process of waste digestion causes temperatures to be higher than in surrounding areas.”

Watts also discovered that failure to adequately account for changes in the technology used by temperature stations over time—including moving from whitewash to latex paint and from mercury thermostats to digital technology—“have further contaminated the data, once again in the direction of falsely raising temperature readings.” Watts is also extremely critical of adjustments to the raw data made by both NOAA and NASA, which “far from correcting the warming biases, actually compounded the measurement errors.”

The results of these several North American studies demonstrate that the impact of population growth on the urban heat island effect is very real and can be very large, overshadowing the effects of natural temperature change. This insight is not new: more than three decades ago, Oke (1973) demonstrated that towns with as few as a thousand inhabitants typically create a warming of the air within them that is more than twice as great as the increase in mean global air temperature believed to have occurred since the end of the Little Ice Age, while the urban heat islands of the great metropolises of the world create warmings that rival those that occur between full-fledged ice ages and interglacials. Extensive research conducted since then by independent scientists has confirmed Oke’s finding. Due to extensive corruption of land-based temperature data from urban heat islands, the North

American temperature record cannot be cited as providing reliable data in support of the greenhouse theory of global warming.

Additional information on this topic, including reviews of newer publications as they become available, can be found at <http://www.co2science.org/subject/u/uhinorthamerica.php>.

### 3.3.3. Asia

Hasanean (2001) investigated surface air temperature trends with data obtained from meteorological stations located in eight Eastern Mediterranean cities: Malta, Athens, Tripoli, Alexandria, Amman, Beirut, Jerusalem, and Latakia. The period of analysis varied from station to station according to available data, with Malta having the longest temperature record (1853-1991) and Latakia the shortest (1952-1991). Four of the cities exhibited overall warming trends and four of them cooling trends. In addition, there was an important warming around 1910 that began nearly simultaneously at all of the longer-record stations, as well as a second warming in the 1970s; but Hasanean reports that the latter warming was “not uniform, continuous or of the same order” as the warming that began about 1910, nor was it evident at all of the stations. One interpretation of this non-uniformity of temperature behavior in the 1970s is that it may have been the result of temporal

differences in city urbanization histories that were accentuated about that time, which could have resulted in significantly different urban heat island trajectories at the several sites over the latter portions of their records.

In a more direct study of the urban heat island effect that was conducted in South Korea, Choi *et al.* (2003) compared the mean station temperatures of three groupings of cities (one comprised of four large urban stations with a mean 1995 population of 4,830,000, one comprised of six smaller urban stations with a mean 1995 population of 548,000, and one comprised of six “rural” stations with a mean 1995 population of 214,000) over the period 1968-1999. This analysis revealed, in their words, that the “temperatures of large urban stations exhibit higher urban bias than those of smaller urban stations and that the magnitude of urban bias has increased since the late 1980s.” Specifically, they note that “estimates of the annual mean magnitude of urban bias range from 0.35°C for smaller urban stations to 0.50°C for large urban stations.” In addition, they indicate that “none of the rural stations used for this study can represent a true non-urbanized environment.” Hence, they correctly conclude that their results are underestimates of the true urban effect, and that “urban growth biases are very serious in South Korea and must be taken into account when assessing the reliability of temperature trends.”

In a second study conducted in South Korea, Chung *et al.* (2004a) report there was an “overlapping of the rapid urbanization-industrialization period with the global warming era,” and that the background climatic trends from urbanized areas might therefore be contaminated by a growing urban heat island effect. To investigate this possibility, they say “monthly averages of daily minimum, maximum, and mean temperature at 14 synoptic stations were prepared for 1951-1980 (past normal) and 1971-2000 (current normal) periods,” after which “regression equations were used to determine potential effects of urbanization and to extract the net contribution of regional climate change to the apparent temperature change.” Twelve of these stations were growing urban sites of various size, while two (where populations actually *decreased*) were rural, one being located inland and one on a remote island.

In terms of change over the 20 years that separated the two normal periods, Chung *et al.* report that in Seoul, where population increase was greatest, annual mean daily minimum temperature increased by 0.7°C, while a mere 0.1°C increase was detected at

one of the two rural sites and a 0.1°C decrease was detected at the other, for no net change in their aggregate mean value. In the case of annual mean daily maximum temperature, a 0.4°C increase was observed at Seoul and a 0.3°C increase was observed at the two rural sites. Hence, the change in the annual mean daily mean temperature was an increase of 0.15°C at the two rural sites (indicative of regional background warming of 0.075°C per decade), while the change of annual mean daily mean temperature at Seoul was an increase of 0.55°C, or 0.275°C per decade (indicative of an urban-induced warming of 0.2°C per decade in addition to the regional background warming of 0.075°C per decade). Also, corresponding results for urban areas of intermediate size defined a linear relationship that connected these two extreme results when plotted against the logarithm of population increase over the two-decade period.

In light of the significantly intensifying urban heat island effect detected in their study, Chung *et al.* say it is “necessary to subtract the computed urbanization effect from the observed data at urban stations in order to prepare an intended nationwide climatic atlas,” noting that “rural climatological normals should be used instead of the conventional normals to simulate ecosystem responses to climatic change, because the urban area is still much smaller than natural and agricultural ecosystems in Korea.”

A third study of South Korea conducted by Chung *et al.* (2004b) evaluated temperature changes at 10 urban and rural Korean stations over the period 1974-2002. They found “during the last 29 years, the increase in annual mean temperature was 1.5°C for Seoul and 0.6°C for the rural and seashore stations,” while increases in mean January temperatures ranged from 0.8 to 2.4°C for the 10 stations. In addition, they state that “rapid industrialization of the Korean Peninsula occurred during the late 1970s and late 1980s,” and that when plotted on a map, “the remarkable industrialization and expansion ... correlate with the distribution of increases in temperature.” Consequently, as in the study of Chung *et al.* (2004a), Chung *et al.* (2004b) found that over the past several decades, much (and in many cases *most*) of the warming experienced in the urban areas of Korea was the result of local urban influences that were not indicative of regional background warming.

Shifting attention to China, Weng (2001) evaluated the effect of land cover changes on surface temperatures of the Zhujiang Delta (an area of slightly more than 17,000 km<sup>2</sup>) via a series of

analyses of remotely sensed Landsat Thematic Mapper data. They found that between 1989 and 1997, the area of land devoted to agriculture declined by nearly 50 percent, while urban land area increased by close to the same percentage. Then, upon normalizing the surface radiant temperature for the years 1989 and 1997, they used image differencing to produce a radiant temperature change image that they overlaid with images of urban expansion. The results indicated, in Weng's words, that "urban development between 1989 and 1997 has given rise to an average increase of 13.01°C in surface radiant temperature."

In Shanghai, Chen *et al.* (2003) evaluated several characteristics of that city's urban heat island, including its likely cause, based on analyses of monthly meteorological data from 1961 to 1997 at 16 stations in and around this hub of economic activity that is one of the most flourishing urban areas in all of China. Defining the urban heat island of Shanghai as the mean annual air temperature difference between urban Longhua and suburban Songjiang, Chen *et al.* found that its strength increased in essentially linear fashion from 1977 to 1997 by 1°C.

Commenting on this finding, Chen *et al.* say "the main factor causing the intensity of the heat island in Shanghai is associated with the increasing energy consumption due to economic development," noting that in 1995 the Environment Research Center of Peking University determined that the annual heating intensity due to energy consumption by human activities was approximately 25 Wm<sup>-2</sup> in the urban area of Shanghai but only 0.5 Wm<sup>-2</sup> in its suburbs. In addition, they point out that the 0.5°C/decade intensification of Shanghai's urban heat island is an order of magnitude greater than the 0.05°C/decade global warming of the earth over the past century, which is indicative of the fact that ongoing intensification of even strong urban heat islands cannot be discounted.

Simultaneously, Kalnay and Cai (2003) used differences between trends in directly observed surface air temperature and trends determined from the NCEP-NCAR 50-year Reanalysis (NNR) project (based on atmospheric vertical soundings derived from satellites and balloons) to estimate the impact of land-use changes on surface warming. Over undisturbed rural areas of the United States, they found that the surface- and reanalysis-derived air temperature data yielded essentially identical trends, implying that differences between the two approaches over urban areas would represent urban heat island effects. Consequently, Zhou *et al.* (2004) applied the

same technique over southeast China, using an improved version of reanalysis that includes newer physics, observed soil moisture forcing, and a more accurate characterization of clouds.

For the period January 1979 to December 1998, the eight scientists involved in the work derived an "estimated warming of mean surface [air] temperature of 0.05°C per decade attributable to urbanization," which they say "is much larger than previous estimates for other periods and locations, including the estimate of 0.027°C for the continental U.S. (Kalnay and Cai, 2003)." They note, however, that because their analysis "is from the winter season over a period of rapid urbanization and for a country with a much higher population density, we expect our results to give higher values than those estimated in other locations and over longer periods."

In a similar study, Frauenfeld *et al.* (2005) used daily surface air temperature measurements from 161 stations located throughout the Tibetan Plateau (TP) to calculate the region's mean annual temperature for each year from 1958 through 2000, while in the second approach they used 2-meter temperatures from the European Centre for Medium-Range Weather Forecasts (ECMWF) reanalysis (ERA-40), which temperatures, in their words, "are derived from rawinsonde profiles, satellite retrievals, aircraft reports, and other sources including some surface observations." This approach, according to them, results in "more temporally homogeneous fields" that provide "a better assessment of large-scale temperature variability across the plateau."

Frauenfeld *et al.* report that over the period 1958-2000, "time series based on aggregating all station data on the TP show a statistically significant positive trend of 0.16°C per decade," as has also been reported by Liu and Chen (2000). However, they say that "no trends are evident in the ERA-40 data for the plateau as a whole."

In discussing this discrepancy, the three scientists suggest that "a potential explanation for the difference between reanalysis and station trends is the extensive local and regional land use change that has occurred across the TP over the last 50 years." They note, for example, that "over the last 30 years, livestock numbers across the TP have increased more than 200% due to inappropriate land management practices and are now at levels that exceed the carrying capacity of the region (Du *et al.*, 2004)." The resultant overgrazing, in their words, "has caused land degradation and desertification at an alarming rate (Zhu and Li, 2000; Zeng *et al.*, 2003)," and they note

that “in other parts of the world, land degradation due to overgrazing has been shown to cause significant local temperature increases (e.g., Balling *et al.*, 1998).”

Another point they raise is that “urbanization, which can result in 8°-11°C higher temperatures than in surrounding rural areas (e.g., Brandsma *et al.*, 2003), has also occurred extensively on the TP,” noting that “construction of a gas pipeline in the 1970s and highway expansion projects in the early 1980s have resulted in a dramatic population influx from other parts of China, contributing to both urbanization and a changed landscape.” In this regard, they say that “the original Tibetan section of Lhasa (i.e., the pre-1950 Lhasa) now only comprises 4% of the city, suggesting a 2400% increase in size over the last 50 years.” And they add that “similar population increases have occurred at other locations across the TP,” and that “even villages and small towns can exhibit a strong urban heat island effect.”

In concluding their analysis of the situation, Frauenfeld *et al.* contend that “these local changes are reflected in station temperature records.” We note that when the surface-generated anomalies are removed, as in the case of the ERA-40 reanalysis results they present, it is clear there has been no warming of the Tibetan Plateau since at least 1958. Likewise, we submit that the other results reported in this section imply much the same about other parts of China and greater Asia.

In conclusion, a large body of research conducted by scores of scientists working in countries around the world reveals that the twentieth century warming claimed by the IPCC, Mann *et al.* (1998, 1999), and Mann and Jones (2003) to represent mean global background conditions is likely significantly biased towards warming over the past 30 years and is therefore not a true representation of earth’s recent thermal history.

### 3.4. Fingerprints

Is there a method that can distinguish anthropogenic global warming from natural warming? The IPCC (IPCC-SAR, 1996, p. 411; IPCC, 2007-I, p. 668) and many scientists believe the “fingerprint” method is the only reliable one. It compares the observed pattern of warming with a pattern calculated from greenhouse models. While an agreement of such fingerprints cannot prove an anthropogenic origin for warming, it would be consistent with such a conclusion. A mismatch would argue strongly against any significant contribution from greenhouse gas (GHG) forcing and support the conclusion that the observed warming is mostly of natural origin.

Climate models all predict that, if GHG is driving climate change, there will be a unique fingerprint in the form of a warming trend increasing with altitude in the tropical troposphere, the region of the atmosphere up to about 15 kilometers. (See Figure 3.4.1.) Climate changes due to solar variability or other known natural factors will not yield this pattern; only sustained greenhouse warming will do so.

The fingerprint method was first attempted in the IPCC’s Second Assessment Report (SAR) (IPCC-SAR, 1996, p. 411). Its Chapter 8, titled “Detection and Attribution,” attributed observed temperature changes to anthropogenic factors—greenhouse gases and aerosols. The attempted match of warming trends with altitude turned out to be spurious, since it depended entirely on a particular choice of time interval for the comparison (Michaels and Knappenberger, 1996). Similarly, an attempt to correlate the observed and calculated geographic

distribution of surface temperature trends (Santer *et al.* 1996) involved making changes on a published graph that could and did mislead readers (Singer, 1999, p. 9; Singer, 2000, pp. 15, 43-44). In spite of these shortcomings, IPCC-SAR concluded that “the balance of evidence” supported AGW.

With the availability of higher-quality temperature data, especially from balloons and satellites, and with improved GH models, it has become possible to apply the fingerprint method in a more realistic way. This was done in a report issued by the U.S. Climate Change Science Program (CCSP) in April 2006—making it readily available to the IPCC for its Fourth Assessment Report—and it permits the most realistic comparison of fingerprints (Karl *et al.*, 2006).

PCM Simulations of Zonal-Mean Atmospheric Temperature Change  
Total linear change computed over January 1958 to December 1999

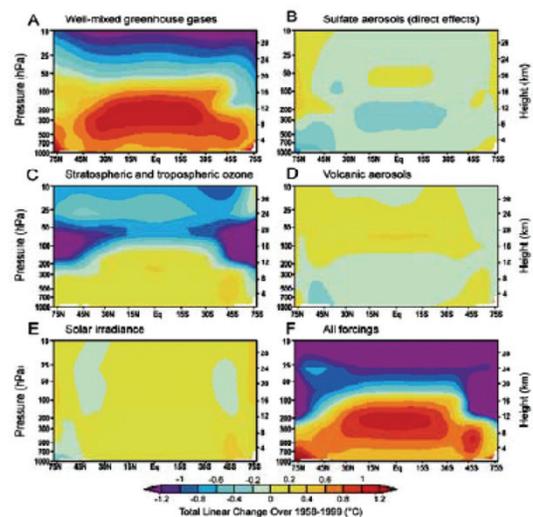

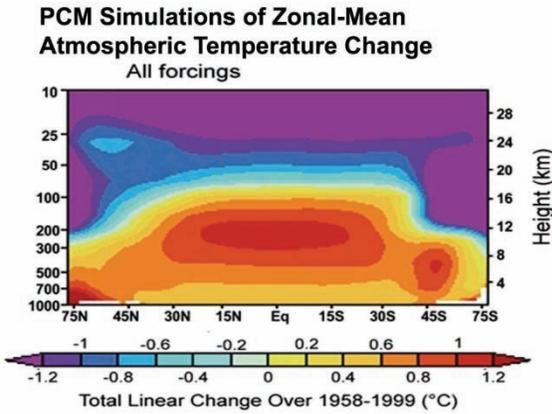

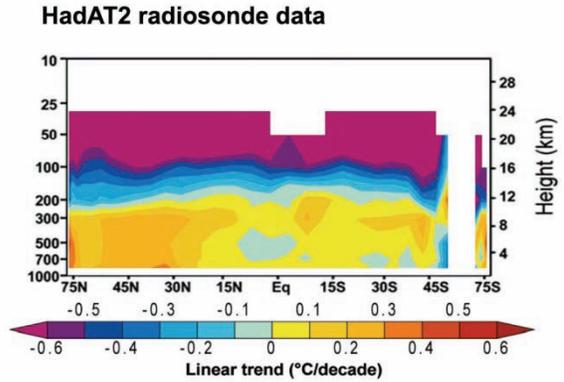

Figure 3.4.1. PCM simulations of the vertical profile of temperature change due to various forcings, and the effect due to all forcings taken together (after Santer *et al.*, 2000).

**Figure 3.4.1.** Model-calculated zonal mean atmospheric temperature change from 1890 to 1999 (degrees C per century) as simulated by climate models from [A] well-mixed greenhouse gases, [B] sulfate aerosols (direct effects only), [C] stratospheric and tropospheric ozone, [D] volcanic aerosols, [E] solar irradiance, and [F] all forcings (U.S. Climate Change Science Program 2006, p. 22). Note the pronounced increase in warming trend with altitude in figures A and F, which the IPCC identified as the ‘fingerprint’ of greenhouse forcing.

The CCSP report is an outgrowth of an NAS report “Reconciling Observations of Global Temperature Change” issued in January 2000 (NAS, 2000). That NAS report compared surface and troposphere temperature trends and concluded they cannot be reconciled. Six years later, the CCSP report expanded considerably on the NAS study. It is

**Figure 3.4.2.** Greenhouse-model-predicted temperature trends versus latitude and altitude; this is figure 1.3F from CCSP 2006, p. 25. Note the increased temperature trends in the tropical mid-troposphere, in agreement also with the IPCC result (IPCC-AR4 2007, p. 675).

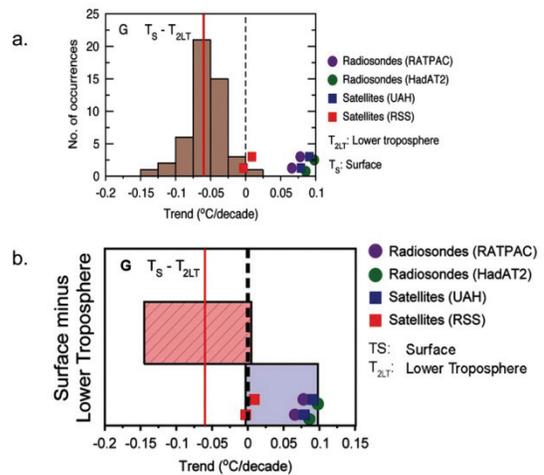

**Figure 3.4.3.** By contrast, observed temperature trends versus latitude and altitude; this is figure 5.7E from CCSP 2006, p. 116. These trends are based on the analysis of radiosonde data by the Hadley Centre and are in good agreement with the corresponding U.S. analyses. Notice the absence of increased temperature trends in the tropical mid-troposphere.

essentially a specialized report addressing the most crucial issue in the global warming debate: Is current global warming anthropogenic or natural? The CCSP result is unequivocal. While all greenhouse models show an increasing warming trend with altitude, peaking around 10 km at roughly two times the surface value, the temperature data from balloons give the opposite result: no increasing warming, but rather a slight cooling with altitude in the tropical zone. See Figures 3.4.2 and 3.4.3, taken directly from the CCSP report.

The CCSP executive summary inexplicably claims agreement between observed and calculated patterns, the opposite of what the report itself documents. It tries to dismiss the obvious disagreement shown in the body of the report by suggesting there might be something wrong with both balloon and satellite data. Unfortunately, many people do not read beyond the summary and have therefore been misled to believe the CCSP report supports anthropogenic warming. It does not.

The same information also can be expressed by plotting the difference between surface trend and troposphere trend for the models and for the data (Singer, 2001). As seen in Figure 3.4.4 and 3.4.5, the models show a histogram of negative values (i.e. surface trend less than troposphere trend) indicating that atmospheric warming will be greater than surface warming. By contrast, the data show mainly positive values for the difference in trends, demonstrating that measured warming is occurring principally on the surface and not in the atmosphere.

**Modeled and Observed Temperature Trends in the Tropics (20°S - 20°N)**

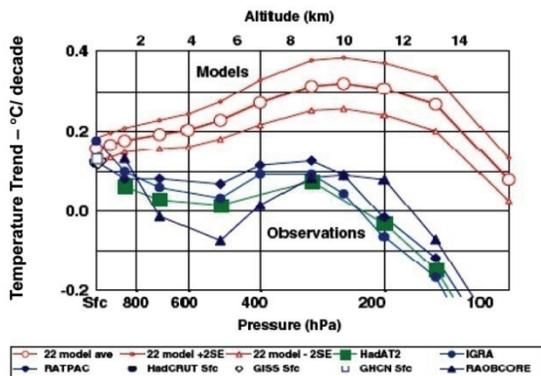

**Figure 3.4.4.** Another way of presenting the difference between temperature trends of surface and lower troposphere; this is figure 5.4G from CCSP 2006, p. 111. The model results show a spread of values (histogram); the data points show balloon and satellite trend values. Note the model results hardly overlap with the actual observed trends. (The apparent deviation of the RSS analysis of the satellite data is as yet unexplained.)

**Figure 3.4.5.** By contrast, the executive summary of the CCSP report presents the same information as Figure 3.4.4 in terms of ‘range’ and shows a slight overlap between modeled and observed temperature trends (Figure 4G, p. 13). However, the use of ‘range’ is clearly inappropriate (Douglass et al. 2007) since it gives undue weight to ‘outliers.’

The same information can be expressed in yet a different way, as seen in research papers by Douglass *et al.* (2004, 2007), as shown in Figure 3.4.6. The models show an increase in temperature trend with altitude but the observations show the opposite.

**Models and Observations Disagree** [Douglass, Christy, Pearson, Singer 2007]

**Figure 3.4.6.** A more detailed view of the disparity of temperature trends is given in this plot of trends (in degrees C/decade) versus altitude in the tropics [Douglass *et al.* 2007]. Models show an increase in the warming trend with altitude, but balloon and satellite observations do not.

This mismatch of observed and calculated fingerprints clearly falsifies the hypothesis of anthropogenic global warming (AGW). We must conclude therefore that anthropogenic greenhouse gases can contribute only in a minor way to the current warming, which is mainly of natural origin. The IPCC seems to be aware of this contrary evidence but has tried to ignore it or wish it away. The summary for policymakers of IPCC's Fourth Assessment Report (IPCC 2007-I, p. 5) distorts the key result of the CCSP report: "New analyses of balloon-borne and satellite measurements of lower- and mid-tropospheric temperature show warming rates that are similar to those of the surface temperature record, and are consistent within their respective uncertainties, largely reconciling a discrepancy noted in the TAR." How is this possible? It is done partly by using the concept of "range" instead of the statistical distribution shown in Figure 12a. But "range" is not a robust statistical measure because it gives undue weight to "outlier" results (Figure 12b). If robust probability distributions were used they would show an exceedingly low probability of any overlap of modeled and the observed temperature trends.

If one takes greenhouse model results seriously, then the greenhouse fingerprint would suggest the

true surface trend should be only 30 to 50 percent of the observed balloon/satellite trends in the troposphere. In that case, one would end up with a much-reduced surface warming trend, an insignificant AGW effect, and a minor greenhouse-induced warming in the future.

### 3.5. Satellite Data

The IPCC claims that data collected by satellite-mounted microwave sounding units (MSU) and advanced MSU measurements since 1979 reveal a warming trend of 0.12° C to 0.19° C per decade, which it says “is broadly consistent with surface temperature trends” (IPCC, 2007-I, p. 237). This would be surprising, since we indicated in the previous section that the surface-based temperature record is unreliable and biased toward a spurious warming trend. In this section we investigate the truth of the IPCC’s claim in this regard and report other findings based on satellite data.

Most climate models predict that the troposphere should warm about 1.2 times more than the surface globally, and about 1.5 times more in the tropics. Although the MSUs mounted on satellites sent into orbit by NASA for the National Oceanic and Atmospheric Administration (NOAA) were not originally intended to be used to measure temperatures in the troposphere, they have been used for this purpose since 1979 and, despite some ongoing debate, are acknowledged to be a reliable source of information about temperatures in the troposphere (Christy *et al.*, 2003, 2007; Santer *et al.*, 2005). As Wentz and Schabel observed in an article in *Nature* in 1998, “the detection and measurement of small changes in the Earth’s climate require extremely precise global observations of a broad spectrum of complementary physical variables. In this endeavour, satellite observations are playing an increasingly important role. As compared to conventional *in situ* observations, satellites provide daily near-global coverage with a very high statistical precision that results from averaging millions of individual observations” (Wentz and Schabel, 1998).

Four groups currently report MSU measurements: the University of Alabama in Huntsville (UAH), Remote Sensing System (RSS) (a small private weather forecasting firm led by the previously cited Frank Wentz), the University of Maryland (UMd),

and a group from NOAA whose data series begins in 1987. RSS and UAH produce estimates of temperatures for the lower troposphere (LT), mid-troposphere (MT), and lower stratosphere (LS). UMD produces estimates only for MT (Christy and Norris, 2006). New data for the UAH series is posted every month on a Web site maintained at the University of Alabama at Huntsville.

The first satellite record was produced by Roy Spencer, then with NASA and now the U.S. Science Team leader for the Advanced Microwave Scanning Radiometer flying on NASA’s Aqua satellite, and John Christy, distinguished professor of atmospheric science and director of the Earth System Science Center at the University of Alabama in Huntsville. Published in *Science* in 1990 (Spencer and Christy, 1990), the article presented the first 10 years of satellite measurements of lower atmospheric temperature changes (from 1979 to 1988) and found “no obvious trend for the 10-year period.” Although this finding covered too short a period of time to prove a trend, it seemed to contradict claims by some scientists at the time that a warming trend was underway. It triggered a long-running debate, which continues to this day, over the accuracy of the satellite data.

In 1997, Kevin Trenberth, of the U.S. National Center for Atmospheric Research (NCAR) and later a lead author of the IPCC’s Third Assessment Report, along with coauthors challenged the reliability of the satellite data (Trenberth, 1997; Trenberth and Hurrell, 1997; Hurrell and Trenberth, 1997). Trenberth argued that Spencer and Christy had failed to properly calibrate the sensors on each new satellite as older satellites were retired and new ones launched into orbit, based on a surface-satellite comparison. Spencer and Christy, however, showed that the surface and tropospheric discrepancy was real, as it also was found in independent balloon comparisons (Christy *et al.*, 1997).

Critics of the satellite data pointed to other possible and actual errors in the satellite record, and Spencer and Christy made two adjustments based on these external criticisms for such things as orbit decay and changes in technology. One of the larger changes was made to correct for drift in local crossing time (i.e., change in the time-of-day that the measures are taken), an error discovered by Mears and Wentz (2005) and subsequently corrected by Christy and Spencer (2005). Many of the adjustments made by Christy and Spencer resulted in the satellite record

showing a small warming trend of 0.123 °C between 1979 and 2005.

In 2006, a panel of the U.S. Climate Change Science Program (CCSP) attempted to reconcile differences between satellite and surface-station data. While the executive summary of the report claimed (as the IPCC does) that “this significant discrepancy [between surface station records and satellite records] no longer exists because errors in the satellite and radiosonde data have been identified and corrected,” in fact significant differences in some values (especially in the important region of the tropics, as discussed in Section 3.4. Fingerprints) remained unsolved (CCSP, 2006).

Satellite data allow us to check the accuracy of the warming trend during the last three decades reported by the three combined land-surface air temperature and sea-surface temperature (SST) records used by the IPCC: CRU (from the Climate Research Unit (CRU) at the University of East Anglia, in Norwich, England), NCDC (from the National Climatic Data Center), and GISS (from NASA’s Goddard Institute for Space Studies). The IPCC lists temperature trends (°C /decade) for each record for the periods 1850-2005, 1901-2005, and 1979-2005 (IPCC, 2007-I, Table 3.3, p. 248). All three surface temperature records used by the IPCC show positive trends in global temperatures during the 1979-2005 period (the period that can be checked against satellite data) of between 0.163° C/decade and 0.174 °C /decade, compared to the UAH record of only 0.123° C/decade. This means the IPCC’s estimates of warming are between 33 percent and 41.5 percent more rapid than the most scientifically accurate record we have of global temperatures during this 26-year period. The IPCC claims an even higher estimate of 0.177° C/decade (44 percent higher than UAH) in a graph on page 253, a variation of which appears in the Summary for Policymakers (p. 6). Finally, we note that none of the warming rates reported in the IPCC’s Table 3.3 reaches the 0.19° C that the IPCC claimed to be the upper end of the range of credible estimates, while the UAH record of 0.128° C/decade sits very close to the lowest estimate of 0.12° C.

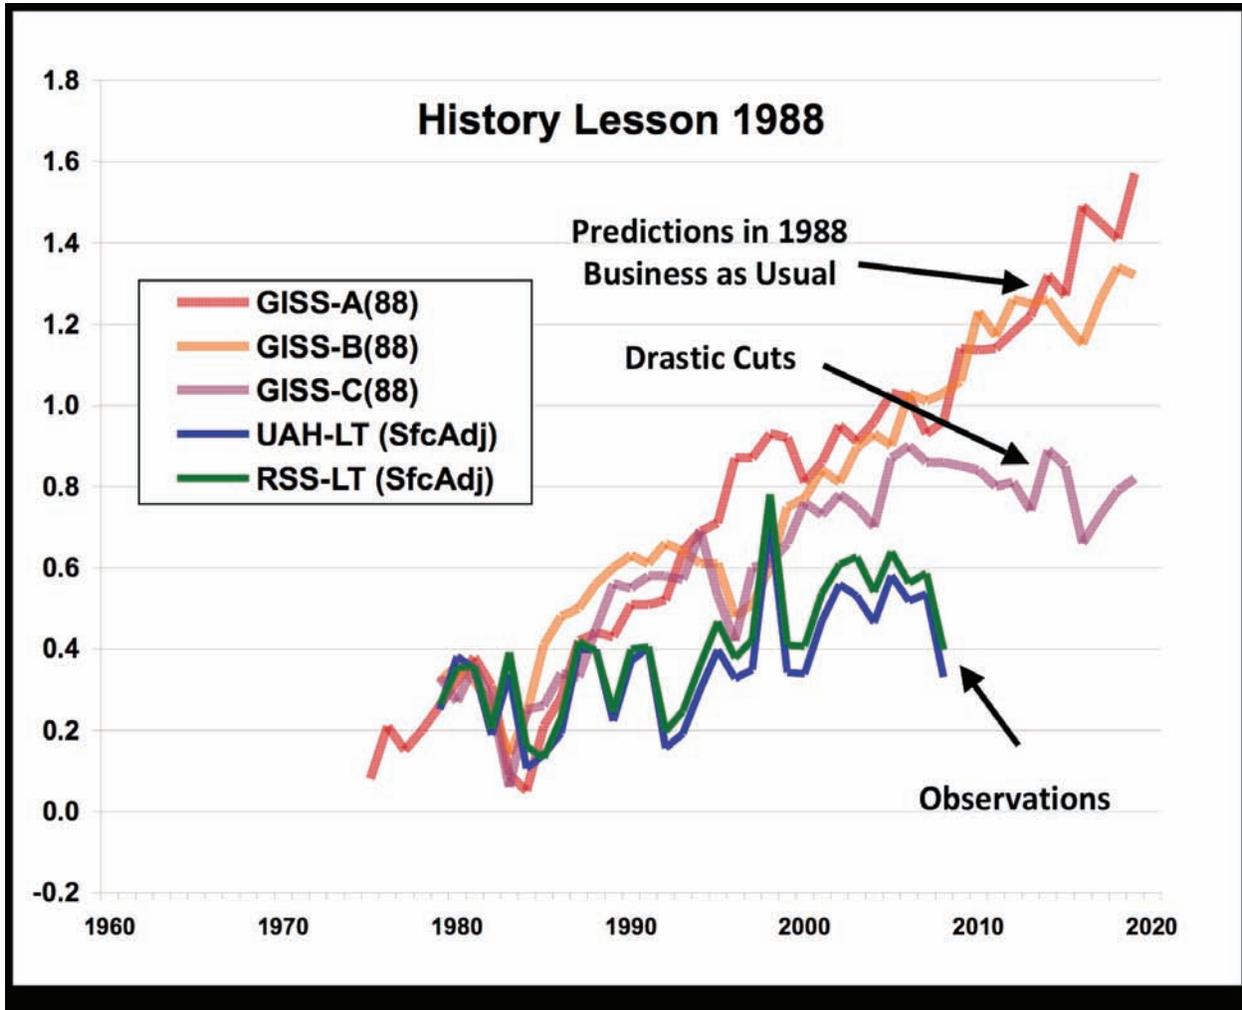

Similarly, the IPCC’s temperature records for the Northern Hemisphere are CRU’s 0.234° C and NCDC’s 0.245° C, approximately 17 percent to 22.5 percent higher than the UAH’s record of 0.20° C. For the Southern Hemisphere, the IPCC’s estimates are 0.092° C (CRU) and 0.096 °C (NCDC), or a very large 84 percent and 92 percent higher than the

UAH’s 0.05° C. To say this is “broadly consistent,” as the IPCC does, is not accurate. In light of the large discrepancy between satellite and surface records for the Southern Hemisphere, it is notable that Christy has been using the UAH database to detect and correct errors in the Australian radiosondes record (Christy and Norris, 2009) and the surface station record in East Africa (Christy *et al.*, 2009).

Satellite data also allow us to compare real-world temperatures to the predictions (or “scenarios”) offered by those who have been predicting warming since the 1980s. Figure 3.5.1. compares the UAH and RSS temperature records “adjusted to mimic surface temperature variations for an apples to apples comparison with the model projections (factor of 1.2, CCSP SAP 1.1)” to three model projections of global surface temperature presented by NASA’s James Hansen in Senate testimony in 1988 (Christy, 2009). “GISS-A 88” and “GISS-B 88,” at the top of the graph, are Hansen’s two “business-as-usual” model projections of temperature which assumed greenhouse gas emissions would be similar to what actually has happened. “GISS-C 88” is Hansen’s temperature forecast if drastic GHG reductions were made. Obviously, real-world temperatures have failed to rise as Hansen had predicted, and indeed, global temperatures in 2009 were no higher than when Hansen testified in 1988. As Christy comments, “Even the model projection for drastic CO<sub>2</sub> cuts still overshoot the observations. This would be considered a failed hypothesis test for the models from 1988” (Christy, 2009).

By 2008, the UAH data series indicated that global temperatures in the lower atmosphere had warmed at the slightly higher rate of about 0.14° C/decade from January 1979 through December 2007, while the RSS data series showed a warming rate of 0.17° C/decade. Recent research by Randall and Herman (2009) using data collected from a subset of weather balloon observations thought to be most reliable suggests the RSS data incorporate an improper handling of diurnal cycle effects that causes a small warming bias over global land areas, thus suggesting that the lower UAH estimate of 0.14° C/decade may have been closer to correct. Graphs showing both data sets and a third graph showing the difference between the two data sets appear in Figure 3.5.2.

Explanations exist for two of the biggest differences between the two datasets. The first is a sudden warming in RSS relative to UAH in January 1992. This feature has been found in comparison with

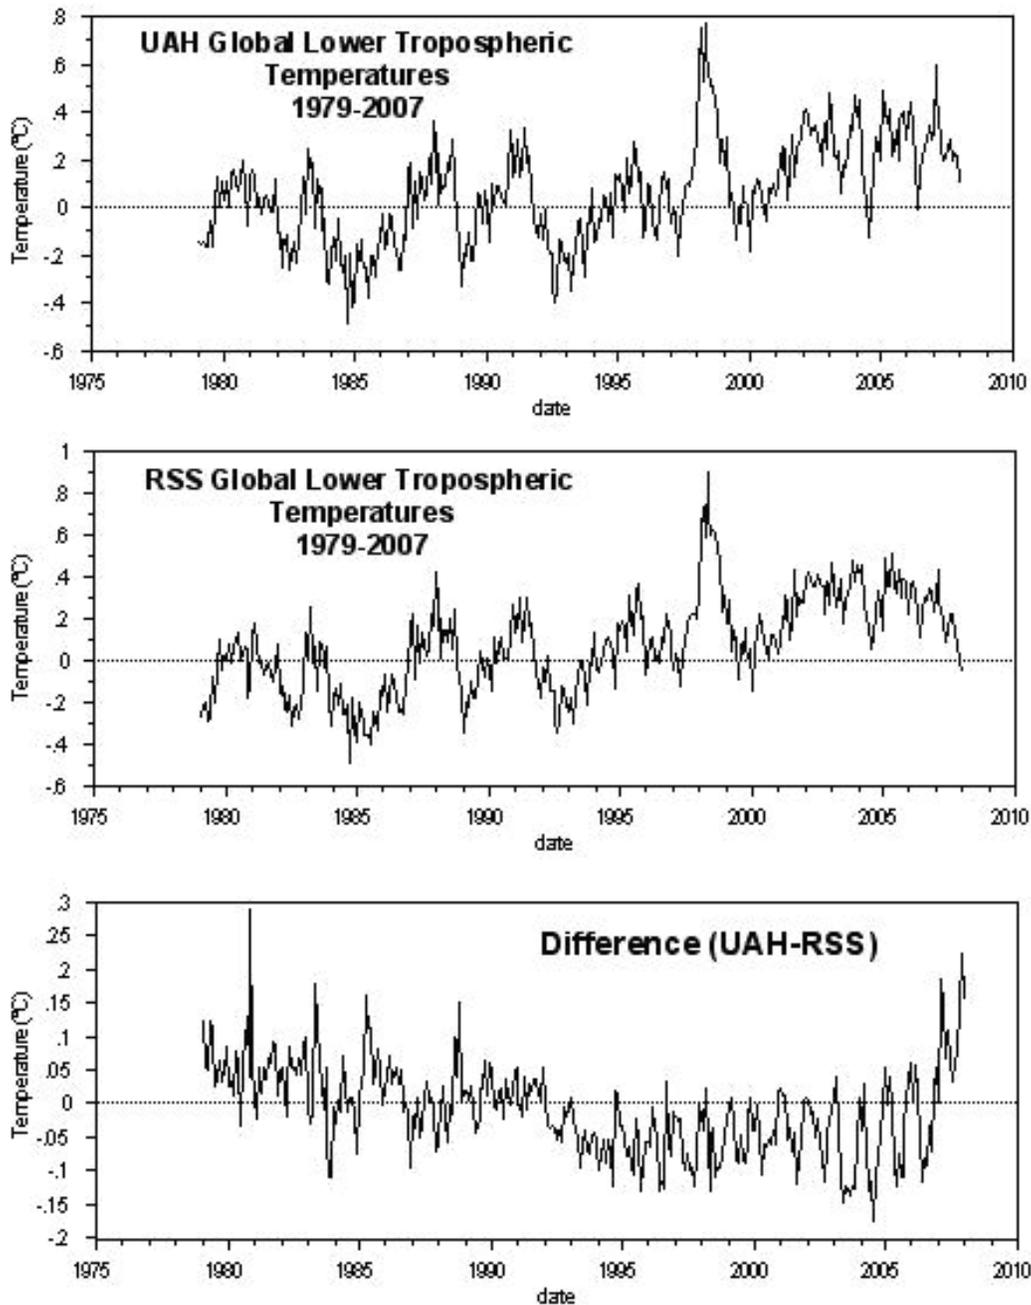

**Figure 3.5.1.** Actual temperature changes from UAH and RSS satellite data, adjusted to mimic surface temperatures, compared to predictions made by James Hansen to Congress in 1988. every other surface and tropospheric temperature dataset, indicating RSS contains a spurious warming shift at that time (Christy *et al.*, 2007). The second feature is the relative cooling of RSS vs. UAH since 2006. This can be explained by the fact UAH uses a spacecraft (NASA’s Aqua) that is not subject to orbital drifting, whereas RSS relies on NOAA-15, which is drifting into warmer diurnal times. The implication here is that RSS is overcorrecting for this spurious warming by reporting too much cooling. Overall, the shifts unique to RSS create a spurious warming in the record, which is being slowly mitigated by the more recent spurious cooling.

The graphs show that the temperature anomalies in the RSS dataset for November 2007 and December 2007 were below the 1979-1998 mean average for the first time since 2000. Both data series show the rate of

warming has slowed dramatically during the past seven to 12 years. Between the end of 2007 and early 2009, global temperature anomalies fell even further, effectively returning the world to the temperatures that prevailed in the late 1980s and early 1990s. See Figure 3.5.3. below.

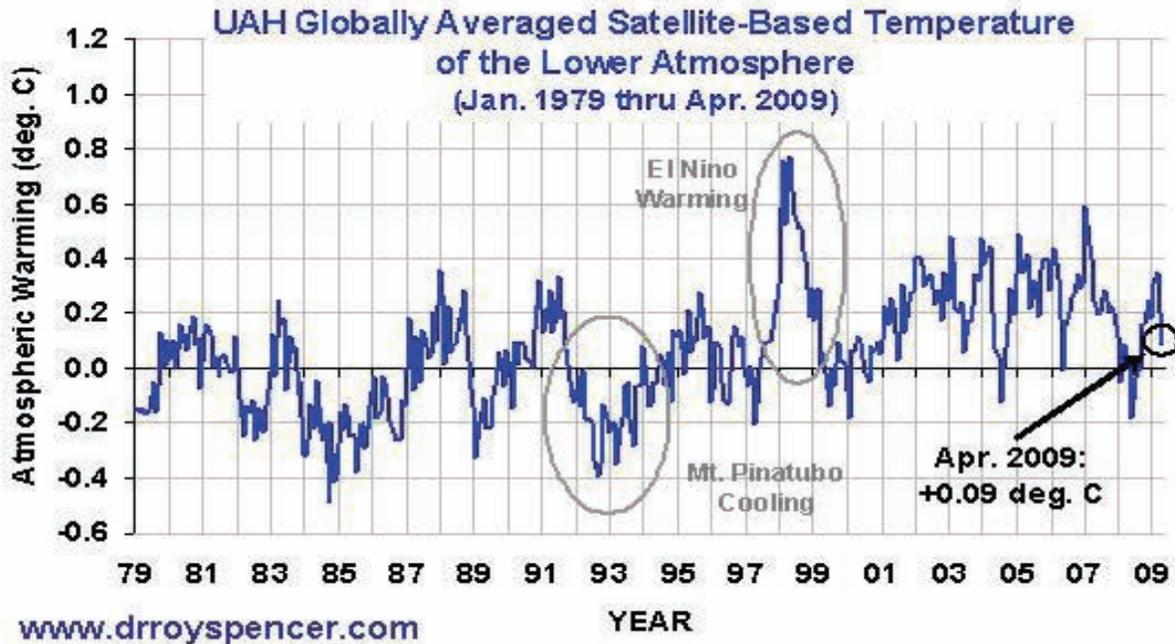

The new trend toward less warming has prompted some scientists to wonder if the world’s climate experienced a trend break in 2001-2002, similar to ones that occurred around 1910 (ending a cooling trend), the early 1940s (ending a warming trend), and the mid-1970s (ending a cooling trend). Swanson and Anastasios (2009), writing in *Geophysical Research Letters*, say “a break in the global mean temperature trend from the consistent warming over the 1976/77–2001/02 period may have occurred.” Moreover, the episodic nature of temperature changes during the

**Figure 3.5.2.** Global temperature anomalies from the lower troposphere. January 1979 through December 2007. (top) Data compiled at the University of Alabama, (middle) data compiled by Remote Sensing Systems, (bottom) difference between the two datasets (UAH minus RSS). Graphs were produced by Patrick Michaels using UAH and RSS data and first appeared in *World Climate Report* on February 7, 2008, <http://www.worldclimaterreport.com/index.php/category/temperature-history/satelliteballoons/>.

past century is “difficult to reconcile with the presumed smooth evolution of anthropogenic greenhouse gas and aerosol radiative forcing with respect to time” and “suggests that an internal reorganization of the climate system may underlie such shifts.”

Noel Keenlyside, a scientist with Germany’s Leibniz Institute of Marine Science, writing with colleagues in a letter published in *Nature*, said “the climate of the North Atlantic region exhibits fluctuations on decadal timescales that have large societal consequences” and “these multidecadal

**Figure 3.5.3.** UAH Globally Averaged Satellite-Based Temperature of the Lower Atmosphere, January 1979 – April 2009. Source: Roy Spencer, <http://www.drroyspencer.com/latest-global-temperatures/>, last accessed May 10, 2009.

variations are potentially predictable if the current state of the ocean is known” (Keenlyside *et al.*, 2008). Using a database of sea-surface temperature (SST) observations, they “make the following forecast: over the next decade, the current Atlantic meridional overturning circulation will weaken to its long-term mean; moreover, North Atlantic SST and European and North American surface temperatures will cool slightly, whereas tropical Pacific SST will remain almost unchanged. Our results suggest that global surface temperature may not increase over the next decade, as natural climate variations in the North Atlantic and tropical Pacific temporarily offset the projected anthropogenic warming.”

We predict more predictions of this kind as more scientists recognize, first, that estimates of past warming have been exaggerated by reliance on surface-station data that have been discredited by physical observation and by testing against superior satellite data; second, that recent temperature trends contradict past and recent forecasts by the IPCC and other prominent advocates of the theory that temperatures will steadily rise in response to increasing forcing by rising CO<sub>2</sub> levels in the atmosphere; and third, as attention turns to natural cycles like those modeled by Keenlyside *et al.*, as most scientists have known all along are more

influential than the small effects of rising CO<sub>2</sub> in the atmosphere.

### 3.6. Arctic

The IPCC claims “average arctic temperatures increased at almost twice the global average rate in the past 100 years,” though it then acknowledges that “arctic temperatures have high decadal variability, and a warm period was also observed from 1925 to 1945” (IPCC 2007-I, p. 7). Later in the report, the IPCC says “the warming over land in the Arctic north of 65°C is more than double the warming in the global mean from the 19<sup>th</sup> century to the 21<sup>st</sup> century and also from about the late 1960s to the present. In the arctic series, 2005 is the warmest year” (p. 248). But the IPCC then admits that “a few areas have cooled since 1901, most notably the northern North Atlantic near southern Greenland” (p. 252). So has the Arctic really experienced the so-called unprecedented warming of the twentieth century?

### 3.6.1. Greenland

Dahl-Jensen *et al.* (1998) used data from two ice sheet boreholes to reconstruct the temperature history of Greenland over the past 50,000 years. Their analysis indicated that temperatures on the Greenland Ice Sheet during the Last Glacial Maximum (about 25,000 years ago) were  $23 \pm 2$  °C colder than at present. After the termination of the glacial period, however, temperatures increased steadily to a value that was 2.5°C warmer than at present, during the Climatic Optimum of 4,000 to 7,000 years ago. The Medieval Warm Period and Little Ice Age were also evident in the borehole data, with temperatures 1°C warmer and 0.5-0.7°C cooler than at present, respectively. Then, after the Little Ice Age, the scientists report “temperatures reached a maximum around 1930 AD” and that “temperatures have *decreased* [our italics] during the last decades.”

The results of this study stand in stark contrast to the predictions of general circulation models of the atmosphere, which consistently suggest there should have been a significant CO<sub>2</sub>-induced warming in high northern latitudes over the past several decades. They also depict large temperature excursions over the past 10,000 years, when the air’s CO<sub>2</sub> content was relatively stable. Each of these observations raises serious doubts about the models’ ability to correctly forecast earth’s climatic response to the ongoing rise in the air’s CO<sub>2</sub> content.

In another study of Greenland climate that included both glacial and interglacial periods, Bard (2002) reviews the concept of rapid climate change. Of this phenomenon, he writes that “it is now recognized that the ocean-atmosphere system exhibits several stable regimes under equivalent external forcings,” and that “the transition from one state to another occurs very rapidly when certain climatic parameters attain threshold values.” Specifically, he notes that in the models “a slight increase in the freshwater flux above the modern level  $F$  produces a decrease in the NADW [North Atlantic Deep Water] convection and a moderate cooling in the North Atlantic,” but that “the system flips to another state once the flux reaches a threshold value  $F + \Delta F$ ,” which state has no deep convection and “is characterized by surface temperatures up to 6°C lower in and around the North Atlantic.”

With respect to what has been learned from observations, Bard concentrates on the region of the North Atlantic, describing glacial-period millennial-scale episodes of dramatic warming called

Dansgaard-Oeschger events (with temperature increases “of more than 10°C”), which are evident in Greenland ice core records, as well as episodes of “drastic cooling” called Heinrich events (with temperature drops “of up to about 5°C”), which are evident in sea surface temperature records derived from the study of North Atlantic deep-sea sediment cores.

In the Greenland record, according to Bard, the progression of these events is such that “the temperature warms abruptly to reach a maximum and then slowly decreases for a few centuries before reaching a threshold, after which it drops back to the cold values that prevailed before the warm event.” He also reports that “models coupling the atmosphere, ocean, and ice sheets are still unable to correctly simulate that variability on all scales in both time and space,” which suggests we do not fully understand the dynamics of these rapid climate changes. Bard states, “all the studies so far carried out fail to answer the crucial question: How close are we to the next bifurcation [which could cause a rapid change-of-state in earth’s climate system]?” In this regard, he notes that “an intense debate continues in the modeling community about the reality of such instabilities under warm conditions,” which is a particularly important point, since all dramatic warming and cooling events that have been detected to date have occurred in either full glacials or transitional periods between glacials and interglacials.

This latter real-world fact clearly suggests we are unlikely to experience any dramatic warming or cooling surprises in the near future, as long as the earth does not begin drifting towards glacial conditions, which is another reason to not be concerned about the ongoing rise in the air’s CO<sub>2</sub> content. In fact, it suggests that allowing more CO<sub>2</sub> to accumulate in the atmosphere provides an “insurance policy” against abrupt climate change; interglacial warmth seems to inoculate the planet against climatic instabilities, allowing only the mild millennial-scale climatic oscillation that alternately brings the earth slightly warmer and cooler conditions typical of the Medieval Warm Period and Little Ice Age.

Focusing on the more pertinent period of the current interglacial or Holocene, we next consider a number of papers that bear upon the reality of the Medieval Warm Period and Little Ice Age: two well-known multi-century periods of significant climatic aberration. These periods of modest climatic aberration, plus the analogous warm and cool periods that preceded them (the Roman Warm Period and

Dark Ages Cold Period), provide strong evidence for the existence of a millennial-scale oscillation of climate that is unforced by changes in the air's CO<sub>2</sub> content, which in turn suggests that the global warming of the Little Ice Age-to-Current Warm Period transition was likely totally independent of the coincidental concomitant increase in the air's CO<sub>2</sub> content that accompanied the Industrial Revolution.

We begin with the study of Keigwin and Boyle (2000), who briefly reviewed what is known about the millennial-scale oscillation of earth's climate that is evident in a wealth of proxy climate data from around the world. Stating that "mounting evidence indicates that the Little Ice Age was a global event, and that its onset was synchronous within a few years in both Greenland and Antarctica," they remark that in Greenland it was characterized by a cooling of approximately 1.7°C. Likewise, in an article titled "Was the Medieval Warm Period Global?" Broecker (2001) answers yes, citing borehole temperature data that reveal the magnitude of the temperature drop over Greenland from the peak warmth of the Medieval Warm Period (800 to 1200 A.D.) to the coldest part of the Little Ice Age (1350 to 1860 A.D.) to have been approximately 2°C, and noting that as many as six thousand borehole records from all continents of the world confirm that the earth was a significantly warmer place a thousand years ago than it is today.

McDermott *et al.* (2001) derived a  $\delta^{18}\text{O}$  record from a stalagmite discovered in Crag Cave in southwestern Ireland, after which they compared this record with the  $\delta^{18}\text{O}$  records from the GRIP and GISP2 ice cores from Greenland. In doing so, they found evidence for "centennial-scale  $\delta^{18}\text{O}$  variations that correlate with subtle  $\delta^{18}\text{O}$  changes in the Greenland ice cores, indicating regionally coherent variability in the early Holocene." They additionally report that the Crag Cave data "exhibit variations that are broadly consistent with a Medieval Warm Period at  $\sim 1000 \pm 200$  years ago and a two-stage Little Ice Age, as reconstructed by inverse modeling of temperature profiles in the Greenland Ice Sheet." Also evident in the Crag Cave data were the  $\delta^{18}\text{O}$  signatures of the earlier Roman Warm Period and Dark Ages Cold Period that comprised the prior such cycle of climate in that region. In concluding they reiterate the important fact that the coherent  $\delta^{18}\text{O}$  variations in the records from both sides of the North Atlantic "indicate that many of the subtle multicentury  $\delta^{18}\text{O}$  variations in the Greenland ice

cores reflect regional North Atlantic margin climate signals rather than local effects."

Another study that looked at temperature variations on both sides of the North Atlantic was that of Seppa and Birks (2002), who used a recently developed pollen-climate reconstruction model and a new pollen stratigraphy from Toskaljavri, a tree-line lake in the continental sector of northern Fennoscandia (located just above 69°N latitude), to derive quantitative estimates of annual precipitation and July mean temperature. The two scientists say their reconstructions "agree with the traditional concept of a 'Medieval Warm Period' (MWP) and 'Little Ice Age' in the North Atlantic region (Dansgaard *et al.*, 1975)." Specifically, they report there is "a clear correlation between our MWP reconstruction and several records from Greenland ice cores," and that "comparisons of a smoothed July temperature record from Toskaljavri with measured borehole temperatures of the GRIP and Dye 3 ice cores (Dahl-Jensen *et al.*, 1998) and the  $\delta^{18}\text{O}$  record from the Crete ice core (Dansgaard *et al.*, 1975) show the strong similarity in timing of the MWP between the records." Last of all, they note that "July temperature values during the Medieval Warm Period (ca. 1400-1000 cal yr B.P.) were ca. 0.8°C higher than at present," where present means the last six decades of the twentieth century.

Concentrating solely on Greenland and its immediate environs are several other papers, among which is the study of Wagner and Melles (2001), who retrieved a sediment core from a lake on an island situated just off Liverpool Land on the east coast of Greenland. Analyzing it for a number of properties related to the past presence of seabirds there, they obtained a 10,000-year record that tells us much about the region's climatic history.

Key to the study were certain biogeochemical data that reflected variations in seabird breeding colonies in the catchment area of the lake. These data revealed high levels of the various parameters measured by Wagner and Melles between about 1,100 and 700 years before present (BP) that were indicative of the summer presence of significant numbers of seabirds during that "medieval warm period," as they describe it, which had been preceded by a several-hundred-year period of little to no inferred bird presence. Then, after the Medieval Warm Period, the data suggested another absence of birds during what they refer to as "a subsequent Little Ice Age," which they note was "the coldest period since the early Holocene in East Greenland." Their

data also showed signs of a “resettlement of seabirds during the last 100 years, indicated by an increase of organic matter in the lake sediment and confirmed by bird observations.” However, values of the most recent data were not as great as those obtained from the earlier Medieval Warm Period; and temperatures derived from two Greenland ice cores led to the same conclusion: it was warmer at various times between 1,100 to 700 years BP than it was over the twentieth century.

Kaplan *et al.* (2002) also worked with data obtained from a small lake, this one in southern Greenland, analyzing sediment physical-chemical properties, including magnetic susceptibility, density, water content, and biogenic silica and organic matter concentrations. They discovered that “the interval from 6000 to 3000 cal yr BP was marked by warmth and stability.” Thereafter, however, the climate cooled “until its culmination during the Little Ice Age,” but from 1,300-900 years BP, there was a partial amelioration of climate (the Medieval Warm Period) that was associated with an approximate 1.5°C rise in temperature.

Following another brief warming between AD 1500 and 1750, the second and more severe portion of the Little Ice Age occurred, which was in turn followed by “naturally initiated post-Little Ice Age warming since AD 1850, which is recorded throughout the Arctic.” They report that Viking “colonization around the northwestern North Atlantic occurred during peak Medieval Warm Period conditions that ended in southern Greenland by AD 1100,” noting that Norse movements around the region thereafter “occurred at perhaps the worst time in the last 10,000 years, in terms of the overall stability of the environment for sustained plant and animal husbandry.”

We can further explore these aspects of Greenland’s climatic history from three important papers that reconstructed environmental conditions in the vicinity of Igaliku Fjord, South Greenland, before, during, and after the period of Norse habitation of this and other parts of the ice-covered island’s coast, beginning with the study of Lassen *et al.* (2004), who provide some historical background to their palaeoclimatic work by reporting that “the Norse, under Eric the Red, were able to colonize South Greenland at AD 985, according to the Icelandic Sagas, owing to the mild Medieval Warm Period climate with favorable open-ocean conditions.” They also mention, in this regard, that the arrival of the gritty Norsemen was “close to the peak of Medieval

warming recorded in the GISP2 ice core which was dated at AD 975 (Stuiver *et al.*, 1995),” while we additionally note that Esper *et al.* (2002) independently identified the peak warmth of this period throughout North American extratropical latitudes as “occurring around 990.” Hence, it would appear that the window of climatic opportunity provided by the peak warmth of the Medieval Warm Period was indeed a major factor enabling seafaring Scandinavians to establish long-enduring settlements on the coast of Greenland.

As time progressed, however, the glowing promise of the apex of Medieval warmth gave way to the debilitating reality of the depth of Little Ice Age cold. Jensen *et al.* (2004), for example, report that the diatom record of Igaliku Fjord “yields evidence of a relatively moist and warm climate at the beginning of settlement, which was crucial for Norse land use,” but that “a regime of more extreme climatic fluctuations began soon after AD 1000, and after AD c. 1350 cooling became more severe.” Lassen *et al.* additionally note that “historical documents on Iceland report the presence of the Norse in South Greenland for the last time in AD 1408,” during what they describe as a period of “unprecedented influx of (ice-loaded) East Greenland Current water masses into the innermost parts of Igaliku Fjord.” They also report that “studies of a Canadian high-Arctic ice core and nearby geothermal data (Koerner and Fisher, 1990) correspondingly show a significant temperature lowering at AD 1350-1400,” when, in their words, “the Norse society in Greenland was declining and reaching its final stage probably before the end of the fifteenth century.” Consequently, what the relative warmth of the Medieval Warm Period provided the Norse settlers, the relative cold of the Little Ice Age took from them: the ability to survive on Greenland.

More details of the saga of five centuries of Nordic survival at the foot of the Greenland Ice Cap are provided by the trio of papers addressing the palaeohistory of Igaliku Fjord. Based on a high-resolution record of the fjord’s subsurface water-mass properties derived from analyses of benthic foraminifera, Lassen *et al.* conclude that stratification of the water column, with Atlantic water masses in its lower reaches, appears to have prevailed throughout the last 3,200 years, except for the Medieval Warm Period. During this period, which they describe as occurring between AD 885 and 1235, the outer part of Igaliku Fjord experienced enhanced vertical mixing (which they attribute to increased wind stress) that would have been expected to increase nutrient

availability there. A similar conclusion was reached by Roncaglia and Kuijpers (2004), who found evidence of increased bottom-water ventilation between AD 960 and 1285. Hence, based on these findings, plus evidence of the presence of *Melonis barleeanus* during the Medieval Warm Period (the distribution of which is mainly controlled by the presence of partly decomposed organic matter), Lassen *et al.* conclude that surface productivity in the fjord during this interval of unusual relative warmth was “high and thus could have provided a good supply of marine food for the Norse people.”

Shortly thereafter, the cooling that led to the Little Ice Age was accompanied by a gradual re-stratification of the water column, which curtailed nutrient upwelling and reduced the high level of marine productivity that had prevailed throughout the Medieval Warm Period. These linked events, according to Lassen *et al.*, “contributed to the loss of the Norse settlement in Greenland.” Indeed, with deteriorating growing conditions on land and simultaneous reductions in oceanic productivity, the odds were truly stacked against the Nordic colonies, and it was only a matter of time before their fate was sealed. As Lassen *et al.* describe it, “around AD 1450, the climate further deteriorated with further increasing stratification of the water-column associated with stronger advection of (ice-loaded) East Greenland Current water masses.” This development, in their words, led to an even greater “increase of the ice season and a decrease of primary production and marine food supply,” which “could also have had a dramatic influence on the local seal population and thus the feeding basis for the Norse population.”

The end result of these several conjoined phenomena, in the words of Lassen *et al.*, was that “climatic and hydrographic changes in the area of the Eastern Settlement were significant in the crucial period when the Norse disappeared.” Also, Jensen *et al.* report that “geomorphological studies in Northeast Greenland have shown evidence of increased winter wind speed, particularly in the period between AD 1420 and 1580 (Christiansen, 1998),” noting that “this climatic deterioration coincides with reports of increased sea-ice conditions that caused difficulties in using the old sailing routes from Iceland westbound and further southward along the east coast of Greenland, forcing sailing on more southerly routes when going to Greenland (Seaver, 1996).”

In light of these observations, Jensen *et al.* state that “life conditions certainly became harsher during

the 500 years of Norse colonization,” and that this severe cooling-induced environmental deterioration “may very likely have hastened the disappearance of the culture.” At the same time, it is also clear that the more favorable living conditions associated with the peak warmth of the Medieval Warm Period—which occurred between approximately AD 975 (Stuiver *et al.*, 1995) and AD 990 (Esper *et al.*, 2002)—were what originally enabled the Norse to successfully colonize the region. In the thousand-plus subsequent years, there has never been a sustained period of comparable warmth, nor of comparable terrestrial or marine productivity, either locally or hemispherically (and likely globally, as well), the strident protestations of Mann *et al.* (2003) notwithstanding.

Concentrating on the twentieth century, Hanna and Cappelen (2003) determined the air temperature history of coastal southern Greenland from 1958-2001, based on data from eight Danish Meteorological Institute stations in coastal and near-coastal southern Greenland, as well as the concomitant sea surface temperature (SST) history of the Labrador Sea off southwest Greenland, based on three previously published and subsequently extended SST datasets (Parker *et al.*, 1995; Rayner *et al.*, 1996; Kalnay *et al.*, 1996). The coastal temperature data showed a *cooling* of 1.29°C over the period of study, while two of the three SST databases also depicted cooling: by 0.44°C in one case and by 0.80°C in the other. Both the land-based air temperature and SST series followed similar patterns and were strongly correlated, but with no obvious lead/lag either way. In addition, it was determined that the cooling was “significantly inversely correlated with an increased phase of the North Atlantic Oscillation (NAO) over the past few decades.” The two researchers say this “NAO-temperature link doesn’t explain what caused the observed cooling in coastal southern Greenland but it does lend it credibility.”

In referring to what they call “this important regional exception to recent ‘global warming’,” Hanna and Cappelen note that the “recent cooling may have significantly added to the mass balance of at least the southern half of the [Greenland] Ice Sheet.” Consequently, since this part of the ice sheet is the portion that would likely be the first to experience melting in a warming world, it would appear that whatever caused the cooling has not only protected the Greenland Ice Sheet against warming-induced disintegration but actually fortified it against that possibility.

Several other studies have also reported late-twentieth century cooling on Greenland. Based on mean monthly temperatures of 37 Arctic and seven sub-Arctic stations, as well as temperature anomalies of 30 grid-boxes from the updated dataset of Jones, for example, Przybylak (2000) found that “the level of temperature in Greenland in the last 10-20 years is similar to that observed in the 19th century.” Likewise, in a study that utilized satellite imagery of the Odden ice tongue (a winter ice cover that occurs in the Greenland Sea with a length of about 1,300 km and an aerial coverage of as much as 330,000 square kilometers) plus surface air temperature data from adjacent Jan Mayen Island, Comiso *et al.* (2001) determined that the ice phenomenon was “a relatively smaller feature several decades ago,” due to the warmer temperatures that were prevalent at that time. In addition, they report that observational evidence from Jan Mayen Island indicates temperatures there cooled at a rate of  $0.15 \pm 0.03^\circ\text{C}$  per decade during the past 75 years.

Taurisano *et al.* (2004) examined the temperature history of the Nuuk fjord during the last century, where their analyses of all pertinent regional data led them to conclude that “at all stations in the Nuuk fjord, both the annual mean and the average temperature of the three summer months (June, July and August) exhibit a pattern in agreement with the trends observed at other stations in south and west Greenland (Humlum 1999; Hanna and Cappelen, 2003).” As they describe it, the temperature data “show that a warming trend occurred in the Nuuk fjord during the first 50 years of the 1900s, followed by a cooling over the second part of the century, when the average annual temperatures decreased by approximately  $1.5^\circ\text{C}$ .” Coincident with this cooling trend there was also what they describe as “a remarkable increase in the number of snowfall days (+59 days).” What is more, they report that “not only did the cooling affect the winter months, as suggested by Hanna and Cappelen (2002), but also the summer mean,” noting that “the summer cooling is rather important information for glaciological studies, due to the ablation-temperature relations.”

In a study of three coastal stations in southern and central Greenland that possess almost uninterrupted temperature records between 1950 and 2000, Chylek *et al.* (2004) discovered that “summer temperatures, which are most relevant to Greenland ice sheet melting rates, do not show any persistent increase during the last fifty years.” In fact, working with the two stations with the longest records (both over a

century in length), they determined that coastal Greenland’s peak temperatures occurred between 1930 and 1940, and that the subsequent decrease in temperature was so substantial and sustained that current coastal temperatures “are about  $1^\circ\text{C}$  below their 1940 values.” Furthermore, they note that “at the summit of the Greenland ice sheet the summer average temperature has decreased at the rate of  $2.2^\circ\text{C}$  per decade since the beginning of the measurements in 1987.” Hence, as with the Arctic as a whole, it would appear that Greenland has not experienced any net warming over the most dramatic period of atmospheric  $\text{CO}_2$  increase on record. In fact, it has *cooled* during this period.

At the start of the twentieth century, however, Greenland was warming, as it emerged, along with the rest of the world, from the depths of the Little Ice Age. Between 1920 and 1930, when the atmosphere’s  $\text{CO}_2$  concentration rose by a mere 3 to 4 ppm, there was a phenomenal warming at all five coastal locations for which contemporary temperature records are available. In the words of Chylek *et al.*, “average annual temperature rose between  $2$  and  $4^\circ\text{C}$  [and by as much as  $6^\circ\text{C}$  in the winter] in less than ten years.” And this warming, as they note, “is also seen in the  $^{18}\text{O}/^{16}\text{O}$  record of the Summit ice core (Steig *et al.*, 1994; Stuiver *et al.*, 1995; White *et al.*, 1997).”

In commenting on this dramatic temperature rise, which they call the “great Greenland warming of the 1920s,” Chylek *et al.* conclude that “since there was no significant increase in the atmospheric greenhouse gas concentration during that time, the Greenland warming of the 1920s demonstrates that a large and rapid temperature increase can occur over Greenland, and perhaps in other regions of the Arctic, due to internal climate variability such as the NAM/NAO [Northern Annular Mode/North Atlantic Oscillation], without a significant anthropogenic influence.” These facts led them to speculate that “the NAO may play a crucial role in determining local Greenland climate during the 21st century, resulting in a local climate that may defy the global climate change.”

Clearly, there is no substance to the claim that Greenland provides evidence for an impending  $\text{CO}_2$ -induced warming. These many studies of the temperature history of Greenland depict long-term oscillatory cooling ever since the Climatic Optimum of the mid-Holocene, when it was perhaps  $2.5^\circ\text{C}$  warmer than it is now, within which cooling trend is included the Medieval Warm Period, when it was about  $1^\circ\text{C}$  warmer than it is currently, and the Little Ice Age, when it was  $0.5$  to  $0.7^\circ\text{C}$  cooler than now,

after which temperatures rebounded to a new maximum in the 1930s, only to fall steadily thereafter.

### 3.6.1.2. Rest of Arctic

Overpeck *et al.* (1997) combined paleoclimatic records obtained from lake and marine sediments, trees, and glaciers to develop a 400-year history of circum-Arctic surface air temperature. From this record they determined that the most dramatic warming of the last four centuries of the past millennium (1.5°C) occurred between 1840 and 1955, over which period the air's CO<sub>2</sub> concentration rose from approximately 285 ppm to 313 ppm, or by 28 ppm. Then, from 1955 to the end of the record (about 1990), the mean circum-Arctic air temperature declined by 0.4°C, while the air's CO<sub>2</sub> concentration rose from 313 ppm to 354 ppm, or by 41 ppm. On the basis of these observations, which apply to the entire Arctic, it is not possible to assess the influence of

atmospheric CO<sub>2</sub> on surface air temperature or even to conclude it has any effect at all. Why? Because over the first 115 years of warming, as the air's CO<sub>2</sub> concentration rose by an average of 0.24 ppm/year, air temperature rose by an average of 0.013°C/year; over the final 35 years of the record, when the air's CO<sub>2</sub> content rose at a mean rate of 1.17 ppm/year (nearly five times the rate at which it had risen in the prior period), the rate-of-rise of surface air temperature decelerated, to a mean value (0.011°C/year) that was nearly the same as the rate at which it had previously risen.

Naurzbaev and Vaganov (2000) developed a 2,200-year temperature history using tree-ring data obtained from 118 trees near the upper-timberline in Siberia for the period 212 BC to AD 1996, as well as a similar history covering the period of the Holocene Climatic Optimum (3300 to 2600 BC). They compared their results with those obtained from an analysis of isotopic oxygen data extracted from a Greenland ice core. This work revealed that fluctuations in average annual temperature derived from the Siberian record agreed well with air temperature variations reconstructed from the Greenland data, suggesting to the two researchers that "the tree ring chronology of [the Siberian] region can be used to analyze both regional peculiarities and global temperature variations in the Northern Hemisphere."

Naurzbaev and Vaganov reported that several warm and cool periods prevailed for several multi-century periods throughout the last two millennia: a cool period in the first two centuries AD, a warm period from AD 200 to 600, cooling again from 600 to 800 AD, followed by the Medieval Warm Period from about AD 850 to 1150, the cooling of the Little Ice Age from AD 1200 through 1800, followed by the recovery warming of the twentieth century. In regard to this latter temperature rise, however, the two scientists say it was "not extraordinary," and that "the warming at the border of the first and second millennia [AD 1000] was longer in time and similar in amplitude." In addition, their reconstructed temperatures for the Holocene Climatic Optimum revealed there was an even warmer period about 5,000 years ago, when temperatures averaged 3.3°C more than they did over the past two millennia.

Contemporaneously, Vaganov *et al.* (2000) also used tree-ring width as a temperature proxy, reporting temperature variations for the Asian subarctic region over the past 600 years. Their graph of these data reveals that temperatures in this region exhibited a

small positive trend from the beginning of the record until about AD 1750. Thereafter, a severe cooling trend ensued, followed by a 130-year warming trend from about 1820 through 1950, after which temperatures fell once again.

In analyzing the entire record, the researchers determined that the amplitude of twentieth century warming “does not go beyond the limits of reconstructed natural temperature fluctuations in the Holocene subarctic zone.” And in attempting to determine the cause or causes of the temperature fluctuations, they report finding a significant correlation with solar radiation and volcanic activity over the entire 600-year period ( $r = 0.32$  for solar radiation,  $r = -0.41$  for volcanic activity), which correlation improved over the shorter interval (1800-1990) of the industrial period ( $r = 0.68$  for solar radiation,  $r = -0.59$  for volcanic activity). It is also enlightening to note, in this regard, that in this region of the world, where climate models predict large increases in temperature as a result of the historical rise in the air’s CO<sub>2</sub> concentration, real-world data show an actual cooling trend since around 1940. Where warming does exist in the record—between about 1820 and 1940—much of it correlates with changes in solar irradiance and volcanic activity, two factors that are free of anthropogenic influence.

One year later, Moore *et al.* (2001) analyzed sediment cores extracted from Donard Lake, Baffin Island, Canada (~66.25°N, 62°W), to produce a 1,240-year record of mean summer temperature for this region that averaged 2.9°C over the period AD 750-1990. Within this period there were several anomalously warm decades with temperatures that were as high as 4°C around AD 1000 and 1100, while at the beginning of the thirteenth century Donard Lake witnessed what they called “one of the largest climatic transitions in over a millennium,” as “average summer temperatures rose rapidly by nearly 2°C from AD 1195-1220, ending in the warmest decade in the record,” with temperatures near 4.5°C. This latter temperature rise was then followed by a period of extended warmth that lasted until an abrupt cooling event occurred around AD 1375, resulting in the following decade being one of the coldest in the record and signaling the onset of the Little Ice Age on Baffin Island, which lasted 400 years. At the modern end of the record, a gradual warming trend occurred over the period 1800-1900, followed by a dramatic cooling event that brought temperatures back to levels characteristic of the Little Ice Age, which chilliness lasted until about 1950. Thereafter, temperatures rose

once more throughout the 1950s and 1960s, whereupon they trended downwards toward cooler conditions to the end of the record in 1990.

Gedalof and Smith (2001) compiled a transect of six tree ring-width chronologies from stands of mountain hemlock growing near the treeline that extends from southern Oregon to the Kenai Peninsula, Alaska. Over the period of their study (AD 1599-1983), they determined that “much of the pre-instrumental record in the Pacific Northwest region of North America [was] characterized by alternating regimes of relatively warmer and cooler SST [sea surface temperature] in the North Pacific, punctuated by abrupt shifts in the mean background state,” which were found to be “relatively common occurrences.” They concluded that “regime shifts in the North Pacific have occurred 11 times since 1650.” A significant aspect of these findings is the fact that the abrupt 1976-77 shift in this Pacific Decadal Oscillation, as it is generally called, is what was responsible for the vast majority of the past half-century’s warming in Alaska, which some commentators wrongly point to as evidence of CO<sub>2</sub>-induced global warming.

About the same time, Kasper and Allard (2001) examined soil deformations caused by ice wedges (a widespread and abundant form of ground ice in permafrost regions that can grow during colder periods and deform and crack the soil). Working near Salluit, northern Québec (approx. 62°N, 75.75°W), they found evidence of ice wedge activity prior to AD 140, reflecting cold climatic conditions. Between AD 140 and 1030, however, this activity decreased, reflective of warmer conditions. Then, from AD 1030 to 1500, conditions cooled; and from 1500 to 1900 ice wedge activity was at its peak, when the Little Ice Age ruled, suggesting this climatic interval exhibited the coldest conditions of the past 4,000 years. Thereafter, a warmer period prevailed, from about 1900 to 1946, which was followed by a return to cold conditions during the last five decades of the twentieth century, during which time more than 90 percent of the ice wedges studied reactivated and grew by 20-30 cm, in harmony with a reported temperature decline of 1.1°C observed at the meteorological station in Salluit.

In another study from the same year, Zeeberg and Forman (2001) analyzed twentieth century changes in glacier terminus positions on north Novaya Zemlya, a Russian island located between the Barents and Kara Seas in the Arctic Ocean, providing in the process a quantitative assessment of the effects of temperature

and precipitation on glacial mass balance. This work revealed a significant and accelerated post-Little Ice Age glacial retreat in the first and second decades of the twentieth century; but by 1952, the region's glaciers had experienced between 75 to 100 percent of their net twentieth century retreat. During the next 50 years, the recession of more than half of the glaciers stopped, and many tidewater glaciers actually began to advance. These glacial stabilizations and advances were attributed by the two scientists to observed increases in precipitation and/or decreases in temperature. In the four decades since 1961, for example, weather stations at Novaya Zemlya show summer temperatures to have been 0.3° to 0.5°C colder than they were over the prior 40 years, while winter temperatures were 2.3° to 2.8°C colder than they were over the prior 40-year period. Such observations, in Zeeberg and Forman's words, are "counter to warming of the Eurasian Arctic predicted for the twenty-first century by climate models, particularly for the winter season."

Comiso *et al.* (2000) utilized satellite imagery to analyze and quantify a number of attributes of the Odden ice, including its average concentration, maximum area, and maximum extent over the period 1979-1998. They used surface air temperature data from Jan Mayen Island, located within the region of study, to infer the behavior of the phenomenon over the past 75 years.

The Odden ice tongue was found to vary in size, shape, and length of occurrence during the 20-year period, displaying a fair amount of interannual variability. Quantitatively, trend analyses revealed that the ice tongue had exhibited no statistically significant change in any of the parameters studied over the short 20-year period. However, a proxy reconstruction of the Odden ice tongue for the past 75 years revealed the ice phenomenon to have been "a relatively smaller feature several decades ago," due to the significantly warmer temperatures that prevailed at that time.

The fact that the Odden ice tongue has persisted, virtually unchanged in the mean during the past 20 years, is in direct contrast with predictions of rapid and increasing warmth in earth's polar regions as a result of CO<sub>2</sub>-induced global warming. This observation, along with the observational evidence from Jan Mayen Island that temperatures there actually cooled at a rate of 0.15 ± 0.03°C per decade during the past 75 years, bolsters the view that there has been little to no warming in this part of the Arctic,

as well as most of its other parts, over the past seven decades.

Polyakov *et al.* (2002b) used newly available long-term Russian observations of surface air temperature from coastal stations to gain new insights into trends and variability in the Arctic environment poleward of 62°N. Throughout the 125-year history they developed, they identified "strong intrinsic variability, dominated by multi-decadal fluctuations with a timescale of 60-80 years"; they found temperature trends in the Arctic to be highly dependent on the particular time period selected for analysis. They found they could "identify periods when Arctic trends were actually smaller or of *different sign* [our italics] than Northern Hemisphere trends." Over the bulk of the twentieth century, when they say "multi-decadal variability had little net effect on computed trends," the temperature histories of the two regions were "similar," but they did "not support amplified warming in polar regions predicted by GCMs."

In a concomitant study, Naurzbaev *et al.* (2002) developed a 2,427-year proxy temperature history for the part of the Taimyr Peninsula, northern Russia, lying between 70°30' and 72°28' North latitude, based on a study of ring-widths of living and preserved larch trees, noting that it has been shown that "the main driver of tree-ring variability at the polar timber-line [where they worked] is temperature (Vaganov *et al.*, 1996; Briffa *et al.*, 1998; Schweingruber and Briffa, 1996)." This work revealed that "the warmest periods over the last two millennia in this region were clearly in the third [Roman Warm Period], tenth to twelfth [Medieval Warm Period] and during the twentieth [Current Warm Period] centuries." With respect to the second of these three periods, they emphasize that "the warmth of the two centuries AD 1058-1157 and 950-1049 attests to the reality of relative mediaeval warmth in this region." Their data also reveal three other important pieces of information: (1) the Roman and Medieval Warm Periods were both warmer than the Current Warm Period has been to date, (2) the beginning of the end of the Little Ice Age was somewhere in the vicinity of 1830, and (3) the Current Warm Period peaked somewhere in the vicinity of 1940.

All of these observations are at odds with what is portrayed in the Northern Hemispheric "hockey stick" temperature history of Mann *et al.* (1998, 1999) and its thousand-year global extension developed by Mann and Jones (2003), wherein (1) the Current

Warm Period is depicted as the warmest such era of the past two millennia, (2) recovery from the Little Ice Age does not begin until after 1910, and (3) the Current Warm Period experiences its highest temperatures in the latter part of the twentieth century's final decade.

Przybylak (2002) conducted a detailed analysis of intraseasonal and interannual variability in maximum, minimum, and average air temperature and diurnal air temperature range for the entire Arctic—as delineated by Treshnikov (1985)—for the period 1951-1990, based on data from 10 stations “representing the majority of the climatic regions in the Arctic.” This work indicated that trends in both the intraseasonal and interannual variability of the temperatures studied did not show any significant changes, leading Przybylak to conclude that “this aspect of climate change, as well as trends in average seasonal and annual values of temperature investigated earlier (Przybylak, 1997, 2000), proves that, in the Arctic in the period 1951-90, no tangible manifestations of the greenhouse effect can be identified.”

Isaksson *et al.* (2003) retrieved two ice cores (one from Lomonosovfonna and one from Austfonna) far above the Arctic Circle in Svalbard, Norway, after which the 12 cooperating scientists from Norway, Finland, Sweden, Canada, Japan, Estonia, and the Netherlands used  $\delta^{18}\text{O}$  data to reconstruct a 600-year temperature history of the region. As would be expected—in light of the earth's transition from the Little Ice Age to the Current Warm Period—the international group of scientists reported that “the  $\delta^{18}\text{O}$  data from both Lomonosovfonna and Austfonna ice cores suggest that the twentieth century was the warmest during at least the past 600 years.” However, the warmest decade of the twentieth century was centered on approximately 1930, while the instrumental temperature record at Longyearbyen also shows the decade of the 1930s to have been the warmest. In addition, the authors remark that, “as on Svalbard, the 1930s were the warmest decade in the Trondheim record.” Consequently, there was no net warming over the last seven decades of the twentieth century in the parts of Norway cited in this study.

In the same year, Polyakov *et al.* (2003) derived a surface air temperature history that stretched from 1875 to 2000, based on measurements carried out at 75 land stations and a number of drifting buoys located poleward of 62°N latitude. From 1875 to about 1917, the team of eight U.S. and Russian scientists found the surface air temperature of the huge northern region rose hardly at all; but then it

climbed 1.7°C in just 20 years to reach a peak in 1937 that was not eclipsed over the remainder of the record. During this 20-year period of rapidly rising air temperature, the atmosphere's CO<sub>2</sub> concentration rose by a mere 8 ppm. But then, over the next six decades, when the air's CO<sub>2</sub> concentration rose by approximately 55 ppm, or nearly seven times more than it did throughout the 20-year period of dramatic warming that preceded it, the surface air temperature of the region poleward of 62°N experienced no net warming and, in fact, may have cooled.

Briffa *et al.* (2004) reviewed several prior analyses of maximum latewood density data obtained from a widespread network of tree-ring chronologies that spanned three to six centuries and were derived from nearly 400 locations. For the land area of the globe poleward of 20°N latitude, they too found that the warmest period of the past six centuries occurred in the 1930s and early 1940s. Thereafter, the region's temperature dropped dramatically, although it did recover somewhat over the last two decades of the twentieth century. Nevertheless, its final value was still less than the mean value of the entire 1400s and portions of the 1500s.

Averaged across all land area poleward of 50°N latitude, there was a large divergence of reconstructed and instrumental temperatures subsequent to 1960, with measured temperatures rising and reconstructed temperatures falling, such that by the end of the record there was an approximate 1.5°C difference between them. Briffa *et al.* attempted to relate this large temperature differential to a hypothesized decrease in tree growth that was caused by a hypothesized increase in ultraviolet radiation that they hypothesized to have been caused by declining stratospheric ozone concentrations over this period. The results of their effort, however, proved “equivocal,” as they themselves described it, leaving room for a growing urban heat island effect in the instrumental temperature record to be the principal cause of the disconcerting data divergence. The three researchers wrote that these unsettled questions prevented them “from claiming unprecedented hemispheric warming during recent decades on the basis of these tree-ring density data.”

About the same time that Briffa *et al.* were struggling with this perplexing problem, Polyakov *et al.* (2004) were developing a long-term history of Atlantic Core Water Temperature (ACWT) in the Arctic Ocean using high-latitude hydrographic measurements that were initiated in the late nineteenth century, after which they compared the

results of this exercise with the long-term history of Arctic Surface Air Temperature (SAT) developed by Polyakov *et al.* (2003). Their ACWT record, to quote them, revealed the existence of “two distinct warm periods from the late 1920s to 1950s and in the late 1980s-90s and two cold periods, one at the beginning of the record (until the 1920s) and another in the 1960s-70s.” The SAT record depicted essentially the same thing, with the peak temperature of the latter warm period being not quite as high as the peak temperature of the former warm period. In the case of the ACWT record, however, this relationship was reversed, with the peak temperature of the latter warm period slightly exceeding the peak temperature of the former warm period. But the most recent temperature peak was very short-lived; and it rapidly declined to hover around a value that was approximately 1°C cooler over the last few years of the record.

In discussing their findings, Polyakov *et al.* say that, like Arctic SATs, Arctic ACWTs are dominated, in their words, “by multidecadal fluctuations with a time scale of 50-80 years.” In addition, both records indicate that late twentieth century warmth was basically no different from that experienced in the late 1930s and early 1940s, a time when the air’s CO<sub>2</sub> concentration was fully 65 ppm less than it is today.

Knudsen *et al.* (2004) documented climatic changes over the past 1,200 years via high-resolution multi-proxy studies of benthic and planktonic foraminiferal assemblages, stable isotopes, and ice-rafted debris found in three sediment cores retrieved from the North Icelandic shelf. These efforts resulted in their learning that “the time period between 1200 and around 7-800 cal. (years) BP, including the Medieval Warm Period, was characterized by relatively high bottom and surface water temperatures,” after which “a general temperature decrease in the area marks the transition to ... the Little Ice Age.” They also found that “minimum sea-surface temperatures were reached at around 350 cal. BP, when very cold conditions were indicated by several proxies.” Thereafter, they report that “a modern warming of surface waters ... is not registered in the proxy data,” and that “there is no clear indication of warming of water masses in the area during the last decades,” even in sea surface temperatures measured over the period 1948-2002.

Raspopov *et al.* (2004) presented and analyzed two temperature-related datasets. The first was “a direct and systematic air temperature record for the Kola Peninsula, in the vicinity of Murmansk,” which covered the period 1880-2000, while the second was

an “annual tree-ring series generalized for 10 regions (Lovelius, 1997) along the northern timberline, from the Kola Peninsula to Chukotka, for the period 1458-1975 in the longitude range from 30°E to 170°E,” which included nearly all of northern Eurasia that borders the Arctic Ocean.

The researchers’ primary objectives in this work were to identify any temporal cycles that might be present in the two datasets and to determine what caused them. With respect to this dual goal, they report discovering “climatic cycles with periods of around 90, 22-23 and 11-12 years,” which were found to “correlate well with the corresponding solar activity cycles.” Of even more interest, however, was what they learned about the temporal development of the Current Warm Period (CWP).

Raspopov *et al.*’s presentation of the mean annual tree-ring series for the northern Eurasia timberline clearly shows that the region’s thermal recovery from the coldest temperatures of the Little Ice Age (LIA) may be considered to have commenced as early as 1820 and was in full swing by at least 1840. In addition, it shows that the rising temperature peaked just prior to 1950 and then declined to the end of the record in 1975. Thereafter, however, the Kola-Murmansk instrumental record indicates a significant temperature rise that peaked in the early 1990s at about the same level as the pre-1950 peak; but after that time, the temperature once again declined to the end of the record in 2000.

The latter of these findings (that there has been no net warming of this expansive high-latitude region over the last half of the twentieth century) is in harmony with the findings of the many studies reviewed above, while the former finding (that the thermal recovery of this climatically sensitive region of the planet began in the first half of the nineteenth century) is also supported by a number of other studies (Esper *et al.*, 2002; Moore *et al.*, 2002; Yoo and D’Odorico, 2002; Gonzalez-Rouco *et al.*, 2003; Jomelli and Pech, 2004), all of which demonstrate that the Little Ice Age-to-Current Warm Period transition began somewhere in the neighborhood of 1820 to 1850, well before the date (~1910) that is indicated in the Mann *et al.* (1998, 1999) “hockey stick” temperature history.

One further study from 2004 yields much the same conclusion, but arrives at it by very different means. Benner *et al.* (2004) set the stage for what they did by stating that “thawing of the permafrost which underlies a substantial fraction of the Arctic could accelerate carbon losses from soils (Goulden *et*

*al.*, 1998).” In addition, they report that “freshwater discharge to the Arctic Ocean is expected to increase with increasing temperatures (Peterson *et al.*, 2002), potentially resulting in greater riverine export of terrigenous organic carbon to the ocean.” And since the organic carbon in Arctic soils, in their words, “is typically old, with average radiocarbon ages ranging from centuries to millennia (Schell, 1983; Schirrmeister *et al.*, 2002),” they set about to measure the age of dissolved organic carbon (DOC) in Arctic rivers to see if there were any indications of increasing amounts of older carbon being transported to the ocean, which (if there were) would be indicative of enhanced regional warming.

Specifically, they sampled two of the largest Eurasian rivers, the Yenisey and Ob’ (which drain vast areas of boreal forest and extensive peat bogs, accounting for about a third of all riverine DOC discharge to the Arctic Ocean), as well as two much smaller rivers on the north slope of Alaska, the Ikpikpuk and Kokolik, whose watersheds are dominated by Arctic tundra. In doing so, they found modern radiocarbon ages for all samples taken from all rivers, which indicates, in their words, that Arctic riverine DOC “is derived primarily from recently fixed plant litter and near-surface soil horizons.” Thus, because warming should have caused the average radiocarbon age of the DOC of Arctic rivers to increase, the absence of aging implied by their findings provides strong evidence for the absence of recent large-scale warming there.

Laidre and Heide-Jorgensen (2005) published a most unusual paper, in that it dealt with the danger of oceanic cooling. Using a combination of long-term satellite tracking data, climate data, and remotely sensed sea ice concentrations to detect localized habitat trends of narwhals—a species of whale with a long spear-like tusk—in Baffin Bay between Greenland and Canada, home to the largest narwhal population in the world. They studied the species’ vulnerability to recent and possible future climate trends. They found “since 1970, the climate in West Greenland has cooled, reflected in both oceanographic and biological conditions (Hanna and Cappelen, 2003),” with the result that “Baffin Bay and Davis Strait display strong significant increasing trends in ice concentrations and extent, as high as 7.5 percent per decade between 1979 and 1996, with comparable increases detected back to 1953 (Parkinson *et al.*, 1999; Deser *et al.*, 2000; Parkinson, 2000a,b; Parkinson and Cavalieri, 2002; Stern and Heide-Jorgensen, 2003).”

Humlum *et al.* (2005) noted that state-of-the-art climate models were predicting that “the effect of any present and future global climatic change will be amplified in the polar regions as a result of feedbacks in which variations in the extent of glaciers, snow, sea ice and permafrost, as well as atmospheric greenhouse gases, play key roles.” However, they also said Polyakov *et al.* (2002a,b) had “presented updated observational trends and variations in Arctic climate and sea-ice cover during the twentieth century, which do not support the modeled polar amplification of surface air-temperature changes observed by surface stations at lower latitudes,” and “there is reason, therefore, to evaluate climate dynamics and their respective impacts on high-latitude glaciers.” They proceeded to do just that for the Archipelago of Svalbard, focusing on Spitsbergen (the Archipelago’s main island) and the Longyearbreen glacier located in its relatively dry central region at 78°13’N latitude.

In reviewing what was already known about the region, Humlum *et al.* report that “a marked warming around 1920 changed the mean annual air temperature (MAAT) at sea level within only 5 years from about -9.5°C to -4.0°C,” which change, in their words, “represents the most pronounced increase in MAAT documented anywhere in the world during the instrumental period.” Then, they report that “from 1957 to 1968, MAAT dropped about 4°C, followed by a more gradual increase towards the end of the twentieth century.”

With respect to the Longyearbreen glacier, their own work revealed that it had “increased in length from about 3 km to its present size of about 5 km during the last c. 1100 years,” and they stated that “this example of late-Holocene glacier growth represents a widespread phenomenon in Svalbard and in adjoining Arctic regions,” which they describe as a “development towards cooler conditions in the Arctic” that “may explain why the Little Ice Age glacier advance in Svalbard usually represents the Holocene maximum glacier extension.”

As for what it all means, climate change in Svalbard over the twentieth century appears to have been a real rollercoaster ride, with temperatures rising more rapidly in the early 1920s than has been documented anywhere else before or since, only to be followed by a nearly equivalent temperature drop four decades later, both of which transitions were totally out of line with what climate models suggest should have occurred. In addition, the current location of the terminus of the Longyearbreen glacier suggests that,

even now, Svalbard and “adjoining Arctic regions” are still experiencing some of the lowest temperatures of the entire Holocene, and at a time when atmospheric CO<sub>2</sub> concentrations are higher than they have been for millions of years.

In one final paper from 2005, Soon (2005) explores the question of what was the more dominant driver of twentieth century temperature change in the Arctic: the rising atmospheric CO<sub>2</sub> concentration or variations in solar irradiance. This he did by examining the roles the two variables may have played in forcing decadal, multi-decadal, and longer-term variations in surface air temperature (SAT). He performed a number of statistical analyses on (1) a composite Arctic-wide SAT record constructed by Polyakov *et al.* (2003), (2) global CO<sub>2</sub> concentrations taken from estimates made by the NASA GISS climate modeling group, and (3) a total solar irradiance (TSI) record developed by Hoyt and Schatten (1993, updated by Hoyt in 2005) over the period 1875-2000.

The results of Soon’s analyses indicated a much stronger statistical relationship exists between SAT and TSI than between SAT and atmospheric CO<sub>2</sub> concentration. Solar forcing generally explained well over 75 percent of the variance in decadal-smoothed seasonal and annual Arctic temperatures, while CO<sub>2</sub> forcing explained only between 8 and 22 percent. Wavelet analysis further supported the case for solar forcing of SAT, revealing similar time-frequency characteristics for annual and seasonally averaged temperatures at decadal and multi-decadal time scales. By contrast, wavelet analysis gave little to no indication of a CO<sub>2</sub> forcing of Arctic SSTs. Based on these findings, it would appear that it is the sun, and not atmospheric CO<sub>2</sub>, that has been driving temperature change in the Arctic over the twentieth century.

Hanna *et al.* (2006) developed a 119-year history of Icelandic Sea Surface Temperature (SST) based on measurements made at 10 coastal stations located between latitudes 63°24’N and 66°32’N. This work revealed the existence of past “long-term variations and trends that are broadly similar to Icelandic air temperature records: that is, generally cold conditions during the late nineteenth and early twentieth centuries; strong warming in the 1920s, with peak SSTs typically being attained around 1940; and cooling thereafter until the 1970s, followed once again by warming—but not generally back up to the level of the 1930s/1940s warm period.”

Hansen *et al.* (2006) analyzed meteorological data from Arctic Station (69°15’N, 53°31’W) on Disko Island (West Greenland) for the period 1991-2004, after which their results were correlated, in the words of the researchers, “to the longest record available from Greenland at Ilulissat/Jakobshavn (since 1873).” Once this was done, marked changes were noted over the course of the study period, including “increasing mean annual air temperatures on the order of 0.4°C per year and 50% decrease in sea ice cover.” In addition, due to “a high correlation between mean monthly air temperatures at the two stations (1991-2004),” Hansen *et al.* were able to place the air temperature trend observed at Disko “in a 130 years perspective.” This exercise led them to conclude that the climate changes of the past decade were “dramatic,” but that “similar changes in air temperatures [had] occurred previous[ly] within the last 130 years.” More specifically, they report that the changes they observed over the last decade “are on the same order as changes [that] occurred between 1920 and 1930.”

In Iceland, Bradwell *et al.* (2006) examined the link between late Holocene fluctuations of Lambatungnajokull (an outlet glacier of the Vatnajokull ice cap of southeast Iceland) and variations in climate, using geomorphological evidence to reconstruct patterns of past glacier fluctuations and lichenometry and tephrostratigraphy to date glacial landforms created by the glacier over the past four centuries. This work revealed “there is a particularly close correspondence between summer air temperature and the rate of ice-front recession of Lambatungnajokull during periods of overall retreat,” and “between 1930 and 1950 this relationship is striking.” They also report that “ice-front recession was greatest during the 1930s and 1940s, when retreat averaged 20 m per year.” Thereafter, however, they say the retreat “slowed in the 1960s,” and “there has been little overall retreat since the 1980s.” The researchers also report that “the 20th-century record of reconstructed glacier-front fluctuations at Lambatungnajokull compares well with those of other similar-sized, non-surgingly, outlets of southern Vatnajokull,” including Skaftafellsjokull, Fjallsjokull, Skalafellsjokull, and Flajajokull. They find “the pattern of glacier fluctuations of Lambatungnajokull over the past 200 years reflects the climatic changes that have occurred in southeast Iceland and the wider region.”

Contemporaneously, Drinkwater (2006) decided “to provide a review of the changes to the marine

ecosystems of the northern North Atlantic during the 1920s and 1930s and to discuss them in the light of contemporary ideas of regime shifts,” where he defined regime shift as “a persistent radical shift in typical levels of abundance or productivity of multiple important components of the marine biological community structure, occurring at multiple trophic levels and on a geographical scale that is at least regional in extent.” As a prologue to this effort, he first determined that “in the 1920s and 1930s, there was a dramatic warming of the air and ocean temperatures in the northern North Atlantic and the high Arctic, with the largest changes occurring north of 60°N,” which warming “led to reduced ice cover in the Arctic and subarctic regions and higher sea temperatures,” as well as northward shifts of multiple marine ecosystems. This change in climate occurred “during the 1920s, and especially after 1925,” according to Drinkwater, when he reports that “average air temperatures began to rise rapidly and continued to do so through the 1930s,” when “mean annual air temperatures increased by approximately 0.5-1°C and the cumulative sums of anomalies varied from 1.5 to 6°C between 1920 and 1940 with the higher values occurring in West Greenland and Iceland.” Thereafter, as he describes it, “through the 1940s and 1950s air temperatures in the northernmost regions varied but generally remained relatively high,” declining in the late 1960s in the northwest Atlantic and slightly earlier in the northeast Atlantic, which cooling has only recently begun to be reversed in certain parts of the region.

In the realm of biology, the early twentieth century warming of North Atlantic waters “contributed to higher primary and secondary production,” in the words of Drinkwater, and “with the reduced extent of ice-covered waters, more open water allow[ed] for higher production than in the colder periods.” As a result, cod “spread approximately 1200 km northward along West Greenland,” and “migration of ‘warmer water’ species also changed with earlier arrivals and later departures.” In addition, Drinkwater notes that “new spawning sites were observed farther north for several species or stocks while for others the relative contribution from northern spawning sites increased.” Also, he writes that “some southern species of fish that were unknown in northern areas prior to the warming event became occasional, and in some cases, frequent visitors.” Consequently, and considering all aspects of the event, Drinkwater states that “the warming in the 1920s and 1930s is considered to

constitute the most significant regime shift experienced in the North Atlantic in the 20<sup>th</sup> century.”

Groisman *et al.* (2006) reported using “a new Global Synoptic Data Network consisting of 2100 stations within the boundaries of the former Soviet Union created jointly by the [U.S.] National Climatic Data Center and Russian Institute for Hydrometeorological Information ... to assess the climatology of snow cover, frozen and unfrozen ground reports, and their temporal variability for the period from 1936 to 2004.” They determined that “during the past 69 years (1936-2004 period), an increase in duration of the period with snow on the ground over Russia and the Russian polar region north of the Arctic circle has been documented by 5 days or 3% and 12 days or 5%, respectively,” and they note this result “is in agreement with other findings.”

In commenting on this development, plus the similar findings of others, the five researchers say “changes in snow cover extent during the 1936-2004 period cannot be linked with ‘warming’ (particularly with the Arctic warming).” Why? Because, as they continue, “in this particular period the Arctic warming was absent.”

A recent essay that appeared in *Ambio: A Journal of the Human Environment*, by Karlén (2005) asks if temperatures in the Arctic are “really rising at an alarming rate,” as some have claimed. His answer is a resounding no. Focusing on Svalbard Lufthavn (located at 78°N latitude), which he later shows to be representative of much of the Arctic, Karlén reports that “the Svalbard mean annual temperature increased rapidly from the 1910s to the late 1930s,” that “the temperature thereafter became lower, and a minimum was reached around 1970,” and that “Svalbard thereafter became warmer, but the mean temperature in the late 1990s was still slightly cooler than it was in the late 1930s,” indicative of a cooling trend of 0.11°C per decade over the last seventy years of the twentieth century.

Karlén goes on to say “the observed warming during the 1930s is supported by data from several stations along the Arctic coasts and on islands in the Arctic, e.g. *Nordklim* data from Bjornoya and Jan Mayen in the north Atlantic, Vardo and Tromso in northern Norway, Sodankylaeand Karasjoki in northern Finland, and Stykkisholmur in Iceland,” and “there is also [similar] data from other reports; e.g. Godthaab, Jakobshavn, and Egedesminde in Greenland, Ostrov Dikson on the north coast of Siberia, Salehard in inland Siberia, and Nome in

western Alaska.” All of these stations, to quote him further, “indicate the same pattern of changes in annual mean temperature: a warm 1930s, a cooling until around 1970, and thereafter a warming, although the temperature remains slightly below the level of the late 1930s.” In addition, he says “many stations with records starting later than the 1930s also indicate cooling, e.g. Vize in the Arctic Sea north of the Siberian coast and Frobisher Bay and Clyde on Baffin Island.” Finally, Karlén reports that the 250-year temperature record of Stockholm “shows that the fluctuations of the 1900s are not unique,” and that “changes of the same magnitude as in the 1900s occurred between 1770 and 1800, and distinct but smaller fluctuations occurred around 1825.”

Karlén notes that “during the 50 years in which the atmospheric concentration of CO<sub>2</sub> has increased considerably, the temperature has decreased,” which leads him to conclude that “the Arctic temperature data do not support the models predicting that there will be a critical future warming of the climate because of an increased concentration of CO<sub>2</sub> in the atmosphere.” And this is especially important, in Karlén’s words, because the model-based prediction “is that changes will be strongest and first noticeable in the Arctic.”

Chylek *et al.* (2006) provides a more up-to-date report on average summer temperatures recorded at Ammassalik, on Greenland’s southeast coast, and Godthab Nuuk on the island’s southwestern coast, covering the period 1905 to 2005. They found “the 1955 to 2005 averages of the summer temperatures and the temperatures of the warmest month at both Godthab Nuuk and Ammassalik are significantly lower than the corresponding averages for the previous 50 years (1905-1955). The summers at both the southwestern and the southeastern coast of Greenland were significantly colder within the 1955-2005 period compared to the 1905-1955.”

Chylek *et al.* also compared temperatures for the 10-year periods of 1920-1930 and 1995-2005. They found the average summer temperature for 2003 in Ammassalik was a record high since 1895, but “the years 2004 and 2005 were closer to normal being well below temperatures reached in the 1930s and 1940s.” Similarly, the record from Godthab Nuuk showed that while temperatures there “were also increasing during the 1995-2005 period, they stayed generally below the values typical for the 1920-1940 period.” The authors conclude that “reports of Greenland temperature changes are .... diverse suggesting a long term cooling and shorter warming periods.”

Additional information on this topic, including reviews of newer publications as they become available, can be found at <http://www.co2science.org/subject/a/arctictemptrends.php>.

### 3.7. Antarctica

The study of Antarctic temperatures has provided valuable insight and spurred contentious debate on issues pertaining to global climate change. Key among the pertinent findings has been the observation of a large-scale correlation between proxy air temperature and atmospheric CO<sub>2</sub> measurements obtained from ice cores drilled in the interior of the continent. In the mid- to late-1980s, this broad

correlation dominated much of the climate change debate. Many jumped on the global warming bandwagon, saying the correlation proved that changes in atmospheric CO<sub>2</sub> concentration caused changes in air temperature, and that future increases in the air's CO<sub>2</sub> content due to anthropogenic CO<sub>2</sub> emissions would therefore intensify global warming.

By the late 1990s and early 2000s, however, ice-coring instrumentation and techniques had improved considerably and newer studies with finer temporal resolution began to reveal that increases (decreases) in air temperature precede increases (decreases) in atmospheric CO<sub>2</sub> content, not vice versa (see Indermuhle *et al.* (2000), Monnin *et al.* (2001)). A recent study by Caillon *et al.* (2003), for example, demonstrated that during Glacial Termination III, “the CO<sub>2</sub> increase lagged Antarctic deglacial warming by  $800 \pm 200$  years.” This finding, in the authors' words, “confirms that CO<sub>2</sub> is not the forcing that initially drives the climatic system during a deglaciation.”

A second major blow to the CO<sub>2</sub>-induced global warming hypothesis comes from the contradiction between observed and model-predicted Antarctic temperature trends of the past several decades. According to nearly all climate models, CO<sub>2</sub>-induced global warming should be most evident in earth's polar regions, but analyses of Antarctic near-surface and tropospheric air temperatures contradict this prediction.

Doran *et al.* (2002) examined temperature trends in the McMurdo Dry Valleys of Antarctica over the period 1986 to 2000, reporting a cooling rate of approximately 0.7°C per decade. This dramatic rate of cooling, they state, “reflects longer term continental Antarctic cooling between 1966 and 2000.” In addition, the 14-year temperature decline in the dry valleys occurred in the summer and autumn, just as most of the 35-year cooling over the continent as a whole (which did not include any data from the dry valleys) also occurred in the summer and autumn.

Comiso (2000) assembled and analyzed Antarctic temperature data obtained from 21 surface stations and from infrared satellites operating since 1979. He found that for all of Antarctica, temperatures had declined by 0.08°C and 0.42°C per decade, respectively. Thompson and Solomon (2002) also report a cooling trend for the interior of Antarctica.

In spite of the decades-long cooling that has been observed for the continent as a whole, one region of Antarctica has actually bucked the mean trend and *warmed* over the same time period: the Antarctic Peninsula/Bellingshausen Sea region. But is the

temperature increase that has occurred there evidence of CO<sub>2</sub>-induced global warming?

According to Vaughan *et al.* (2001), “rapid regional warming” has led to the loss of seven ice shelves in this region during the past 50 years. However, they note that sediment cores from 6,000 to 1,900 years ago suggest the Prince Gustav Channel Ice Shelf—which collapsed in this region in 1995—“was absent and climate was as warm as it has been recently,” when, of course there was much less CO<sub>2</sub> in the air.

Although it is tempting to cite the twentieth century increase in atmospheric CO<sub>2</sub> concentration as the cause of the recent regional warming, “to do so without offering a mechanism,” say Vaughan *et al.*, “is superficial.” And so it is, as the recent work of Thompson and Solomon (2002) suggests that much of the warming can be explained by “a systematic bias toward the high-index polarity of the SAM,” or Southern Hemispheric Annular Mode, such that the ring of westerly winds encircling Antarctica has recently been spending more time in its strong-wind phase.

That is also the conclusion of Kwok and Comiso (2002), who report that over the 17-year period 1982-1998, the SAM index shifted towards more positive values (0.22/decade), noting that a positive polarity of the SAM index “is associated with cold anomalies over most of Antarctica with the center of action over the East Antarctic plateau.” At the same time, the SO index shifted in a negative direction, indicating “a drift toward a spatial pattern with warmer temperatures around the Antarctic Peninsula, and cooler temperatures over much of the continent.” Together, the authors say the positive trend in the *coupled* mode of variability of these two indices (0.3/decade) represents a “significant bias toward positive polarity” that they describe as “remarkable.”

Kwok and Comiso additionally report that “the tropospheric SH annular mode has been shown to be related to changes in the lower stratosphere (Thompson and Wallace, 2000),” noting that “the high index polarity of the SH annular mode is associated with the trend toward a cooling and strengthening of the SH stratospheric polar vortex during the stratosphere's relatively short active season in November,” which is pretty much the same theory that has been put forth by Thompson and Solomon (2002).

In another slant on the issue, Yoon *et al.* (2002) report that “the maritime record on the Antarctic Peninsula shelf suggests close chronological

correlation with Holocene glacial events in the Northern Hemisphere, indicating the possibility of coherent climate variability in the Holocene.” In the same vein, Khim *et al.* (2002) say that “two of the most significant climatic events during the late Holocene are the Little Ice Age (LIA) and Medieval Warm Period (MWP), both of which occurred globally (Lamb, 1965; Grove, 1988),” noting further that “evidence of the LIA has been found in several studies of Antarctic marine sediments (Leventer and Dunbar, 1988; Leventer *et al.*, 1996; Domack *et al.*, 2000).” To this list of scientific journal articles documenting the existence of the LIA in Antarctica can now be added Khim *et al.*’s own paper, which also demonstrates the presence of the MWP in Antarctica, as well as earlier cold and warm periods of similar intensity and duration.

Further evidence that the Antarctic as a whole is in the midst of a cooling trend comes from Watkins and Simmonds (2000), who analyzed region-wide changes in sea ice. Reporting on trends in a number of Southern Ocean sea ice parameters over the period 1987 to 1996, they found statistically significant increases in sea ice area and total sea ice extent, as well as an increase in sea ice season length since the 1990s. Combining these results with those from a previous study revealed these trends to be consistent back to at least 1978. And in another study of Antarctic sea ice extent, Yuan and Martinson (2000) report that the net trend in the mean Antarctic ice edge over the past 18 years has been an equatorward expansion of 0.011 degree of latitude per year.

The temperature history of Antarctica provides no evidence for the CO<sub>2</sub>-induced global warming hypothesis. In fact, it argues strongly against it. But what if the Antarctic *were* to warm as a result of some natural or anthropogenic-induced change in earth’s climate? What would the consequences be?

For one thing, it would likely help to increase both the number and diversity of penguin species (Sun *et al.*, 2000; Smith *et al.*, 1999), and it would also tend to increase the size and number of populations of the continent’s only two vascular plant species (Xiong *et al.*, 2000). With respect to the continent’s great ice sheets, there would not be much of a problem either, as not even a warming event as dramatic as 10°C is predicted to result in a net change in the East Antarctic Ice Sheet (Näslund *et al.*, 2000), which suggests that predictions of catastrophic coastal flooding due to the melting of the world’s polar ice sheets are way off the mark.

## Observations: Glaciers, Sea Ice, Precipitation, and Sea Level

---

### 4. Observations: Glaciers, Sea Ice, Precipitation, and Sea Level

- 4.1. Glaciers
- 4.2. Sea Ice
- 4.3. Precipitation Trends
- 4.4. Streamflow
- 4.5. Sea-level Rise

### Introduction

The Intergovernmental Panel on Climate Change (IPCC) alleges that “recent decreases in ice mass are correlated with rising surface air temperatures,” and more specifically that “the late 20<sup>th</sup>-century glacier wastage likely has been a response to post-1970 warming. Strongest mass losses per unit area have been observed in Patagonia, Alaska and northwest USA and southwest Canada. Because of the corresponding large areas, the largest contributions to sea level rise came from Alaska, the Arctic and the Asian high mountains. Taken together, the ice sheets in Greenland and Antarctica have *very likely* been contributing to sea level rise over 1993 to 2003 [italics in the original]” (IPCC, 2007-I, p. 339).

It should be obvious, but apparently is not, that such facts as melting glaciers and disappearing Arctic sea ice, while interesting, are entirely irrelevant to illuminating the causes of warming. Any significant warming, whether anthropogenic or natural, will melt ice—often quite slowly. Therefore, claims that anthropogenic global warming (AGW) is occurring that are backed by such accounts are simply confusing the consequences of warming with the causes—a common logical error. In addition, fluctuations of glacier mass, sea ice, precipitation, and sea level depend on many factors other than temperature and are poor measuring devices for global warming.

This chapter summarizes the extensive scientific literature on glaciers, sea ice, precipitation, and sea level rise that frequently contradicts and rarely reinforces the IPCC’s claims quoted above. Glaciers around the world are continuously advancing and retreating, with no evidence of a trend that can be linked to CO<sub>2</sub> concentrations in the air. The same is largely true of sea ice, precipitation patterns, and sea levels: all fluctuate in response to processes that are unrelated to CO<sub>2</sub>, and therefore cannot be taken either as signs of anthropogenic global warming or of climate disasters that may be yet to come.

### 4.1. Glaciers

Model studies indicate that CO<sub>2</sub>-induced global warming will result in significant melting of earth’s glaciers, contributing to a rise in global sea level. In this section, we examine global trends and data from

Africa, Antarctica, the Arctic, Europe, North America, and South America. Additional information on this topic, including reviews of glaciers not discussed here, can be found at [http://www.co2science.org/subject/g/subject\\_g.php](http://www.co2science.org/subject/g/subject_g.php) under the heading Glaciers.

#### 4.1.1. Global

The full story must begin with a recognition of just how few glacier data exist. Of the 160,000 glaciers presently known to exist, only 67,000 (42 percent) have been inventoried to any degree (Kieffer *et al.*, 2000). Mass balance data (which would be positive for growth, negative for shrinkage) exist for more than a single year for only slightly more than 200 (Braithwaite and Zhang, 2000). When the length of record increases to *five* years, this number drops to 115; and if both winter and summer mass balances are required, the number drops to 79. Furthermore, if 10 years of record is used as a cutoff, only 42 glaciers qualify. This lack of glacial data, in the words of Braithwaite and Zhang, highlights “one of the most important problems for mass-balance glaciology” and demonstrates the “sad fact that many glacierized regions of the world remain unsampled, or only poorly sampled,” suggesting we really know very little about the true state of most of the world’s glaciers.

During the fifteenth through nineteenth centuries, widespread and major glacier advances occurred during a period of colder global temperature known as the Little Ice Age (Broecker, 2001; Grove, 2001). Many records indicate widespread glacial retreat as temperatures began to rise in the mid- to late-1800s and many glaciers returned to positions characteristic of pre-Little Ice Age times. In many instances the *rate* of glacier retreat has not increased over the past 70 years, during a time when the atmosphere experienced the bulk of the increase in its CO<sub>2</sub> content.

In an analysis of Arctic glacier mass balance, Dowdeswell *et al.* (1997) found that of the 18 glaciers with the longest mass balance histories, just over 80 percent displayed negative mass balances over their periods of record. Yet they additionally report that “almost 80% of the mass balance time series also have a positive trend, toward a less negative mass balance.” Although these Arctic glaciers continue to lose mass, as they have probably done since the end of the Little Ice Age, they are losing smaller amounts

each year, which is hardly what one would expect in the face of what some incorrectly call the “unprecedented” warming of the latter part of the twentieth century.

Similar results have been reported by Braithwaite (2002), who reviewed and analyzed mass balance measurements of 246 glaciers from around the world that were made between 1946 and 1995. According to Braithwaite, “there are several regions with highly negative mass balances in agreement with a public perception of ‘the glaciers are melting,’ but there are also regions with positive balances.” Within Europe, for example, he notes that “Alpine glaciers are generally shrinking, Scandinavian glaciers are growing, and glaciers in the Caucasus are close to equilibrium for 1980-95.” And when results for the whole world are combined for this most recent period of time, Braithwaite notes that “there is no obvious common or global trend of increasing glacier melt in recent years.”

As for the glacier with the longest mass balance record of all, the Storglaciaren in northern Sweden, for the first 15 years of its 50-year record it exhibited a negative mass balance of little trend. Thereafter, however, its mass balance began to trend upward, actually becoming positive over about the last decade (Braithwaite and Zhang, 2000).

Global data on glaciers do not support claims made by the IPCC that most glaciers are retreating or melting. Additional information on this topic, including reviews of newer publications as they become available, can be found at <http://www.co2science.org/subject/g/glaciers.php>.

#### 4.1.2. Africa

On the floor of the U.S. Senate in 2004, Arizona Senator John McCain described his affection for the writings of Ernest Hemingway, especially his famous short story, “The Snows of Kilimanjaro.” Then, showing photos of the magnificent landmark taken in 1993 and 2000, he attributed the decline of glacial ice atop the mount during the intervening years to CO<sub>2</sub>-induced global warming, calling this attribution a fact “that cannot be refuted by any scientist.”

New York Senator Hillary Clinton echoed Senator McCain’s sentiments. Displaying a second set of photos taken from the same vantage point in 1970 and 1999—the first depicting “a 20-foot-high glacier” and the second “only a trace of ice”—she said that in those pictures “we have evidence in the most dramatic way possible of the effects of 29 years of global warming.” In spite of the absolute certitude with which the two senators expressed their views on the subject, which allowed for no “wobble room” whatsoever, both of them were wrong.

Modern glacier recession on Kilimanjaro began around 1880, approximately the same time the planet began to recover from the several-hundred-year cold spell of the Little Ice Age. As a result, a number of people, including the aforementioned senators, declared that the ice fields retreated *because* of the rising temperatures, encouraged in this contention by a few reports in the scientific literature (Alverson *et al.*, 2001; Irion, 2001; Thompson *et al.*, 2002). This view of the subject, however, is “highly simplified,” in the words of a trio of glaciologists (Molg *et al.*, 2003b), who noted that “glacierization in East Africa is limited to three massifs close to the equator:

Kilimanjaro (Tanzania, Kenya), Mount Kenya (Kenya), and Rwenzori (Zaire, Uganda).” All three sites experienced strong ice field recession over the past century or more. In that part of the world, however, they report “there is no evidence of a sudden change in temperature at the end of the 19th century (Hastenrath, 2001),” and that “East African long-term temperature records of the twentieth century show diverse trends and do not exhibit a uniform warming signal (King’uyu *et al.*, 2000; Hay *et al.*, 2002).” With respect to Kilimanjaro, they say “since February 2000 an automatic weather station has operated on a horizontal glacier surface at the summit’s Northern Icefield,” and “monthly mean air temperatures only vary slightly around the annual mean of -7.1°C, and air temperatures [measured by ventilated sensors, e.g., Georges and Kaser (2002)] never rise above the freezing point,” which makes it pretty difficult to understand how ice could *melt* under such conditions.

So what caused the ice fields of Kilimanjaro to recede so steadily for so many years? Citing “historical accounts of lake levels (Hastenrath, 1984; Nicholson and Yin, 2001), wind and current observations in the Indian Ocean and their relationship to East African rainfall (Hastenrath, 2001), water balance models of lakes (Nicholson and Yin, 2001), and paleolimnological data (Verschuren *et al.*, 2000),” Molg *et al.* say “all data indicate that modern East African climate experienced an abrupt and marked drop in air humidity around 1880,” and they add that the resultant “strong reduction in precipitation at the end of the 19th century is the main reason for modern glacier recession in East Africa,” as it considerably reduces glacier mass balance accumulation, as has been demonstrated for the region by Kruss (1983) and Hastenrath (1984). In addition, they note that “increased incoming shortwave radiation due to decreases in cloudiness—both effects of the drier climatic conditions—plays a decisive role for glacier retreat by increasing ablation, as demonstrated for Mount Kenya and Rwenzori (Kruss and Hastenrath, 1987; Molg *et al.*, 2003a).”

In further investigating this phenomenon, Molg *et al.* applied a radiation model to an idealized representation of the 1880 ice cap of Kilimanjaro, calculating the spatial extent and geometry of the ice cap for a number of subsequent points in time and finding that “the basic evolution in spatial distribution of ice bodies on the summit is modeled well.” The model they used, which specifically addresses the unique configuration of the summit’s vertical ice

walls, provided “a clear indication that solar radiation is the main climatic parameter governing and maintaining ice retreat on the mountain’s summit plateau in the drier climate since ca. 1880.” Consequently, Molg *et al.* concluded that “modern glacier retreat on Kilimanjaro is much more complex than simply attributable to ‘global warming only’.” Indeed, they say it is “a process driven by a complex combination of changes in several different climatic parameters [e.g., Kruss, 1983; Kruss and Hastenrath, 1987; Hastenrath and Kruss, 1992; Kaser and Georges, 1997; Wagnon *et al.*, 2001; Kaser and Osmaston, 2002; Francou *et al.*, 2003; Molg *et al.*, 2003b], with humidity-related variables dominating this combination.”

Kaser *et al.* (2004) similarly concluded that “changes in air humidity and atmospheric moisture content (e.g. Soden and Schroeder, 2000) seem to play an underestimated key role in tropical high-mountain climate (Broecker, 1997).” Noting that all glaciers in equatorial East Africa exhibited strong recession trends over the past century, they report that “the dominant reasons for this strong recession in modern times are reduced precipitation (Kruss, 1983; Hastenrath, 1984; Kruss and Hastenrath, 1987; Kaser and Noggler, 1996) and increased availability of shortwave radiation due to decreases in cloudiness (Kruss and Hastenrath, 1987; Molg *et al.*, 2003b),” both of which phenomena they relate to a dramatic drying of the regional atmosphere that occurred around 1880 and the ensuing dry climate that subsequently prevailed throughout the twentieth century. Kaser *et al.* conclude that all relevant “observations and facts” clearly indicate that “climatological processes other than air temperature control the ice recession in a direct manner” on Kilimanjaro, and that “positive air temperatures have not contributed to the recession process on the summit,” directly contradicting Irion (2002) and Thompson *et al.* (2002), who, in their words, see the recession of Kilimanjaro’s glaciers as “a direct consequence solely of increased air temperature.”

In a subsequent study of the ice fields of Kilimanjaro, Molg and Hardy (2004) derived an energy balance for the horizontal surface of the glacier that comprises the northern ice field of Kibo—the only one of the East African massif’s three peaks that is presently glaciated—based on data obtained from an automated weather station. This work revealed, in their words, that “the main energy exchange at the glacier-atmosphere interface results from the terms accounting for net radiation, governed

by the variation in net shortwave radiation,” which is controlled by surface albedo and, thus, precipitation variability, which determines the reflective characteristics of the glacier’s surface. Much less significant, according to the two researchers, is the temperature-driven turbulent exchange of sensible heat, which they say “remains considerably smaller and of little importance.”

Molg and Hardy conclude that “modern glacier retreat on Kilimanjaro and in East Africa in general [was] initiated by a drastic reduction in precipitation at the end of the nineteenth century (Hastenrath, 1984, 2001; Kaser *et al.*, 2004),” and that reduced accumulation and increased ablation have “maintained the retreat until the present (Molg *et al.*, 2003b).” Buttressing their findings is the fact, as they report it, that “detailed analyses of glacier retreat in the global tropics uniformly reveal that changes in climate variables related to air humidity prevail in controlling the modern retreat [e.g., Kaser and Georges (1997) for the Peruvian Cordillera Blanca and Francou *et al.* (2003) for the Bolivian Cordillera Real (both South American Andes); Kruss (1983), Kruss and Hastenrath (1987), and Hastenrath (1995) for Mount Kenya (East Africa); and Molg *et al.* (2003a) for the Rwenzori massif (East Africa)].” The take-home message of their study is essentially the same as that of Kaser *et al.* (2004): “Positive air temperatures have not contributed to the recession process on the summit.”

Two years later, Cullen *et al.* (2006) report that “all ice bodies on Kilimanjaro have retreated drastically between 1912-2003,” but they add that the highest glacial recession rates on Kilimanjaro “occurred in the first part of the twentieth century, with the most recent retreat rates (1989-2003) smaller than in any other interval.” In addition, they say no temperature trends over the period 1948-2005 have been observed at the approximate height of the Kilimanjaro glaciers, but that there has been a small decrease in the region’s specific humidity over this period.

In terms of why glacier retreat on Kilimanjaro was so dramatic over the twentieth century, the six researchers note that for the mountain’s plateau glaciers, there is no alternative for them “other than to continuously retreat once their vertical margins are exposed to solar radiation,” which appears to have happened sometime in the latter part of the nineteenth century. They also say, in this regard, that the “vertical wall retreat that governs the retreat of plateau glaciers is irreversible, and changes in

twentieth century climate have not altered their continuous demise.” Consequently, the twentieth century retreat of Kilimanjaro’s plateau glaciers is a long-term response to what we could call “relict climate change” that likely occurred in the late nineteenth century.

In the case of the mountain’s slope glaciers, Cullen *et al.* say that their rapid recession in the first part of the twentieth century shows they “were drastically out of equilibrium,” which they take as evidence that the glaciers “were responding to a large prior shift in climate.” In addition, they report that “no footprint of multidecadal changes in areal extent of slope glaciers to fluctuations in twentieth century climate is observed, but their ongoing demise does suggest they are still out of equilibrium,” and in this regard they add that their continuing but decelerating demise could be helped along by the continuous slow decline in the air’s specific humidity. Consequently, and in light of all the facts they present and the analyses they and others have conducted over many years, Cullen *et al.* confidently conclude that the glaciers of Kilimanjaro “are merely remnants of a past climate rather than sensitive indicators of 20th century climate change.”

Two more recent studies, Mote and Kaser (2007) and Duane *et al.* (2008) additionally reject the temperature-induced decline hypothesis for Kilimanjaro, with Duane *et al.* concluding that “the reasons for the rapid decline in Kilimanjaro’s glaciers are not primarily due to increased air temperatures, but a lack of precipitation,” and Mote and Kaser reporting that “warming fails spectacularly to explain the behavior of the glaciers and plateau ice on Africa’s Kilimanjaro massif ... and to a lesser extent other tropical glaciers.”

Clearly, the misguided rushes to judgment that have elevated Kilimanjaro’s predicted demise by CO<sub>2</sub>-induced global warming to iconic status should give everyone pause to more carefully evaluate the evidence, or lack thereof, for many similar claims related to the ongoing rise in the air’s CO<sub>2</sub> content.

#### 4.1.3. Antarctica

In early November 2001, a large iceberg separated from West Antarctica's Pine Island Glacier. This event was of great interest to scientists because the Pine Island Glacier is currently the fastest-moving glacier in Antarctica and the continent's largest discharger of ice. Some speculate this event could herald the "beginning of the end" of the West Antarctic Ice Sheet. Scientific studies, however, suggest otherwise.

Rignot (1998) employed satellite radar measurements of the grounding line of Pine Island Glacier from 1992 to 1996 to determine whether it was advancing or retreating. The data indicated a retreat rate of  $1.2 \pm 0.3$  kilometers per year over the four-year period of the study. Because the study period was so short, Rignot says the questions the study raises concerning the long-term stability of the West Antarctic Ice Sheet "cannot be answered at present."

In a subsequent study, Stenoien and Bentley (2000) mapped the catchment region of Pine Island Glacier using radar altimetry and synthetic aperture radar interferometry, after which they used the data to develop a velocity map that revealed a system of tributaries that channel ice from the catchment area into the fast-flowing glacier. By combining these velocity data with information on ice thickness and snow accumulation rates, they were able to calculate an approximate mass balance for the glacier within an uncertainty of approximately 30 percent. Their results suggested the mass balance of the catchment region was not significantly different from zero.

Shepherd *et al.* (2001) used satellite altimetry and interferometry to determine the rate of change of thickness of Pine Island Glacier's entire drainage basin between 1992 and 1999, determining that the grounded glacier thinned by up to 1.6 meters per year over this period. They note "the thinning cannot be explained by short-term variability in accumulation and must result from glacier dynamics." And since glacier dynamics are typically driven by phenomena operating on time scales of hundreds to thousands of

years, this observation would argue against twentieth century warming being the cause of the thinning. Shepherd *et al.* also say they could “detect no change in the rate of ice thinning across the glacier over [the] 7-year period,” which also suggests that a long-term phenomenon of considerable inertia must be at work.

What if the rate of glacier thinning—1.6 meters per year—continues unabated? Shepherd *et al.* state that “if the trunk continues to lose mass at the present rate it will be entirely afloat within 600 years.” And if that happens? They say they “estimate the net contribution to eustatic sea level to be 6 mm.” This means that for each century of the foreseeable future, we could expect global mean sea level to rise by one millimeter ... about the thickness of a common paper clip.

Turning to other glaciers, Hall and Denton (2002) mapped the distribution and elevation of surficial deposits along the southern Scott Coast of Antarctica in the vicinity of the Wilson Piedmont Glacier, which runs parallel to the coast of the western Ross Sea from McMurdo Sound north to Granite Harbor. The chronology of the raised beaches was determined from more than 60 <sup>14</sup>C dates of organic materials they had previously collected from hand-dug excavations (Hall and Denton, 1999). They also evaluated more recent changes in snow and ice cover based on aerial photography and observations carried out since the late 1950s.

Near the end of the Medieval Warm Period—“as late as 890 <sup>14</sup>C yr BP,” as Hall and Denton put it—“the Wilson Piedmont Glacier was still less extensive than it is now.” They rightly conclude that the glacier had to have advanced in the past several hundred years, although they note its eastern margin has retreated in the past 50 years. They report a number of similar observations by other investigators. Citing evidence collected by Baroni and Orombelli (1994a), they note there was “an advance of at least one kilometer of the Hell’s Gate Ice Shelf ... within the past few hundred years.” And they report that Baroni and Orombelli (1994b) “documented post-fourteenth century advance of a glacier near Edmonson’s Point.” Summarizing these and other findings, they conclude that evidence from the Ross Sea area suggests “late-Holocene climatic deterioration and glacial advance (within the past few hundred years) and twentieth century retreat.”

In speaking of the significance of the “recent advance of the Wilson Piedmont Glacier,” Hall and Denton report that it “overlaps in time with the readvance phase known in the Alps [of Europe] as the

‘Little Ice Age’,” which they further note “has been documented in glacial records as far afield as the Southern Alps of New Zealand (Wardle, 1973; Black, 2001), the temperate land mass closest to the Ross Sea region.” They further note that “Kreutz *et al.* (1997) interpreted the Siple Dome [Antarctica] glaciochemical record as indicating enhanced atmospheric circulation intensity at AD ~1400, similar to that in Greenland during the ‘Little Ice Age’ (O’Brien *et al.*, 1995).” In addition, they report that “farther north, glaciers in the South Shetland Islands adjacent to the Antarctic Peninsula underwent a late-Holocene advance, which has been correlated with the ‘Little Ice Age’ (Birkenmajer, 1981; Clapperton and Sugden, 1988; Martinez de Pison *et al.*, 1996; Björck *et al.*, 1996).”

In summarizing the results of their work, Hall and Denton say “the Wilson Piedmont Glacier appears to have undergone advance at approximately the same time as the main phase of the ‘Little Ice Age’, followed by twentieth-century retreat at some localities along the Scott Coast.” This result and the others they cite make it clear that glacial activity on Antarctica has followed the pattern of millennial-scale variability that is evident elsewhere in the world: recession to positions during the Medieval Warm Period that have not yet been reached in our day, followed by significant advances during the intervening Little Ice Age.

#### 4.1.4. Arctic

Computer simulations of global climate change have long indicated the world's polar regions should show the first and severest signs of CO<sub>2</sub>-induced global warming. If the models are correct, these signs should be especially evident in the second half of the twentieth century, when approximately two-thirds of the modern-era rise in atmospheric CO<sub>2</sub> occurred and earth's temperature supposedly rose to a level

unprecedented in the past millennium. In this subsection, we examine historic trends in Arctic glacier behavior to determine the credibility of current climate models with respect to their polar predictions.

In a review of "the most current and comprehensive research of Holocene glaciation," along the northernmost Gulf of Alaska between the Kenai Peninsula and Yakutat Bay, Calkin *et al.* (2001) report there were several periods of glacial advance and retreat over the past 7,000 years. Over the most recent of those seven millennia, there was a general retreat during the Medieval Warm Period that lasted for "at least a few centuries prior to A.D. 1200." Then came three major intervals of Little Ice Age glacial advance: the early fifteenth century, the middle seventeenth century, and the last half of the nineteenth century. During these very cold periods, glacier equilibrium-line altitudes were depressed from 150 to 200 m below present values, as Alaskan glaciers "reached their Holocene maximum extensions."

The mass balance records of the 18 Arctic glaciers with the longest observational histories subsequent to this time, as the planet emerged from the depths of the Little Ice Age, were studied by Dowdeswell *et al.* (1997). Their analysis showed that more than 80 percent of the glaciers displayed negative mass balances over the periods of their observation, as would be expected for glaciers emerging from the coldest part of the past millennium. Nevertheless, the scientists report that "ice-core records from the Canadian High Arctic islands indicate that the generally negative glacier mass balances observed over the past 50 years have probably been typical of Arctic glaciers since the end of the Little Ice Age," when the magnitude of anthropogenic CO<sub>2</sub> emissions was much less than it has been from 1950 onward.

These observations suggest that Arctic glaciers are not experiencing any adverse effects of anthropogenic CO<sub>2</sub> emissions. In fact, Dowdeswell *et al.* say "there is no compelling indication of increasingly negative balance conditions which might, *a priori*, be expected from anthropogenically induced global warming." Quite to the contrary, they report that "almost 80 percent of the mass balance time series also have a positive trend, toward a less negative mass balance." Hence, although most Arctic glaciers continue to lose mass, as they have probably done since the end of the Little Ice Age, they are losing smaller amounts each year.

Additional evidence that the Arctic's glaciers are not responding to human-induced warming comes from the studies of Zeeberg and Forman (2001) and Mackintosh *et al.* (2002), who indicate there has been an *expansion* of glaciers in the European Arctic over the past few decades.

Zeeberg and Forman analyzed twentieth century changes in glacier terminus positions on north Novaya Zemlya—a Russian island located between the Barents and Kara Seas in the Arctic Ocean—providing a quantitative assessment of the effects of temperature and precipitation on glacial mass balance. Their study showed a significant and accelerated post-Little Ice Age glacial retreat in the first and second decades of the twentieth century. By 1952, the region's glaciers had experienced between 75 percent to 100 percent of their net twentieth century retreat; and during the next 50 years, the recession of more than half of the glaciers stopped, while many tidewater glaciers actually began to advance.

These glacial stabilizations and advances were attributed by the authors to observed increases in precipitation and/or decreases in temperature. For the four decades since 1961, weather stations on Novaya Zemlya, for example, show summer temperatures were 0.3 to 0.5°C colder than they were over the prior 40 years, while winter temperatures were 2.3 to 2.8°C colder than they were over that earlier period. These observations, the authors say, are “counter to warming of the Eurasian Arctic predicted for the twenty-first century by climate models, particularly for the winter season.”

Other glacier observations that run counter to climate model predictions are discussed by Mackintosh *et al.* (2002), who concentrated on the 300-year history of the Solheimajokull outlet glacier on the southern coast of Iceland. In 1705, this glacier had a length of about 14.8 km; by 1740 it had grown to 15.2 km in length. Thereafter, it began to retreat, reaching a minimum length of 13.2 km in 1783. Rebounding rapidly, however, the glacier returned to its 1705 position by 1794; by 1820 it equaled its 1740 length. This maximum length was maintained for the next half-century, after which the glacier began a slow retreat that continued to about 1932, when its length was approximately 14.75 km. Then it wasted away more rapidly, reaching a second minimum-length value of approximately 13.8 km about 1970, whereupon it began to rapidly expand, growing to 14.3 km by 1995.

The current position of the outlet glacier terminus is by no means unusual. In fact, it is about midway

between its maximum and minimum positions of the past three centuries. It is also interesting to note that the glacier has been growing in length since about 1970. Mackintosh *et al.* report that “the recent advance (1970-1995) resulted from a combination of cooling and enhancement of precipitation.”

In another study of the Arctic, Humlum *et al.* (2005) evaluated climate dynamics and their respective impacts on high-latitude glaciers for the Archipelago of Svalbard, focusing on Spitsbergen (the Archipelago's main island) and the Longyearbreen glacier located in its relatively dry central region at 78°13'N latitude. In reviewing what was already known about the region, Humlum *et al.* report that “a marked warming around 1920 changed the mean annual air temperature (MAAT) at sea level within only 5 years from about -9.5°C to -4.0°C,” which change, in their words, “represents the most pronounced increase in MAAT documented anywhere in the world during the instrumental period.” Then, they report that “from 1957 to 1968, MAAT dropped about 4°C, followed by a more gradual increase towards the end of the twentieth century.”

With respect to the Longyearbreen glacier, their work reveals it “has increased in length from about 3 km to its present size of about 5 km during the last c. 1100 years,” and they say that “the meteorological setting of non-surging Longyearbreen suggest this example of late-Holocene glacier growth represents a widespread phenomenon in Svalbard and in adjoining Arctic regions,” which they describe as a “development towards cooler conditions in the Arctic” that “may explain why the Little Ice Age glacier advance in Svalbard usually represents the Holocene maximum glacier extension.”

Climate change in Svalbard over the twentieth century was a rollercoaster ride, with temperatures rising more rapidly in the early 1920s than has been documented anywhere else before or since, only to be followed by a nearly equivalent temperature drop four decades later, both of which climatic transitions were totally out of line with what climate models suggest should have occurred. The current location of the terminus of the Longyearbreen glacier suggests that, even now, Svalbard and “adjoining Arctic regions” are experiencing some of the lowest temperatures of the entire Holocene or current interglacial, at a time when atmospheric CO<sub>2</sub> concentrations are higher than they have likely been for millions of years. Both of these observations are at odds with what the IPCC claims about the strong warming power of atmospheric CO<sub>2</sub> enrichment.

Bradwell *et al.* (2006) examined the link between late Holocene fluctuations of Lambatungnajokull (an outlet glacier of the Vatnajokull ice cap of southeast Iceland) and variations in climate, using geomorphological evidence to reconstruct patterns of glacier fluctuations and using lichenometry and tephrostratigraphy to date glacial landforms created by the glacier over the past four centuries. Results indicated that “there is a particularly close correspondence between summer air temperature and the rate of ice-front recession of Lambatungnajokull during periods of overall retreat,” and that “between 1930 and 1950 this relationship is striking.” They also report that “ice-front recession was greatest during the 1930s and 1940s, when retreat averaged 20 m per year.” Thereafter, they say the retreat “slowed in the 1960s,” and they report “there has been little overall retreat since the 1980s.”

The researchers also report that “the 20th-century record of reconstructed glacier-front fluctuations at Lambatungnajokull compares well with those of other similar-sized, non-surgings, outlets of southern Vatnajokull,” including Skaftafellsjokull, Fjallsjokull, Skalafellsjokull, and Flaajokull. In fact, they find “the pattern of glacier fluctuations of Lambatungnajokull over the past 200 years reflects the climatic changes that have occurred in southeast Iceland and the wider region.”

Bradwell *et al.*'s findings suggest that twentieth century summer air temperature in southeast Iceland and the wider region peaked in the 1930s and 1940s, and was followed by a cooling that persisted through the end of the century. This thermal behavior is about as different as one could imagine from the claim that the warming of the globe over the last two decades of the twentieth century was unprecedented over the past two millennia. Especially is this so for a high-northern-latitude region, where the IPCC claims CO<sub>2</sub>-induced global warming should be earliest and most strongly expressed.

### 4.1.5. Europe

Joerin *et al.* (2006) examined glacier recessions in the Swiss Alps over the past ten thousand years based on radiocarbon-derived ages of materials found in proglacial fluvial sediments of subglacial origin, focusing on subfossil remains of wood and peat. Combining their results with earlier data of a similar nature, they then constructed a master chronology of Swiss glacier fluctuations over the course of the Holocene.

Joerin *et al.* first report discovering that “alpine glacier recessions occurred at least 12 times during the Holocene,” once again demonstrating that millennial-scale oscillation of climate has reverberated throughout glacial and interglacial periods as far back in time as scientists have searched for the phenomenon. Second, they determined that glacier recessions have been decreasing in frequency since approximately 7,000 years ago, and especially since 3,200 years ago, “culminating in the maximum glacier extent of the ‘Little Ice Age’.” Third, the last of the major glacier recessions in the Swiss Alps occurred between about 1,400 and 1,200 years ago, according to Joerin *et al.*'s data, but between 1200 and 800 years ago, according to the data of Holzhauser *et al.* (2005) for the Great Aletsch Glacier. Of this discrepancy, Joerin *et al.* say that given the uncertainty of the radiocarbon dates, the two records need not be considered inconsistent with

each other. What is more, their presentation of the Great Aletsch Glacier data indicates the glacier's length at about AD 1000—when there was fully 100 ppm *less* CO<sub>2</sub> in the air than there is today—was just slightly less than its length in 2002.

Also in the Swiss Alps, Huss *et al.* (2008) examined various ice and meteorological measurements made between 1865 and 2006 in an effort to compute the yearly mass balances of four glaciers. The results of their computations can be seen in Figure 4.1.5.1.

**Figure 4.1.5.1.** Huss *et al.* (2008) examined various ice and meteorological measurements made between 1865 and 2006 in the Swiss Alps to compute the yearly mass balances of four glaciers.

The most obvious conclusion to be drawn from these data is the fact that each of the four glaciers has decreased in size. But more important is the fact that the rate of shrinkage has not accelerated over time, as evidenced by the long-term trend lines we have fit to the data. There is no compelling evidence that this 14-decade-long glacial decline has had anything to do with the air's CO<sub>2</sub> content.

Consider, for example, the changes in atmospheric CO<sub>2</sub> concentration experienced over the same time period, also shown in the figure. If we compute the mean rate-of-rise of the air's CO<sub>2</sub> content from the start of the record to about 1950, and from about 1970 to 2006, we see that between 1950 and 1970 the rate-of-rise of the atmosphere's CO<sub>2</sub> concentration increased by more than five-fold, yet there were no related increases in the long-term mass balance trends of the four glaciers. It is clear that the ice loss history of the glaciers was not unduly influenced by the increase in the rate-of-rise of the air's CO<sub>2</sub> content that occurred between 1950 and 1970, and that their rate of shrinkage was also not

materially altered by what the IPCC calls the unprecedented warming of the past few decades.

Moving to northern Europe, Linderholm *et al.* (2007) examined “the world's longest ongoing continuous mass-balance record” of “Storglaciaren in northernmost Sweden,” which they report “is generally well correlated to glaciers included in the regional mass balance program (Holmlund and Jansson, 1999), suggesting that it represents northern Swedish glaciers.” The results of their work are depicted in Figure 4.1.5.2, where we have also plotted the contemporaneous history of the atmosphere's CO<sub>2</sub> concentration.

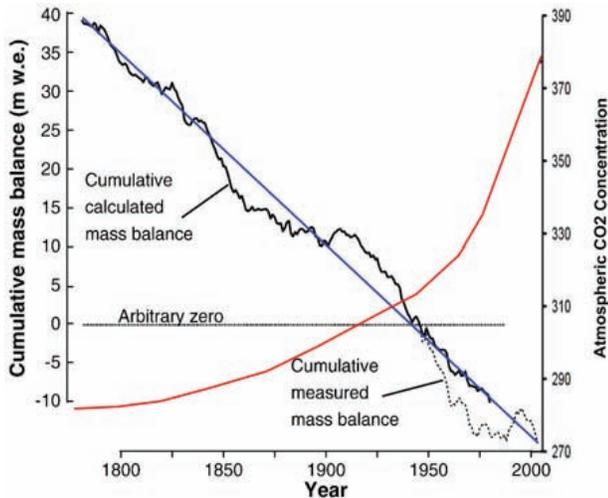

In viewing the figure, it should be evident that the historical increase in the air's CO<sub>2</sub> content has had absolutely no discernable impact on the net mass balance history of Sweden's Storglaciaren over the past two-and-a-quarter centuries. Whereas the mean rate-of-rise of the air's CO<sub>2</sub> concentration over the last half-century of Storglaciaren mass balance data is fully 15 times greater than what it was over the first half-century of mass balance data (and some 40 times greater if the first and last quarter-centuries are considered), there has been no sign of any change in the long-term trend of Storglaciaren's net mass balance.

D'Orefice *et al.* (2000) assembled and analyzed a wealth of historical data to derive a history of post-Little Ice Age (LIA) shrinkage of the surface area of the southernmost glacier of Europe, Ghiacciaio del Calderone. From the first available information on the glacier's surface area in 1794, there was a very slow ice wastage that lasted until 1884, whereupon the glacier began to experience a more rapid area reduction that continued, with some irregularities, to 1990, resulting in a loss of just over half the glacier's LIA surface area.

Not all European glaciers, however, have experienced continuous declines since the end of the Little Ice Age. Hormes *et al.* (2001) report that glaciers in the Central Swiss Alps experienced two periods of readvancement, one around 1920 and another as recent as 1980. In addition, Braithwaite (2002) reports that for the period 1980-1995, “Scandinavian glaciers [have been] growing, and glaciers in the Caucasus are close to equilibrium,” while “there is no obvious common or global trend of increasing glacier melt.”

Fifty years of mass balance data from the storied Storglaciaren of northwestern Sweden also demonstrate a trend reversal in the late twentieth century. According to Braithwaite and Zhang (2000),

there has been a significant upward trend in the mass balance of this glacier over the past 30-40 years, and it has been in a state of mass accumulation for at least the past decade.

**Figure 4.1.5.2.** The cumulative reconstructed net mass balance (bN) history of Sweden's Storglaciaren, to which we have added the fit-by-eye descending linear relationship, in blue, and the history of the atmosphere's CO<sub>2</sub> concentration, in red. Adapted from Linderholm et al. (2007).

Additional evidence for post-LIA glacial expansion is provided by the history of the Solheimajokull outlet glacier on the southern coast of Iceland. In a review of its length over the past 300 years, Mackintosh *et al.* (2002) report a post-LIA minimum of 13.8 km in 1970, whereupon the glacier began to expand, growing to a length of about 14.3 km by 1995. The minimum length of 13.8 km observed in 1970 also did not eclipse an earlier minimum in which the glacier had decreased from a 300-year maximum length of 15.2 km in 1740 to a 300-year minimum of 13.2 km in 1783.

More recent glacial advances have been reported in Norway. According to Chin *et al.* (2005), glacial recession in Norway was most strongly expressed in "the middle of the 20th century," ending during the late 1950s to early 1960s." Then, "after some years with more or less stationary glacier front positions, [the glaciers] began to advance, accelerating in the late 1980s." Around 2000, a portion of the glaciers began to slow, while some even ceased moving; but they say that "most of the larger outlets with longer reaction times are continuing to advance." Chin *et al.* report that "the distances regained and the duration of this recent advance episode are both far greater than

any previous readvance since the Little Ice Age maximum, making the recent resurgence a significant event." Mass balance data reveal much the same thing, "especially since 1988" and "at all [western] maritime glaciers in both southern and northern Norway," where "frequent above-average winter balances are a main cause of the positive net balances at the maritime glaciers during the last few decades."

In considering the results of the studies summarized above, it appears there is no correlation between atmospheric CO<sub>2</sub> levels and glacier melting or advancement in Europe. Several European glaciers are holding their own or actually advancing over the past quarter-century, a period of time in which the IPCC claims the earth has warmed to its highest temperature of the past thousand years.

#### 4.1.6. North America

The history of North American glacial activity also fails to support the claim that anthropogenic CO<sub>2</sub> emissions are causing glaciers to melt. Dowdeswell *et al.* (1997) analyzed the mass balance histories of the 18 Arctic glaciers with the longest observational records, finding that just over 80 percent of them displayed negative mass balances over the last half of the twentieth century. However, they note that “ice-core records from the Canadian High Arctic islands indicate that the generally negative glacier mass balances observed over the past 50 years have probably been typical of Arctic glaciers since the end of the Little Ice Age.” They say “there is no compelling indication of increasingly negative balance conditions which might, *a priori*, be expected from anthropogenically induced global warming.”

Clague *et al.* (2004) documented glacier and vegetation changes at high elevations in the upper Bowser River basin in the northern Coast Mountains of British Columbia, based on studies of the distributions of glacial moraines and trimlines, tree-ring data, cores from two small lakes that were sampled for a variety of analyses (magnetic susceptibility, pollen, diatoms, chironomids, carbon and nitrogen content, <sup>210</sup>Pb, <sup>137</sup>Cs, <sup>14</sup>C), similar analyses of materials obtained from pits and cores from a nearby fen, and by accelerator mass spectrometry radiocarbon dating of plant fossils,

including wood fragments, tree bark, twigs and conifer needles and cones. All this evidence suggested a glacial advance that began about 3,000 years ago and may have lasted for hundreds of years, which would have placed it within the unnamed cold period that preceded the Roman Warm Period. There was also evidence for a second minor phase of activity that began about 1,300 years ago but was of short duration, which would have placed it within the Dark Ages Cold Period. Finally, the third and most extensive Neoglacial interval began shortly after AD 1200, following the Medieval Warm Period, and ended in the late 1800s, which was, of course, the Little Ice Age, during which time Clague *et al.* say “glaciers achieved their greatest extent of the past 3,000 years and probably the last 10,000 years.”

These data clearly depict the regular alternation between non-CO<sub>2</sub>-forced multi-century cold and warm periods that is the trademark of the millennial-scale oscillation of climate that reverberates throughout glacial and interglacial periods alike. That a significant, but by no means unprecedented, warming followed the most recent cold phase of this cycle is in no way unusual, particularly since the Little Ice Age was likely the coldest period of the last 10,000 years.

Alaska, Calkin *et al.* (2001) reviewed the most current and comprehensive research of Holocene glaciation along the northernmost portion of the Gulf of Alaska between the Kenai Peninsula and Yakutat Bay, where several periods of glacial advance and retreat were noted during the past 7,000 years. Over the latter part of this record, there was a general glacial retreat during the Medieval Warm Period that lasted for a few centuries prior to A.D. 1200, after which there were three major intervals of Little Ice Age glacial advance: the early fifteenth century, the middle seventeenth century, and the last half of the nineteenth century. During these latter time periods, glacier equilibrium line altitudes were depressed from 150 to 200 m below present values as Alaskan glaciers also “reached their Holocene maximum extensions.”

Wiles *et al.* (2004) derived a composite Glacier Expansion Index (GEI) for Alaska based on “dendrochronologically derived calendar dates from forests overrun by advancing ice and age estimates of moraines using tree-rings and lichens” for three climatically distinct regions—the Arctic Brooks Range, the southern transitional interior straddled by the Wrangell and St. Elias mountain ranges, and the Kenai, Chugach, and St. Elias coastal ranges—after

which they compared this history of glacial activity with “the  $^{14}\text{C}$  record preserved in tree rings corrected for marine and terrestrial reservoir effects as a proxy for solar variability” and with the history of the Pacific Decadal Oscillation (PDO) derived by Cook (2002).

As a result of their efforts, Wiles *et al.* discovered that “Alaska shows ice expansions approximately every 200 years, compatible with a solar mode of variability,” specifically, the de Vries 208-year solar cycle; and by merging this cycle with the cyclical behavior of the PDO, they obtained a dual-parameter forcing function that was even better correlated with the Alaskan composite GEI, with major glacial advances clearly associated with the Sporer, Maunder, and Dalton solar minima.

Wiles *et al.* said “increased understanding of solar variability and its climatic impacts is critical for separating anthropogenic from natural forcing and for predicting anticipated temperature change for future centuries.” They made no mention of possible  $\text{CO}_2$ -induced global warming in discussing their results, presumably because there was no need to do so. Alaskan glacial activity, which in their words “has been shown to be primarily a record of summer temperature change (Barclay *et al.*, 1999),” appears to be sufficiently well described within the context of centennial (solar) and decadal (PDO) variability superimposed upon the millennial-scale (non- $\text{CO}_2$ -forced) variability that produces longer-lasting Medieval Warm Period and Little Ice Age conditions.

Pederson *et al.* (2004) used tree-ring reconstructions of North Pacific surface temperature anomalies and summer drought as proxies for winter glacial accumulation and summer ablation, respectively, to create a 300-year history of regional glacial Mass Balance Potential (MBP), which they compared with historic retreats and advances of Glacier Park’s extensively studied Jackson and Agassiz glaciers in northwest Montana.

As they describe it, “the maximum glacial advance of the Little Ice Age coincides with a sustained period of positive MBP that began in the mid-1770s and was interrupted by only one brief ablation phase (~1790s) prior to the 1830s,” after which they report “the mid-19th century retreat of the Jackson and Agassiz glaciers then coincides with a period marked by strong negative MBP.” From about 1850 onward, they note “Carrara and McGimsey (1981) indicate a modest retreat (~3-14 m/yr) for both glaciers until approximately 1917.” At that point, they report that “the MBP shifts to an extreme negative

phase that persists for ~25 yr,” during which period the glaciers retreated “at rates of greater than 100 m/yr.”

Continuing with their history, Pederson *et al.* report that “from the mid-1940s through the 1970s retreat rates slowed substantially, and several modest advances were documented as the North Pacific transitioned to a cool phase [and] relatively mild summer conditions also prevailed.” From the late 1970s through the 1990s, they say, “instrumental records indicate a shift in the PDO back to warmer conditions resulting in continuous, moderate retreat of the Jackson and Agassiz glaciers.”

The first illuminating aspect of this glacial history is that the post-Little Ice Age retreat of the Jackson and Agassiz glaciers began just after 1830, in harmony with the findings of a number of other studies from various parts of the world (Vincent and Vallon, 1997; Vincent, 2001, 2002; Moore *et al.*, 2002; Yoo and D’Odorico, 2002; Gonzalez-Rouco *et al.* 2003; Jomelli and Pech, 2004), including the entire Northern Hemisphere (Briffa and Osborn, 2002; Esper *et al.*, 2002). These findings stand in stark contrast to what is suggested by the IPCC-endorsed “hockeystick” temperature history of Mann *et al.* (1998, 1999), which does not portray *any* Northern Hemispheric warming until around 1910.

The second illuminating aspect of the glacial record is that the vast bulk of the glacial retreat in Glacier National Park occurred between 1830 and 1942, over which time the air’s  $\text{CO}_2$  concentration rose by only 27 ppm, which is less than a third of the total  $\text{CO}_2$  increase experienced since the start of glacial recession. Then, from the mid-1940s through the 1970s, when the air’s  $\text{CO}_2$  concentration rose by another 27 ppm, Pederson *et al.* report that “retreat rates slowed substantially, and several modest advances were documented.”

The first 27 ppm increase in atmospheric  $\text{CO}_2$  concentration coincided with the great preponderance of glacial retreat experienced since the start of the warming that marked the “beginning of the end” of the Little Ice Age, but the next 27 ppm increase in the air’s  $\text{CO}_2$  concentration was accompanied by little if any additional glacial retreat, when, of course, there was little if any additional warming.

Something other than the historic rise in the air’s  $\text{CO}_2$  content was responsible for the disappearing ice fields of Glacier National Park. The historical behavior of North America’s glaciers provides no evidence for unprecedented or unnatural  $\text{CO}_2$ -induced

global warming over any part of the twentieth century.

### 4.1.7. South America

Harrison and Winchester (2000) used dendrochronology, lichenometry, and aerial photography to date nineteenth and twentieth century fluctuations of the Arco, Colonia, and Arenales glaciers on the eastern side of the Hielo Patagonico Norte in southern Chile. This work revealed that these glaciers, plus four others on the western side of the ice field, began to retreat, in the words of the two researchers, "from their Little Ice Age maximum positions" somewhere between 1850 and 1880, well before the air's CO<sub>2</sub> content began to rise at a significant rate. They also note that the trend continued "through the first half of the 20th century with various still-stands and oscillations between 1925 and 1960 ... with retreat increasing since the

1960s,” just as has been observed at many sites in the Northern Hemisphere.

Glasser *et al.* (2004) described a large body of evidence related to glacier fluctuations in the two major ice fields of Patagonia: the Hielo Patagonico Norte and the Hielo Patagonico Sur. This evidence indicates that the most recent glacial advances in Patagonia occurred during the Little Ice Age. Prior to then, their data indicate an interval of higher temperatures known as the Medieval Warm Period, when glaciers decreased in size and extent; this warm interlude was in turn preceded by an era of pronounced glacial activity that is designated the Dark Ages Cold Period, which was also preceded by a period of higher temperatures and retreating glaciers that is denoted the Roman Warm Period.

Glasser *et al.* documented cycles of glacial advances and retreats each lasting hundreds of years going back to sometime between 6,000 and 5,000 <sup>14</sup>C years before present (BP). They cited the works of other scientists that reveal a similar pattern of cyclical glacial activity over the preceding millennia in several other locations. Immediately to the east of the Hielo Patagonico Sur in the Rio Guanaco region of the Precordillera, for example, they report that Wenzens (1999) detected five distinct periods of glacial advancement: “4500-4200, 3600-3300, 2300-2000, 1300-1000 <sup>14</sup>C years BP and AD 1600-1850.” With respect to the glacial advancements that occurred during the cold interval that preceded the Roman Warm Period, they say they constitute “part of a body of evidence for global climatic change around this time (e.g., Grosjean *et al.*, 1998; Wasson and Claussen, 2002) which coincides with an abrupt decrease in solar activity,” and they say that this observation was what “led van Geel *et al.* (2000) to suggest that variations in solar irradiance are more important as a driving force in variations in climate than previously believed.”

Finally, with respect to the most recent recession of Hielo Patagonico Norte outlet glaciers from their late historic moraine limits at the end of the nineteenth century, Glasser *et al.* say that “a similar pattern can be observed in other parts of southern Chile (e.g., Kuylenstierna *et al.*, 1996; Koch and Kilian, 2001),” to which we would also add the findings of Kaser and Georges (1997) for the Peruvian Cordillera Blanca and Francou *et al.* (2003) for the Bolivian Cordillera Real. Likewise, they note that “in areas peripheral to the North Atlantic and in central Asia the available evidence shows that

glaciers underwent significant recession at this time (cf. Grove, 1988; Savoskul, 1997).”

Georges (2004) constructed a twentieth century history of glacial fluctuations in the Cordillera Blanca of Peru, which is the largest glaciated area within the tropics. This history reveals, in Georges words, that “the beginning of the century was characterized by a glacier recession of unknown extent, followed by a marked readvance in the 1920s that nearly reached the Little Ice Age maximum.” Then came the “very strong” 1930s-1940s glacial mass *shrinkage*, after which there was a period of quiescence that was followed by an “intermediate retreat from the mid-1970s until the end of the century.”

In comparing the two periods of glacial wasting, Georges says that “the intensity of the 1930s-1940s retreat was more pronounced than that of the one at the end of the century.” In fact, his graph of the ice area lost in both time periods suggests that the rate of wastage in the 1930s-1940s was *twice as great* as that of last two decades of the twentieth century.

Georges is quite at ease talking about the Little Ice Age south of the equator in Peru, which is a very long way from the lands that border the North Atlantic Ocean, which is the only region on earth where the IPCC is willing to admit the existence of this chilly era of the planet’s climatic history. The glacial extensions of the Cordillera Blanca in the late 1920s were almost equivalent to those experienced there during the depths of the Little Ice Age.

Koch and Kilian (2005) mapped and dated, by dendrochronological means, a number of moraine systems of Glaciar Lengua and neighboring glaciers of Gran Campo Nevado in the southernmost Andes of Chile, after which they compared their results with those of researchers who studied the subject in other parts of South America. According to their findings, in the Patagonian Andes “the culmination of the Little Ice Age glacier advances occurred between AD 1600 and 1700 (e.g., Mercer, 1970; Rothlisberger, 1986; Aniya, 1996),” but “various glaciers at Hielo Patagonico Norte and Hielo Patagonico Sur also formed prominent moraines around 1870 and 1880 (Warren and Sugden, 1993; Winchester *et al.*, 2001; Luckman and Villalba, 2001).” In addition, they note their study “further supports this scenario,” and that from their observations at Glaciar Lengua and neighboring glaciers at Gran Campo Nevado, it would appear that “the ‘Little Ice Age’ advance was possibly the most extensive one during the Holocene for this ice cap.”

Working with biogenic silica, magnetic susceptibility, total organic carbon (TOC), total nitrogen (TN),  $\delta^{13}\text{C}_{\text{TOC}}$ ,  $\delta^{15}\text{N}_{\text{TN}}$ , and C/N ratios derived from the sediment records of two Venezuelan watersheds, which they obtained from cores retrieved from Lakes Mucubaji and Blanca, together with ancillary data obtained from other studies that had been conducted in the same general region, Polissar *et al.* (2006) developed continuous decadal-scale histories of glacier activity and moisture balance in that part of the tropical Andes (the Cordillera de Merida) over the past millennium and a half, from which they were able to deduce contemporary histories of regional temperature and precipitation.

The international team of scientists—representing Canada, Spain, the United States, and Venezuela—write that “comparison of the Little Ice Age history of glacier activity with reconstructions of solar and volcanic forcing suggests that solar variability is the primary underlying cause of the glacier fluctuations,” because (1) “the peaks and troughs in the susceptibility records match fluctuations of solar irradiance reconstructed from  $^{10}\text{Be}$  and  $\delta^{14}\text{C}$  measurements,” (2) “spectral analysis shows significant peaks at 227 and 125 years in both the irradiance and magnetic susceptibility records, closely matching the de Vreis and Gleissberg oscillations identified from solar irradiance reconstructions,” and (3) “solar and volcanic forcing are uncorrelated between AD 1520 and 1650, and the magnetic susceptibility record follows the solar-irradiance reconstruction during this interval.” In addition, they write that “four glacial advances occurred between AD 1250 and 1810, coincident with solar-activity minima,” and that “temperature declines of  $-3.2 \pm 1.4^\circ\text{C}$  and precipitation increases of  $\sim 20\%$  are required to produce the observed glacial responses.”

In discussing their findings, Polissar *et al.* say their results “suggest considerable sensitivity of tropical climate to small changes in radiative forcing from solar irradiance variability.” The six scientists also say their findings imply “even greater probable responses to future anthropogenic forcing,” and that “profound climatic impacts can be predicted for tropical montane regions.”

With respect to these latter ominous remarks, we note that whereas Polissar *et al.*'s linking of significant climate changes with solar radiation variability is a factual finding of their work, their latter statements with respect to hypothesized  $\text{CO}_2$ -induced increases in down-welling thermal radiation

are speculations that need not follow from what they learned.

Another point worth noting in this regard is Polissar *et al.*'s acknowledgement that “during most of the past 10,000 years, glaciers were absent from all but the highest peaks in the Cordillera de Merida,” which indicates that warmer-than-present temperatures are the norm for this part of the planet, and that any significant warming that might yet occur in this region (as well as most of the rest of the world) would mark only a return to more typical Holocene (or current interglacial) temperatures, which have themselves been significantly lower than those of all four prior interglacials. What is more, atmospheric  $\text{CO}_2$  concentrations were much lower during all of those much warmer periods.

## 4.2. Sea Ice

A number of claims have been made that CO<sub>2</sub>-induced global warming is melting sea ice in the Arctic and Antarctic and that such melting will accelerate as time passes. In this section we analyze Antarctic and Arctic sea ice trends as reported in the scientific literature. We revisit the issue of ice melting in much greater depth in Section 4.5.

### 4.2.1. Antarctic

Utilizing Special Sensor Microwave Imager (SSM/I) data obtained from the Defense Meteorological Satellite Program (DMSP) for the period December 1987-December 1996, Watkins and Simmonds (2000) analyzed temporal trends in different measures of the sea ice that surrounds Antarctica, noting that "it has been suggested that the Antarctic sea ice may show high sensitivity to any anthropogenic increase in temperature," and that most climate models predict that "any rise in surface temperature would result in a decrease in sea ice coverage."

Contrary to what one would expect on the basis of these predictions, the two scientists observed statistically significant *increases* in both sea ice area and sea ice extent over the period studied; and when they combined their results with results for the preceding period of 1978-1987, both parameters continued to show increases over the sum of the two periods (1978-1996). In addition, they determined that the 1990s also experienced increases in the length of the sea ice season.

Watkins and Simmonds' findings, i.e., that Southern Ocean sea ice has increased in area, extent, and season length since at least 1978, are supported by other studies. Hanna (2001) published an updated analysis of Antarctic sea ice cover based on SSM/I data for the period October 1987-September 1999, finding the serial sea ice data depict "an ongoing slight but significant hemispheric increase of 3.7(±0.3)% in extent and 6.6(±1.5)% in area." Parkinson (2002) utilized satellite passive-microwave data to calculate and map the length of the sea-ice season throughout the Southern Ocean for each year of the period 1979-1999, finding that although there are opposing regional trends, a "much larger area of the Southern Ocean experienced an overall lengthening of the sea-ice season ... than experienced a shortening." Updating the analysis two years later for the period November 1978 through

December 2002, Parkinson (2004) reported a linear increase in 12-month running means of Southern Ocean sea ice extent of  $12,380 \pm 1,730$  km<sup>2</sup> per year.

Zwally *et al.* (2002) also utilized passive-microwave satellite data to study Antarctic sea ice trends. Over the 20-year period 1979-1998, they report that the sea ice extent of the entire Southern Ocean increased by  $11,181 \pm 4,190$  square km per year, or by  $0.98 \pm 0.37$  percent per decade, while sea ice area increased by nearly the same amount:  $10,860 \pm 3,720$  square km per year, or by  $1.26 \pm 0.43$  percent per decade. They observed that the variability of monthly sea ice extent declined from 4.0 percent over the first 10 years of the record, to 2.7 percent over the last 10 years.

Yuan and Martinson (2000) analyzed Special SSM/I data together with data derived from brightness temperatures measured by the Nimbus-7 Scanning Multichannel Microwave Radiometer. Among other things, they determined that the mean trend in the latitudinal location of the Antarctic sea ice edge over the prior 18 years was an equatorward expansion of 0.011 degree of latitude per year.

Vyas *et al.* (2003) analyzed data from the multi-channel scanning microwave radiometer carried aboard India's OCEANSAT-1 satellite for the period June 1999-May 2001, which they combined with data for the period 1978-1987 that were derived from space-based passive microwave radiometers carried aboard earlier Nimbus-5, Nimbus-7, and DMSP satellites to study secular trends in sea ice extent about Antarctica over the period 1978-2001. Their work revealed that the mean rate of change of sea ice extent for the entire Antarctic region over this period was an increase of 0.043 M km<sup>2</sup> per year. In fact, they concluded that "the increasing trend in the sea ice extent over the Antarctic region may be slowly accelerating in time, particularly over the last decade," noting that the "continually increasing sea ice extent over the Antarctic Southern Polar Ocean, along with the observed decreasing trends in Antarctic ice surface temperature (Comiso, 2000) over the last two decades, is paradoxical in the global warming scenario resulting from increasing greenhouse gases in the atmosphere."

In a somewhat similar study, Cavalieri *et al.* (2003) extended prior satellite-derived Antarctic sea ice records several years by bridging the gap between Nimbus 7 and earlier Nimbus 5 satellite datasets with National Ice Center digital sea ice data, finding that sea ice extent about the continent increased at a mean rate of  $0.10 \pm 0.05 \times 10^6$  km<sup>2</sup> per decade between

1977 and 2002. Likewise, Liu *et al.* (2004) used sea ice concentration data retrieved from the scanning multichannel microwave radiometer on the Nimbus 7 satellite and the spatial sensor microwave/imager on several defense meteorological satellites to develop a quality-controlled history of Antarctic sea ice variability covering the period 1979-2002, which includes different states of the Antarctic Oscillation and several ENSO events, after which they evaluated total sea ice extent and area trends by means of linear least-squares regression. They found that "overall, the total Antarctic sea ice extent (the cumulative area of grid boxes covering at least 15% ice concentrations) has shown an increasing trend ( $\sim 4,801$  km<sup>2</sup>/yr)." In addition, they determined that "the total Antarctic sea ice area (the cumulative area of the ocean actually covered by at least 15% ice concentrations) has increased significantly by  $\sim 13,295$  km<sup>2</sup>/yr, exceeding the 95% confidence level," noting that "the upward trends in the total ice extent and area are robust for different cutoffs of 15, 20, and 30% ice concentrations (used to define the ice extent and area)."

Elderfield and Rickaby (2000) concluded that the sea ice cover of the Southern Ocean during glacial periods may have been as much as double the coverage of modern winter ice, suggesting that "by restricting communication between the ocean and atmosphere, sea ice expansion also provides a mechanism for reduced CO<sub>2</sub> release by the Southern Ocean and lower glacial atmospheric CO<sub>2</sub>."

Three papers on Antarctic sea ice were published in 2008. Laine (2008) determined 1981-2000 trends of Antarctic sea-ice concentration and extent, based on the Scanning Multichannel Microwave Radiometer (SSMR) and SSM/I for the spring-summer period of November/December/ January. These analyses were carried out for the continent as a whole, as well as five longitudinal sectors emanating from the south pole: 20°E-90°E, 90°E-160°E, 160°E-130°W, 130°W-60°W, and 60°W-20°E. Results indicated that "the sea ice concentration shows slight increasing trends in most sectors, where the sea ice extent trends seem to be near zero." Laine also reports that "the Antarctic region as a whole and all the sectors separately show slightly positive spring-summer albedo trends."

Comiso and Nishio (2008) set out to provide updated and improved estimates of trends in Arctic and Antarctic sea ice cover for the period extending from November 1978 to December 2006, based on data obtained from the Advanced Microwave

Scanning Radiometer (AMSR-E), the SSM/I, and the SMMR, where the data from the last two instruments were adjusted to be consistent with the AMSR-E data. Their findings indicate that sea ice extent and area in the Antarctic grew by  $+0.9 \pm 0.2$  and  $+1.7 \pm 0.3$  percent per decade, respectively.

A study that “extends the analyses of the sea ice time series reported by Zwally *et al.* (2002) from 20 years (1979-1998) to 28 years (1979-2006)” by Cavalieri and Parkinson (2008) derived new linear trends of Antarctic sea ice extent and area based on satellite-borne passive microwave radiometer data. Results indicate “the total Antarctic sea ice extent trend increased slightly, from  $0.96 \pm 0.61$  percent per decade to  $1.0 \pm 0.4$  percent per decade, from the 20- to 28-year period,” noting the latter trend is significant at the 95 percent confidence level. Corresponding numbers for the Antarctic sea ice area trend were  $1.2 \pm 0.7$  percent per decade and  $1.2 \pm 0.5$  percent per decade. Both sets of results indicate a “tightening up” of the two relationships: Over the last eight years of the study period, both the extent and area of Antarctic sea ice have continued to increase, with the former parameter increasing at a more rapid rate than it did over the 1979-1998 period.

Additional information on this topic, including reviews of newer publications as they become available, can be found at <http://www.co2science.org/subject/s/seaiceantarctic.php>.

### 4.2.2. Arctic

Arctic climate is incredibly complex, varying simultaneously on a number of different timescales for a number of different reasons (Venegas and Mysak, 2000). Against this backdrop of multiple causation and timeframe variability, it is difficult to identify a change in either the extent or thickness of Arctic sea ice that could be attributed to the increase in temperature that has been predicted to result from the burning of fossil fuels. The task is further complicated because many of the records that do exist contain only a few years to a few decades of data, and they yield different trends depending on the period of time studied.

#### 4.2.2.1. Extent

Johannessen *et al.* (1999) analyzed Arctic sea ice extent over the period 1978-1998 and found it to have decreased by about 14 percent. This finding led them to suggest that “the balance of evidence,” as small as it then was, indicates “an ice cover in transition,” and that “if this apparent transformation continues, it may lead to a markedly different ice regime in the Arctic,” as was also suggested by Vinnikov *et al.* (1999).

Reading Johannessen *et al.*'s assessment of the situation, one is left with the impression that a relatively consistent and persistent reduction in the area of Arctic sea ice is in progress. However, and according to their own data, that assessment is highly debatable and possibly false. In viewing their plots of sea ice area, for example, it is readily evident that the decline in this parameter did not occur smoothly over the 20-year period of study. In fact, essentially all of the drop it experienced occurred abruptly over a single period of not more than three years (87/88-90/91) and possibly only one year (89/90-90/91). Furthermore, it could be argued from their data that from 1990/91 onward, sea ice area in the Arctic may have actually *increased*.

Support for this assessment of the data is found in Kwok (2004), who estimated “the time-varying perennial ice zone (PIZ) coverage and construct[s] the annual cycles of multiyear (MY, including second year) ice coverage of the Arctic Ocean using QuikSCAT backscatter, MY fractions from RADARSAT, and the record of ice export from satellite passive microwave observations” for the years 1999-2003. Kwok calculated the coverage of Arctic MY sea ice at the beginning of each year of the study was  $3774 \times 10^3 \text{ km}^2$  in 2000,  $3896 \times 10^3 \text{ km}^2$  in 2001,  $4475 \times 10^3 \text{ km}^2$  in 2002, and  $4122 \times 10^3 \text{ km}^2$  in 2003, representing an *increase* in sea ice coverage of 9 percent over a third of a decade.

More questions are raised Parkinson (2000b), who utilized satellite-derived data of sea ice extent to calculate changes in this parameter for the periods 1979-1990 and 1990-1999. He reports that in seven of the nine regions into which he divided the Arctic for his analysis, the “sign of the trend reversed from the 1979-1990 period to the 1990-1999 period,” indicative of the ease with which significant decadal trends are often reversed in this part of the world.

In another study, Belchansky *et al.* (2004) report that from 1988 to 2001, total January multiyear ice area declined at a mean rate of 1.4 percent per year. In the autumn of 1996, however, they note that “a large

multiyear ice recruitment of over  $10^6 \text{ km}^2$  fully replenished the previous 8-year decline in total area.” They add that the replenishment “was followed by an accelerated and compensatory decline during the subsequent 4 years.” In addition, they learned that 75 percent of the interannual variation in January multiyear sea area “was explained by linear regression on two atmospheric parameters: the previous winter’s Arctic Oscillation index as a proxy to melt duration and the previous year’s average sea level pressure gradient across the Fram Strait as a proxy to annual ice export.”

Belchansky *et al.* conclude that their 14-year analysis of multiyear ice dynamics is “insufficient to project long-term trends.” They also conclude it is insufficient to reveal “whether recent declines in multiyear ice area and thickness are indicators of anthropogenic exacerbations to positive feedbacks that will lead the Arctic to an unprecedented future of reduced ice cover, or whether they are simply ephemeral expressions of natural low frequency oscillations.” It should be noted in this regard, however, that low frequency oscillations are what the data actually reveal; and such behavior is not what one would predict from a gradually increasing atmospheric  $\text{CO}_2$  concentration.

In another study, Heide-Jorgensen and Laidre (2004) examined changes in the fraction of open-water found within various pack-ice microhabitats of Foxe Basin, Hudson Bay, Hudson Strait, Baffin Bay-Davis Strait, northern Baffin Bay, and Lancaster Sound over a 23-year interval (1979-2001) using remotely sensed microwave measurements of sea-ice extent, after which the trends they documented were “related to the relative importance of each wintering microhabitat for eight marine indicator species and potential impacts on winter success and survival were examined.”

Results of the analysis indicate that Foxe Basin, Hudson Bay, and Hudson Strait showed small increasing trends in the fraction of open-water, with the upward trends at all microhabitats studied ranging from 0.2 to 0.7 percent per decade. In Baffin Bay-Davis Strait and northern Baffin Bay, on the other hand, the open-water trend was *downward*, and at a mean rate for all open-water microhabitats studied of fully 1 percent per decade, while the trend in all Lancaster Sound open-water microhabitats was also downward, in this case at a mean rate of 0.6 percent per decade.

With respect to the context of these open-water declines, Heide-Jorgensen and Laidre report that

“increasing trends in sea ice coverage in Baffin Bay and Davis Strait (resulting in declining open-water) were as high as 7.5 percent per decade between 1979-1999 (Parkinson *et al.*, 1999; Deser *et al.*, 2000; Parkinson, 2000a,b; Parkinson and Cavalieri, 2002) and comparable significant increases have been detected back to 1953 (Stern and Heide-Jorgensen, 2003).” They additionally note that “similar trends in sea ice have also been detected locally along the West Greenland coast, with slightly lower increases of 2.8 percent per decade (Stern and Heide-Jorgensen, 2003).”

Cavalieri *et al.* (2003) extended prior satellite-derived Arctic sea ice records several years back in time by bridging the gap between Nimbus 7 and earlier Nimbus 5 satellite datasets via comparisons with National Ice Center digital sea ice data. For the newly extended period of 1972-2002, they determined that Arctic sea ice extent had declined at a mean rate of  $0.30 \pm 0.03 \times 10^6 \text{ km}^2$  per decade; while for the shortened period from 1979-2002, they found a mean rate of decline of  $0.36 \pm 0.05 \times 10^6 \text{ km}^2$  per decade, or at a rate that was 20 percent greater than the full-period rate. In addition Serreze *et al.* (2002) determined that the downward trend in Arctic sea ice extent during the passive microwave era culminated with a record minimum value in 2002.

These results could readily be construed to indicate an increasingly greater rate of Arctic sea ice melting during the latter part of the twentieth century. However, the results of these studies are not the end of the story. As Grumet *et al.* (2001) have described the situation, recent trends in Arctic sea ice cover “can be viewed out of context because their brevity does not account for interdecadal variability, nor are the records sufficiently long to clearly establish a climate trend.”

In an effort to overcome this “short-sightedness,” Grumet *et al.* developed a 1,000-year record of spring sea ice conditions in the Arctic region of Baffin Bay based on sea-salt records from an ice core obtained from the Penny Ice Cap on Baffin Island. In doing so, they determined that after a period of reduced sea ice during the eleventh through fourteenth centuries, enhanced sea ice conditions prevailed during the following 600 years. For the final (twentieth) century of this period, however, they report that “despite warmer temperatures during the turn of the century, sea-ice conditions in the Baffin Bay/Labrador Sea region, at least during the last 50 years, are within ‘Little Ice Age’ variability,” suggesting that sea ice

extent there has not yet emerged from the range of conditions characteristic of the Little Ice Age.

In an adjacent sector of the Arctic, this latter period of time was also studied by Comiso *et al.* (2001), who used satellite imagery to analyze and quantify a number of attributes of the Odden ice tongue—a winter ice-cover phenomenon that occurs in the Greenland Sea with a length of about 1,300 km and an aerial coverage of as much as 330,000 square kilometers—over the period 1979-1998. By utilizing surface air temperature data from Jan Mayen Island, which is located within the region of study, they were able to infer the behavior of this phenomenon over the past 75 years. Trend analyses revealed that the ice tongue has exhibited no statistically significant change in any of the parameters studied over the past 20 years; but the proxy reconstruction of the Odden ice tongue for the past 75 years revealed the ice phenomenon to have been “a relatively smaller feature several decades ago,” due to the warmer temperatures that prevailed at that time.

In another study of Arctic climate variability, Omstedt and Chen (2001) obtained a proxy record of the annual maximum extent of sea ice in the region of the Baltic Sea over the period 1720-1997. In analyzing this record, they found that a significant decline in sea ice occurred around 1877. In addition, they reported finding greater variability in sea ice extent in the colder 1720-1877 period than in the warmer 1878-1997 period.

Also at work in the Baltic Sea region, Jevrejeva (2001) reconstructed an even longer record of sea ice duration (and, therefore, extent) by examining historical data for the observed time of ice break-up between 1529 and 1990 in the northern port of Riga, Latvia. The long date-of-ice-break-up time series was best described by a fifth-order polynomial, which identified four distinct periods of climatic transition: (1) 1530-1640, warming with a tendency toward earlier ice break-up of nine days/century, (2) 1640-1770, cooling with a tendency toward later ice break-up of five days/century, (3) 1770-1920, warming with a tendency toward earlier ice break-up of 15 days/century, and (4) 1920-1990, *cooling* with a tendency toward later ice break-up of 12 days/century.

On the other hand, in a study of the Nordic Seas (the Greenland, Iceland, Norwegian, Barents, and Western Kara Seas), Vinje (2001) determined that “the extent of ice in the Nordic Seas measured in April has decreased by 33% over the past 135 years.” He notes, however, that “nearly half of this reduction

is observed over the period 1860-1900,” and we note, in this regard, that the first half of this sea-ice decline occurred over a period of time when the atmosphere’s CO<sub>2</sub> concentration rose by only 7 ppm, whereas the second half of the sea-ice decline occurred over a period of time when the air’s CO<sub>2</sub> concentration rose by more than 70 ppm. If the historical rise in the air’s CO<sub>2</sub> content has been responsible for the historical decrease in sea-ice extent, its impact over the last century has declined to less than a tenth of what its impact was over the preceding four decades. This in turn suggests that the increase in the air’s CO<sub>2</sub> content over the past 135 years has likely had nothing to do with the concomitant decline in sea-ice cover.

In a similar study of the Kara, Laptev, East Siberian, and Chuckchi Seas, based on newly available long-term Russian observations, Polyakov *et al.* (2002) found “smaller than expected” trends in sea ice cover that, in their words, “do not support the hypothesized polar amplification of global warming.” Likewise, in a study published the following year, Polyakov *et al.* (2003) report that “over the entire Siberian marginal-ice zone the century-long trend is only -0.5% per decade,” while “in the Kara, Laptev, East Siberian, and Chukchi Seas the ice extent trends are not large either: -1.1%, -0.4%, +0.3%, and -1.0% per decade, respectively.” Moreover, they say “these trends, except for the Chukchi Sea, are not statistically significant.”

Divine and Dick (2006) used historical April through August ice observations made in the Nordic Seas—comprised of the Iceland, Greenland, Norwegian, and Barents Seas, extending from 30°W to 70°E—to construct time series of ice-edge position anomalies spanning the period 1750-2002, which they analyzed for evidence of long-term trend and oscillatory behavior. The authors report that “evidence was found of oscillations in ice cover with periods of about 60 to 80 years and 20 to 30 years, superimposed on a continuous negative trend,” which observations are indicative of a “persistent ice retreat since the second half of the 19th century” that began well before anthropogenic CO<sub>2</sub> emissions could have had much effect on earth’s climate.

Noting that the last cold period observed in the Arctic occurred at the end of the 1960s, the two Norwegian researchers say their results suggest that “the Arctic ice pack is now at the periodical apogee of the low-frequency variability,” and that “this could explain the strong negative trend in ice extent during the last decades as a possible superposition of natural low frequency variability and greenhouse gas induced

warming of the last decades.” However, as they immediately caution, “a similar shrinkage of ice cover was observed in the 1920s-1930s, during the previous warm phase of the low frequency oscillation, when any anthropogenic influence is believed to have still been negligible.” They suggest, therefore, “that during decades to come ... the retreat of ice cover may change to an expansion.”

In light of this litany of findings, it is difficult to accept the claim that Northern Hemispheric sea ice is rapidly disintegrating in response to CO<sub>2</sub>-induced global warming. Rather, the oscillatory behavior observed in so many of the sea ice studies suggests, in the words of Parkinson (2000b), “the possibility of close connections between the sea ice cover and major oscillatory patterns in the atmosphere and oceans,” including connections with: “(1) the North Atlantic Oscillation (e.g., Hurrell and van Loon, 1997; Johannessen *et al.*, 1999; Kwok and Rothrock, 1999; Deser *et al.*, 2000; Kwok, 2000; Vinje, 2001) and the spatially broader Arctic Oscillation (e.g., Deser *et al.*, 2000; Wang and Ikeda, 2000); (2) the Arctic Ocean Oscillation (Polyakov *et al.*, 1999; Proshutinsky *et al.*, 1999); (3) a ‘see-saw’ in winter temperatures between Greenland and northern Europe (Rogers and van Loon, 1979); and (4) an interdecadal Arctic climate cycle (Mysak *et al.*, 1990; Mysak and Power, 1992).” The likelihood that Arctic sea ice trends are the product of such natural oscillations, Parkinson continues, “provides a strong rationale for considerable caution when extrapolating into the future the widely reported decreases in the Arctic ice cover over the past few decades or when attributing the decreases primarily to global warming,” a caution with which we heartily agree.

One final study of note is that of Bamber *et al.* (2004), who used high-accuracy ice-surface elevation measurements (Krabill *et al.*, 2000) of the largest ice cap in the Eurasian Arctic—Austfonna, on the island of Nordaustlandet in northeastern Svalbard—to evaluate ice cap elevation changes between 1996 and 2002. They determined that the central and highest-altitude area of the ice cap, which comprises 15 percent of its total area, “increased in elevation by an average of 50 cm per year between 1996 and 2002,” while “to the northeast of this region, thickening of about 10 cm per year was also observed.” They further note that the highest of these growth rates represents “as much as a 40% increase in accumulation rate (Pinglot *et al.*, 2001).”

Based on the ancillary sea-ice and meteorological data they analyzed, Bamber *et al.* concluded that the

best explanation for the dramatic increase in ice cap growth over the six-year study period was a large increase in precipitation caused by a concomitant reduction in sea-ice cover in this sector of the Arctic. Their way of characterizing this phenomenon is simply to say that it represents the transference of ice from the top of the sea (in this case, the Barents Sea) to the top of the adjacent land (in this case, the Austfonna ice cap). And as what has been observed to date is only the beginning of the phenomenon, which will become even stronger in the absence of nearby sea-ice, “projected changes in Arctic sea-ice cover,” as they say in the concluding sentence of their paper, “will have a significant impact on the mass-balance of land ice around the Arctic Basin over at least the next 50 years.” Which result, we might add, may be just the opposite of that forecast by the IPCC.

#### 4.2.2.2. Thickness

Based on analyses of submarine sonar data, Rothrock *et al.* (1999) suggested that Arctic sea ice in the mid 1990s had thinned by about 42 percent of the average 1958-1977 thickness. The IPCC reports the Rothrock finding but then reports that other more recent studies found “the reduction in ice thickness was not gradual, but occurred abruptly before 1991,” and acknowledges that “ice thickness varies considerably from year to year at a given location and so the rather sparse temporal sampling provided by submarine data makes inferences regarding long term change difficult” (IPCC 2007, p. 353). Johannessen *et al.* (1999), for example, found that essentially all of the drop occurred rather abruptly over a single period of not more than three years (1987/88-1990/91) and possibly only one year (1989/90-1990/91).

Two years after Johannessen *et al.*, Winsor (2001) analyzed a more comprehensive set of Arctic sea-ice data obtained from six submarine cruises conducted between 1991 and 1997 that had covered the central Arctic Basin from 76° N to 90° N, as well as two areas that had been particularly densely sampled, one centered at the North Pole (>87° N) and one in the central part of the Beaufort Sea (centered at approximately 76° N, 145°W). The transect data across the entire Arctic Basin revealed that the mean Arctic sea-ice thickness had remained “almost constant” over the period of study. Data from the North Pole also showed little variability, and a linear regression of the data revealed a “slight increasing trend for the whole period.” As for the Beaufort Sea region, annual variability in sea ice thickness was greater than at the North Pole but once again, in Winsor’s words, “no significant trend” in mean sea-ice thickness was found. Combining the North Pole results with the results of an earlier study, Winsor concluded that “mean ice thickness has remained on a near-constant level around the North Pole from 1986 to 1997.”

The following year, Holloway and Sou (2002) explored “how observations, theory, and modeling work together to clarify perceived changes to Arctic sea ice,” incorporating data from “the atmosphere, rivers, and ocean along with dynamics expressed in an ocean-ice-snow model.” On the basis of a number of different data-fed model runs, they found that for

the last half of the past century, “no linear trend [in Arctic sea ice volume] over 50 years is appropriate,” noting their results indicated “increasing volume to the mid-1960s, decadal variability without significant trend from the mid-1960s to the mid-1980s, then a loss of volume from the mid-1980s to the mid-1990s.” The net effect of this behavior, in their words, was that “the volume estimated in 2000 is close to the volume estimated in 1950.” They suggest that the initial inferred rapid thinning of Arctic sea ice was, as they put it, “unlikely,” due to problems arising from under-sampling. They also report that “varying winds that readily redistribute Arctic ice create a recurring pattern whereby ice shifts between the central Arctic and peripheral regions, especially in the Canadian sector,” and that the “timing and tracks of the submarine surveys missed this dominant mode of variability.”

In the same year, Polyakov *et al.* (2002) employed newly available long-term Russian landfast-ice data obtained from the Kara, Laptev, East Siberian, and Chuckchi Seas to investigate trends and variability in the Arctic environment poleward of 62°N. This study revealed that fast-ice thickness trends in the different seas were “relatively small, positive or negative in sign at different locations, and not statistically significant at the 95% level.” A year later, these results were reconfirmed by Polyakov *et al.* (2003), who reported that the available fast-ice records “do not show a significant trend,” while noting that “in the Kara and Chukchi Seas trends are positive, and in the Laptev and East Siberian Seas trends are negative,” but stating that “these trends are not statistically significant at the 95% confidence level.”

Laxon *et al.* (2003) used an eight-year time series (1993-2001) of Arctic sea-ice thickness data derived from measurements of ice freeboard made by radar altimeters carried aboard ERS-1 and 2 satellites to determine the mean thickness and variability of Arctic sea ice between latitudes 65° and 81.5°N, which region covers the entire circumference of the Arctic Ocean, including the Beaufort, Chukchi, East Siberian, Kara, Laptev, Barents, and Greenland Seas. These real-world observations (1) revealed “an interannual variability in ice thickness at higher frequency, and of greater amplitude, than simulated by regional Arctic models,” (2) undermined “the conclusion from numerical models that changes in ice thickness occur on much longer timescales than changes in ice extent,” and (3) showed that “sea ice mass can change by up to 16% within one year,”

which finding “contrasts with the concept of a slowly dwindling ice pack, produced by greenhouse warming.” Laxon *et al.* concluded that “errors are present in current simulations of Arctic sea ice,” stating in their closing sentence that “until models properly reproduce the observed high-frequency, and thermodynamically driven, variability in sea ice thickness, simulations of both recent, and future, changes in Arctic ice cover will be open to question.”

Pfirman *et al.* (2004) analyzed Arctic sea-ice drift dynamics from 1979-1997, based on monthly fields of ice motion obtained from the International Arctic Buoy Program, using a Lagrangian perspective that “shows the complexities of ice drift response to variations in atmospheric conditions.” This analysis indicated that “large amounts of sea ice form over shallow Arctic shelves, are transported across the central basin and are exported primarily through Fram Strait and, to lesser degrees, the Barents Sea and Canadian Archipelago,” consistent with the observations of several other investigators. They also determined that within the central Arctic, ice travel times averaged 4.0 years from 1984-85 through 1988-89, but only 3.0 years from 1990-91 through 1996-97. This enhanced rate of export of old ice to Fram Strait from the Beaufort Gyre over the latter period decreased the fraction of thick-ridged ice within the central basin of the Arctic, and was deemed by Pfirman *et al.* to be responsible for some of the sea-ice thinning observed between the 1980s and 1990s. They also note that the rapid change in ice dynamics that occurred between 1988 and 1990 was “in response to a weakening of the Beaufort high pressure system and a strengthening of the European Arctic low (a shift from lower North Atlantic Oscillation/Arctic Oscillation to higher NAO/OA index) [Walsh *et al.*, 1996; Proshutinsky and Johnson, 1997; Kwok, 2000; Zhang *et al.*, 2000; Rigor *et al.*, 2002].”

Lastly, in a paper on landfast ice in Canada’s Hudson Bay, Gagnon and Gough (2006) cite nine different studies of sea-ice cover, duration, and thickness in the Northern Hemisphere, noting that the Hudson Bay region “has been omitted from those studies with the exception of Parkinson *et al.* (1999).” For 13 stations located on the shores of Hudson Bay (seven) and surrounding nearby lakes (six), Gagnon and Gough then analyzed long-term weekly measurements of ice thickness and associated weather conditions that began and ended, in the mean, in 1963 and 1993, respectively.

Results of the study revealed that a “statistically significant thickening of the ice cover over time was detected on the western side of Hudson Bay, while a slight thinning lacking statistical significance was observed on the eastern side.” This asymmetry, in their words, was “related to the variability of air temperature, snow depth, and the dates of ice freeze-up and break-up,” with “increasing maximum ice thickness at a number of stations” being “correlated to earlier freeze-up due to negative temperature trends in autumn,” and with high snow accumulation being associated with low ice thickness, “because the snow cover insulates the ice surface, reducing heat conduction and thereby ice growth.” Noting that their findings “are in contrast to the projections from general circulation models, and to the reduction in sea-ice extent and thickness observed in other regions of the Arctic,” Gagnon and Gough say “this contradiction must be addressed in regional climate change impact assessments.”

These observations suggest that much of the reported thinning of Arctic sea ice that occurred in the 1990s—if real, as per Winsor (2001)—was not the result of CO<sub>2</sub>-induced global warming. Rather, it was a natural consequence of changes in ice dynamics caused by an atmospheric regime shift, of which there have been several in decades past and will likely be several in decades to come, irrespective of past or future changes in the air’s CO<sub>2</sub> content. Whether any portion of possible past sea ice thinning was due to global warming is consequently still impossible to know, for temporal variability in Arctic sea-ice behavior is simply too great to allow such a small and slowly developing signal to be detected yet. In describing an earlier regime shift, for example, Dumas *et al.* (2003) noted that “a sharp decrease in ice thickness of roughly 0.6 m over 4 years (1970-74) [was] followed by an abrupt increase of roughly 0.8 m over 2 years (1974-76).”

It will likely be a number of years before anything definitive can be said about CO<sub>2</sub>-induced global warming on the basis of the thickness of Arctic sea-ice, other than that its impact on sea-ice thickness is too small to be detected at the present time.

Additional information on this topic, including reviews of newer publications as they become available, can be found at <http://www.co2science.org/subject/s/seaicearcticthick.php>.

### 4.3. Precipitation Trends

In spite of the fact that global circulation models (GCMs) have failed to accurately reproduce observed patterns and totals of precipitation (Lebel *et al.*, 2000), model predictions of imminent CO<sub>2</sub>-induced global warming often suggest that this phenomenon should lead to increases in rainfall amounts and intensities. Rawlins *et al.* (2006) state that “warming is predicted to enhance atmospheric moisture storage resulting in increased net precipitation,” citing as the basis for this statement the Arctic Climate Impact Assessment (2005). Peterson *et al.* (2002) have written that “both theoretical arguments and models suggest that net high-latitude precipitation increases in proportion to increases in mean hemispheric temperature,” citing the works of Manabe and Stouffer (1994) and Rahmstorf and Ganopolski (1999). Similarly, Kunkel (2003) says “several studies have argued that increasing greenhouse gas concentrations will result in an increase of heavy precipitation (Cubasch *et al.*, 2001; Yonetani and Gordon, 2001; Kharin and Zwiers, 2000; Zwiers and Kharin, 1998; Trenberth, 1998).”

Many scientists are examining historical precipitation records in an effort to determine how temperature changes of the past millennium have impacted these aspects of earth’s hydrologic cycle. In this section, we review what some of them have learned about rainfall across the globe, starting with Africa.

### 4.3.1. Global

Huntington (2006) notes there is “a theoretical expectation that climate warming will result in increases in evaporation and precipitation, leading to the hypothesis that one of the major consequences will be an intensification (or acceleration) of the water cycle (DelGenio *et al.*, 1991; Loaciga *et al.*, 1996; Trenberth, 1999; Held and Soden, 2000; Arnell *et al.*, 2001),” and in reviewing the scientific literature on precipitation, he concludes that on a globally averaged basis, “precipitation over land increased by about 2% over the period 1900-1998 (Dai *et al.*, 1997; Hulme *et al.*, 1998).”

New *et al.* (2001) also reviewed several global precipitation datasets, analyzing the information they contain to obtain a picture of precipitation patterns over the twentieth century. In their case, they determined that precipitation over the land area of the globe was mostly below the century-long mean over the first decade-and-a-half of the record, but that it increased from 1901 to the mid-1950s, whereupon it remained above the century-long mean until the 1970s, after which it declined by about the same amount to 1992 (taking it well below the century-long mean), whereupon it recovered and edged upward towards the century mean. Hence, for the entire century, there was indeed a slight increase in global land area precipitation; but since 1915 there was essentially no net change.

For the oceanic portion of the world between 30°N and 30°S, the record of which begins in 1920, there was an overall decrease of about 0.3 percent per decade. For the world as a whole, which is 70 percent covered by water, there may well have been a slight decrease in precipitation since about 1917 or 1918.

Concentrating on the last half of the twentieth century, Neng *et al.* (2002) analyzed data from 1948 to 2000 in a quest to determine the effect of warm ENSO years on annual precipitation over the land area of the globe. In doing so, they found some regions experienced more rainfall in warm ENSO years, while others experienced *less*. However, in the words of the researchers, “in warm event years, the land area where the annual rainfall was reduced is far greater than that where the annual rainfall was increased, and the reduction is more significant than the increase.” Consequently, whereas state-of-the-art climate models nearly always predict more precipitation in a warming world, the data of Neng *et al.*’s study depict just the opposite effect over the land area of the globe.

Most recently—and noting that “the Global Precipitation Climatology Project (GPCP) has produced merged satellite and in situ global precipitation estimates, with a record length now over 26 years beginning 1979 (Huffman *et al.*, 1997; Adler *et al.*, 2003)”—Smith *et al.* (2006) used empirical orthogonal function (EOF) analysis to study annual GPCP-derived precipitation variations over the period of record. In doing so, they found that the first three EOFs accounted for 52 percent of the observed variance in the precipitation data. Mode 1 was associated with mature ENSO conditions and correlated strongly with the Southern Oscillation Index, while Mode 2 was associated with the strong warm ENSO episodes of 1982/83 and 1997/98. Mode 3 was uncorrelated with ENSO but was associated with tropical trend-like changes that were correlated with interdecadal warming of tropical sea surface temperatures.

Globally, Smith *et al.* report that “the mode 3 variations average to near zero, so this mode does not represent any net change in the amount of precipitation over the analysis period.” Consequently, over the period 1979-2004, when the IPCC claims the world warmed at a rate and to a degree that was unprecedented over the past two millennia, Smith *et al.* found that most of the precipitation variations in their global dataset were “associated with ENSO and have no trend.” As for the variations that were *not* associated with ENSO and that *did* exhibit trends, they say that the trends were associated “with increased tropical precipitation over the Pacific and Indian Oceans associated with local warming of the sea.” However, they note that this increased precipitation was “balanced by decreased precipitation in other regions,” so that “the global average change [was] near zero.”

Over the earth as a whole, therefore, it would appear from Smith *et al.*’s study, as well as from the other studies described above, that one of the major theoretical expectations of the climate modeling community remains unfulfilled, even under the supposedly highly favorable thermal conditions of the last quarter-century.

## 4.3.2. Africa

Richard *et al.* (2001) analyzed summer (January-March) rainfall totals in southern Africa over the period 1900-1998, finding that interannual variability was higher for the periods 1900-1933 and 1970-1998, but lower for the period 1934-1969. The strongest rainfall anomalies (greater than two standard deviations) were observed at the beginning of the century. However, the authors conclude there were “no significant changes in the January-March rainfall totals,” nor any evidence of “abrupt shifts during the 20th century,” suggesting that rainfall trends in southern Africa do not appear to have been influenced by CO<sub>2</sub>-induced—or any other type of—global warming.

Nicholson and Yin (2001) report there have been “two starkly contrasting climatic episodes” in the equatorial region of East Africa since the late 1700s. The first, which began sometime prior to 1800, was characterized by “drought and desiccation.” Extremely low lake levels were the norm, as drought reached its extreme during the 1820s and 1830s. In the mid to latter part of the 1800s, however, the drought began to weaken and floods became “continually high,” but by the turn of the century lake levels began to fall as mild drought conditions returned. The drought did not last long, however, and the latter half of the twentieth century has seen an enhanced hydrologic cycle with a return of some lake levels to the high stands of the mid to late 1800s.

Verschuren *et al.* (2000) also examined hydrologic conditions in equatorial East Africa, but over a much longer time scale, i.e., a full thousand years. They report the region was significantly drier than it is today during the Medieval Warm Period from AD 1000 to 1270, while it was relatively wet during the Little Ice Age from AD 1270 to 1850. However, this latter period was interrupted by three episodes of prolonged dryness: 1390-1420, 1560-1625, and 1760-1840. These “episodes of persistent aridity,” according to the authors, were “more severe than any recorded drought of the twentieth century.”

The dry episode of the late eighteenth/early nineteenth centuries recorded in Eastern Africa has also been identified in Western Africa. In analyzing the climate of the past two centuries, Nicholson (2001) reports that the most significant climatic change that has occurred “has been a long-term reduction in rainfall in the semi-arid regions of West Africa,” which has been “on the order of 20 to 40% in parts of the Sahel.” There have been, she says, “three decades of protracted aridity,” and “nearly all of Africa has been affected ... particularly since the 1980s.” However, she goes on to note that “the rainfall conditions over Africa during the last 2 to 3 decades are not unprecedented,” and that “a similar dry episode prevailed during most of the first half of the 19th century.”

The importance of these findings is best summarized by Nicholson herself, when she states that “the 3 decades of dry conditions evidenced in the Sahel are not in themselves evidence of irreversible global change.” Why not? Because an even longer period of similar dry conditions occurred between 1800 and 1850, when the earth was still in the clutches of the Little Ice Age, even in Africa (Lee-Thorp *et al.*, 2001). There is no reason to think that the past two- to three-decade Sahelian drought is unusual or caused by the putative higher temperatures of that period.

### 4.3.3. Arctic

Curtis *et al.* (1998) examined a number of climatic variables at two first-order Arctic weather stations (Barrow and Barter Island, Alaska) that began in 1949, finding that both the frequency and mean intensity of precipitation at these two locations decreased over the period of record. Contemporaneously, they report that temperatures in the western Arctic increased, but that “the observed mean increase varies strongly from month-to-month making it difficult to explain the annual trend solely on the basis of an anthropogenic effect resulting from the increase in greenhouse gases in the atmosphere.” Be that as it may, the four researchers concluded that the theoretical model-based assumption that “increased temperature leads to high precipitation ... is not valid,” at least for the part of the western Arctic that was the focus of their analysis.

Lamoureux (2000) analyzed varved lake sediments obtained from Nicolay Lake, Cornwall Island, Nunavut, Canada, which were compared with rainfall events recorded at a nearby weather station over the period 1948-1978 and thereby used to reconstruct a rainfall history for the surrounding region over the 487-year period from 1500 to 1987. The results were suggestive of a small, but statistically insignificant, increase in rainfall over the course of the record. However, *heavy* rainfall was most frequent during the seventeenth and nineteenth centuries, which were the *coldest* periods of the past 400 years in the Canadian High Arctic, as well as the Arctic as a whole. In addition, Lamoureux found that “more frequent extremes and increased variance in yield occurred during the 17th and 19th centuries, likely due to increased occurrences of cool, wet synoptic types during the coldest periods of the Little Ice Age.” Here, in a part of the planet predicted to be most impacted by CO<sub>2</sub>-induced global warming—the Canadian High Arctic—a warming of the climate is demonstrated to *reduce* weather extremes related to precipitation.

Most recently, Rawlins *et al.* (2006) calculated trends in the spatially averaged water equivalent of annual rainfall and snowfall across the six largest Eurasian drainage basins that feed major rivers that

deliver water to the Arctic Ocean for the period 1936-1999. Their results indicated that annual rainfall across the total area of the six basins decreased consistently and significantly over the 64-year period. Annual snowfall, on the other hand, exhibited “a strongly significant increase,” but only “until the late 1950s.” Thereafter, it exhibited “a moderately significant decrease,” so that “no significant change [was] determined in Eurasian-basin snowfall over the entire 64-year period.” The researchers’ bottom-line finding, therefore, was that annual total precipitation (including both rainfall and snowfall) *decreased* over the period of their study; they note that this finding is “consistent with the reported (Berezovskaya *et al.*, 2004) decline in total precipitation.”

In light of the findings reviewed above, either (1) the theoretical arguments and model predictions that suggest that “high-latitude precipitation increases in proportion to increases in mean hemispheric temperature” are not incredibly robust, or (2) late twentieth century temperatures may not have been much warmer than those of the mid-1930s and 40s, or (3) both of the above. Any or all of these choices fail to provide support for a key claim of the IPCC.

Additional information on this topic, including reviews of newer publications as they become available, can be found at <http://www.co2science.org/subject/p/preciparctic.php>.

### 4.3.4. Asia

Kripalani *et al.* (2003) note that globally averaged temperatures are projected to rise under all scenarios of future energy use, according to the IPCC, leading to “increased variability and strength of the Asian monsoon.” To see if there is any sign of such a precipitation response in real-world measurements, they examined Indian monsoon rainfall using observational data for the period 1871-2001 obtained from 306 stations distributed across the country. They discovered “distinct alternate epochs of above and below normal rainfall,” which epochs “tend to last for about three decades.” In addition, they report “there is no clear evidence to suggest that the strength and variability of the Indian Monsoon Rainfall (IMR) nor the epochal changes are affected by the global warming.” They also report that “studies by several authors in India have shown that there is no statistically significant trend in IMR for the country as a whole.” They further report that “Singh (2001) investigated the long term trends in the frequency of cyclonic disturbances over the Bay of Bengal and the Arabian Sea using 100-year (1890-1999) data and found significant decreasing trends.” As a result, Kripalani *et al.* conclude that “there seem[s] to be no support for the intensification of the monsoon nor any support for the increased hydrological cycle as hypothesized by [the] greenhouse warming scenario in model simulations.” In addition, they say that “the analysis of observed data for the 131-year period (1871-2001) suggests no clear role of global warming in the variability of monsoon rainfall over India,” much as Kripalani and Kulkarni (2001) had concluded two years earlier.

Kanae *et al.* (2004) note that the number and intensity of heavy precipitation events are projected to increase in a warming world, according to the IPCC. They investigate this climate-model-derived hypothesis with digitalized hourly precipitation data recorded at the Tokyo Observatory of the Japan Meteorological Agency for the period 1890-1999. They report “many hourly heavy precipitation events (above 20 mm/hour) occurred in the 1990s compared with the 1970s and the 1980s,” and that against that backdrop, “the 1990s seems to be unprecedented.” However, they note that “hourly heavy precipitation around the 1940s is even stronger/more frequent than in the 1990s.” In fact, their plots of maximum hourly precipitation and the number of extreme hourly precipitation events rise fairly regularly from the 1890s to peak in the 1940s, after which declines set in

that bottom out in the 1970s and then reverse to rise to endpoints in the 1990s that are not yet as high as the peaks of the 1940s.

Taking a longer view of the subject, Pederson *et al.* (2001) used tree-ring chronologies from northeastern Mongolia to reconstruct annual precipitation and streamflow histories for the period 1651-1995. Analyses of both standard deviations and five-year intervals of extreme wet and dry periods of this record revealed that “variations over the recent period of instrumental data are not unusual relative to the prior record.” The authors do state, however, that the reconstructions “appear to show more frequent extended wet periods in more recent decades,” but they say this observation “does not demonstrate unequivocal evidence of an increase in precipitation as suggested by some climate models.” In addition, they report that spectral analysis of the data revealed significant periodicities around 12 and 20-24 years, suggesting, in their words, “possible evidence for solar influences in these reconstructions for northeastern Mongolia.”

Going back even further in time, Touchan *et al.* (2003) developed two reconstructions of spring (May-June) precipitation for southwestern Turkey from tree-ring width measurements, one of which extended from 1776 to 1998 and one from 1339 to 1998. These reconstructions, in their words, “show clear evidence of multi-year to decadal variations in spring precipitation,” but they report that “dry periods of 1-2 years were well distributed throughout the record” and that the same was true of wet periods of one to two years’ duration. With respect to more extreme events, the period that preceded the Industrial Revolution stood out. They say “all of the wettest 5-year periods occurred prior to 1756,” while the longest period of reconstructed spring drought was the four-year period 1476-79, and the single driest spring was 1746. Turkey’s greatest precipitation extremes, in other words, occurred prior to the Modern Warm Period, which is just the opposite of what the IPCC claims about extreme weather and its response to global warming.

Neff *et al.* (2001) looked much further back in time (from 9,600 to 6,100 years ago), using the relationship between a  $^{14}\text{C}$  tree-ring record and a  $\delta^{18}\text{O}$  proxy record of monsoon rainfall intensity as recorded in calcite  $\delta^{18}\text{O}$  data obtained from a stalagmite in northern Oman. They found the correlation between the two datasets was “extremely strong,” and a spectral analysis of the data revealed statistically significant periodicities centered on 779,

205, 134, and 87 years for the  $\delta^{18}\text{O}$  record and periodicities of 206, 148, 126, 89, 26, and 10.4 years for the  $^{14}\text{C}$  record. Consequently, because variations in  $^{14}\text{C}$  tree-ring records are generally attributed to variations in solar activity, and because of the  $^{14}\text{C}$  record’s strong correlation with the  $\delta^{18}\text{O}$  record, as well as the closely corresponding results of their spectral analyses, Neff *et al.* conclude there is “solid evidence” that both signals are responding to solar forcing.

In conclusion, evidence from Asia provides no support for the claim that precipitation in a warming world becomes more variable and intense. In fact, in some cases it tends to suggest just the opposite and provides support for the proposition that precipitation responds to cyclical variations in solar activity.

### 4.3.5. Europe

#### 4.3.5.1. Central

Koning and Franses (2005) conducted a detailed analysis of a century of daily precipitation data acquired at the de Bilt meteorological station in the Netherlands. Using what they call “robust nonparametric techniques,” they found the cumulative distribution function of annual maximum precipitation levels remained constant throughout the period 1906-2002, leading them to conclude that “precipitation levels are not getting higher.” They report that similar analyses they performed for the Netherlands’ five other meteorological stations “did not find qualitatively different results.”

Wilson *et al.* (2005) developed two versions of a March-August precipitation chronology based on living and historical tree-ring widths obtained from the Bavarian Forest of southeast Germany for the period 1456-2001. The first version, standardized with a fixed 80-year spline function (SPL), was designed to retain decadal and higher frequency variations, while the second version used regional curve standardization (RCS) to retain lower frequency variations. Their efforts revealed significant yearly and decadal variability in the SPL chronology, but there did not appear to be any trend toward either wetter or drier conditions over the 500-year period. The RCS reconstruction, on the other hand, better captured lower frequency variation, suggesting that March-August precipitation was substantially greater than the long-term average during the periods 1730-1810 and 1870-2000 and drier than the long-term average during the periods 1500-1560, 1610-1730, and 1810-1870. Once again, however, there was little evidence of a long-term trend.

Moving still further east in Central Europe, and covering a full millennium and a half, Solomina *et al.* (2005) derived the first tree-ring reconstruction of spring (April-July) precipitation for the Crimean peninsula, located on the northern coast of the Black Sea in the Ukraine, for the period 1620-2002, after which they utilized this chronology to correctly date and correlate with an earlier precipitation reconstruction derived from a sediment core taken in 1931 from nearby Saki Lake, thus ending up with a proxy precipitation record for the region that stretched all the way back to AD 500. In describing their findings, Solomina *et al.* say no trend in precipitation was evident over the period 1896-1988 in an instrumental record obtained at a location adjacent to

the tree-sampling site. Also, the reconstructed precipitation values from the tree-ring series revealed year-to-year and decadal variability, but remained “near-average with relatively few extreme values” from about the middle 1700s to the early 1800s and again since about 1920. The most notable anomaly of the 1500-year reconstruction was an “extremely wet” period that occurred between AD 1050 and 1250, which Solomina *et al.* describe as broadly coinciding with the Medieval Warm Epoch, when humidity was higher than during the instrumental era.

The results of these several analyses demonstrate that over the period of twentieth century global warming, enhanced precipitation was not observed in Central Europe.

#### 4.3.5.2. Mediterranean

Starting at the western extreme of the continent, Rodrigo *et al.* (2001) used a variety of documentary data to reconstruct seasonal rainfall in Andalusia (southern Spain) from 1501 to 1997, after which they developed a relationship between seasonal rainfall and the North Atlantic Oscillation (NAO) over the period 1851-1997, which they used to reconstruct a history of the NAO from 1501 to 1997. This work revealed that the NAO influence on climate is stronger in winter than in other seasons of the year in Andalusia, explaining 40 percent of the total variance in precipitation; Rodrigo *et al.* make a point of noting that “the recent positive temperature anomalies over

western Europe and recent dry winter conditions over southern Europe and the Mediterranean are strongly related to the persistent and exceptionally strong positive phase of the NAO index since the early 1980s,” as opposed to an intensification of global warming.

Also working in the Andalusia region of southern Spain, Sousa and Garcia-Murillo (2003) studied proxy indicators of climatic change in Doñana Natural Park over a period of several hundred years, comparing their results with those of other such studies conducted in neighboring regions. This work revealed that the Little Ice Age (LIA) was by no means uniform in their region of study, as it included both wetter and drier periods. Nevertheless, they cite Rodrigo *et al.* (2000) as indicating that “the LIA was characterized in the southern Iberian Peninsula by increased rainfall,” and they cite Grove (2001) as indicating that “climatic conditions inducing the LIA glacier advances [of Northern Europe] were also responsible for an increase in flooding frequency and sedimentation in Mediterranean Europe.” Sousa and Garcia-Murillo’s work complements these findings by indicating “an aridization of the climatic conditions after the last peak of the LIA (1830-1870),” which suggests that much of Europe became drier, not wetter, as the earth recovered from the global chill of the Little Ice Age.

Moving eastward into Italy, Crisci *et al.* (2002) analyzed rainfall data collected from 81 gauges spread throughout the Tuscany region for three different periods: (1) from the beginning of each record through 1994, (2) the shorter 1951-1994 period, and (3) the still-shorter 1970-1994 period. For each of these periods, trends were derived for extreme rainfall durations of 1, 3, 6, 12, and 24 hours. This work revealed that for the period 1970-1994, the majority of all stations exhibited no trends in extreme rainfall at any of the durations tested; four had positive trends at all durations and none had negative trends at all durations. For the longer 1951-1994 period, the majority of all stations exhibited no trends in extreme rainfall at any of the durations tested; none had positive trends at all durations and one had negative trends at all durations. For the still-longer complete period of record, the majority of all stations again continued to exhibit no trends in extreme rainfall at any of the durations tested; none had positive trends at all durations and one had negative trends at all durations, revealing no impact of twentieth century global warming one way or the other.

Working in northern Italy, Tomozeiu *et al.* (2002) performed a series of statistical tests to investigate the nature and potential causes of trends in winter (Dec-Feb) mean precipitation recorded at 40 stations over the period 1960-1995. This work revealed that nearly all of the stations experienced significant *decreases* in winter precipitation over the 35-year period of study; and by subjecting the data to a Pettitt test, they detected a significant downward shift at all stations around 1985. An Empirical Orthogonal Function analysis also was performed on the precipitation data, revealing a principal component that represented a common large-scale process that was likely responsible for the phenomenon. Strong correlation between this component and the North Atlantic Oscillation (NAO) suggested, in their words, that the changes in winter precipitation around 1985 “could be due to an intensification of the positive phase of the NAO.”

Working in the eastern Basilicata region of southern Italy, where they concentrated on characterizing trends in extreme rainfall events, as well as resultant flood events and landslide events, Clark and Rendell (2006) analyzed 50 years of rainfall records (1951-2000). This work indicated, in their words, that “the frequency of extreme rainfall events in this area declined by more than 50% in the 1990s compared to the 1950s.” In addition, they report that “impact frequency also decreased, with landslide-event frequency changing from 1.6/year in the period 1955-1962 to 0.3/year from 1985 to 2005, while flood frequency peaked at 1.0/year in the late 1970s before declining to less than 0.2/year from 1990.” They concluded that if the climate-driven changes they observed over the latter part of the twentieth century continue, “the landscape of southern Italy and the west-central Mediterranean will become increasingly stable,” or as they say in their concluding paragraph, “increased land-surface stability will be the result.”

Alexandrov *et al.* (2004) analyzed a number of twentieth century datasets from throughout Bulgaria, finding “a decreasing trend in annual and especially summer precipitation from the end of the 1970s” and “variations of annual precipitation in Bulgaria showed an overall decrease.” In addition, they report the region stretching from the Mediterranean into European Russia and the Ukraine “has experienced decreases in precipitation by as much as 20% in some areas.”

Using analyses of tree-ring data and their connection to large-scale atmospheric circulation,

Touchan *et al.* (2005) developed summer (May-August) precipitation reconstructions for several parts of the eastern Mediterranean region, including Turkey, Syria, Lebanon, Cyprus and Greece, which extend back in time as much as 600 years. Over this period, they found that May-August precipitation varied on multi-annual and decadal timescales, but that on the whole there were no long-term trends. The longest dry period occurred in the late sixteenth century (1591-1595), while there were two extreme wet periods: 1601-1605 and 1751-1755. In addition, both extreme wet and dry precipitation events were found to be more variable over the intervals 1520-1590, 1650-1670, and 1850-1930, indicating that as the globe experienced the supposedly unprecedented warming of the last decades of the twentieth century, May-August precipitation in the eastern Mediterranean region actually became *less* variable than it had been in the earlier part of the century.

In conclusion, these studies of precipitation characteristics of Mediterranean Europe do not find evidence of the rising or more variable precipitation predicted by global climate models.

### 4.3.5.3. Northern

Hanna *et al.* (2004) analyzed variations in several climatic variables in Iceland, including precipitation, over the past century in an effort to determine if there is "possible evidence of recent climatic changes" in that cold island nation. For the period 1923-2002, precipitation appeared to have increased slightly, although they questioned the veracity of the trend, citing several biases that may have corrupted the data base.

Linderholm and Molin (2005) analyzed two independent precipitation proxies, one derived from tree-ring data and one from a farmer's diary, to produce a 250-year record of summer (June-August) precipitation in east central Sweden. This work revealed there had been a high degree of variability in summer precipitation on inter-annual to decadal time scales throughout the record. Over the past century of supposedly unprecedented global warming, however, precipitation was found to have exhibited *less* variability than it did during the 150 years that preceded it.

In a study covering the longest time span of all, Linderholm and Chen (2005) derived a 500-year winter (September-April) precipitation chronology from tree-ring data obtained within the northern boreal forest zone of west-central Scandinavia. They found considerable variability, with the exception of a fairly stable period of above-average precipitation between AD 1730 and 1790. Additionally, above-average winter precipitation was found to have

occurred in 1520-1561, 1626-1647, 1670-1695, 1732-1851, 1872-1892, and 1959 to the present, with the highest values reported in the early to mid-1500s; below-average winter precipitation was observed during 1504-1520, 1562-1625, 1648-1669, 1696-1731, 1852-1871, and 1893-1958, with the lowest values occurring at the beginning of the record and the beginning of the seventeenth century.

These findings demonstrate that non-CO<sub>2</sub>-forced wetter and drier conditions than those of the present have occurred repeatedly within this region throughout the past five centuries. Similar extreme conditions may therefore be expected to naturally recur in the future.

Additional information on this topic, including reviews of newer publications as they become available, can be found at <http://www.co2science.org/subject/p/precipeuropenorth.php>.

### 4.3.6. United States

Molnar and Ramirez (2001) conducted a detailed watershed-based analysis of precipitation and streamflow trends for the period 1948-97 in the semiarid region of the Rio Puerco Basin of New Mexico. They found “at the annual timescale, a statistically significant increasing trend in precipitation in the basin was detected.” This trend was driven primarily by an increase in the number of rainy days in the moderate rainfall intensity range, with essentially no change being observed at the high-intensity end of the spectrum. In the case of streamflow, however, there was no trend at the annual timescale; but monthly totals increased in low-flow months and decreased in high-flow months. Generally

speaking, these trends are all positive for plant and animal life.

Cowles *et al.* (2002) analyzed snow water equivalent (SWE) data obtained from four different measuring systems—snow courses, snow telemetry, aerial markers and airborne gamma radiation—at more than 2,000 sites in the eleven westernmost states over the period 1910-1998. This work revealed that the long-term SWE trend of this entire region was negative, but with some significant within-region differences. In the northern Rocky Mountains and Cascades of the Pacific Northwest, for example, the trend was decidedly negative, with SWE decreasing at a rate of 0.1 to 0.2 inches per year. In the intermountain region and southern Rockies, however, there was no change in SWE with time. Cowles *et al.* additionally note that their results “reinforce more tenuous conclusions made by previous authors,” citing Changnon *et al.* (1993) and McCabe and Legates (1995), who studied snow course data from 1951-1985 and 1948-1987, respectively, at 275 and 311 sites. They too found a decreasing trend in SWE at most sites in the Pacific Northwest but more ambiguity in the southern Rockies.

These findings are particularly interesting in light of the fact that nearly all climate models suggest the planet’s hydrologic cycle will be enhanced in a warming world and that precipitation will increase. This prediction is especially applicable to the Pacific Northwest of the United States, where Kusnierczyk and Ettl (2002) report that climate models predict “increasingly warm and wet winters,” as do Leung and Wigmosta (1999). Over the period of Cowles *et al.*’s study, however, when there was well-documented worldwide warming, precipitation that fell and accumulated as snow in the western USA did not respond as predicted. In fact, over the Pacific Northwest, it did just the opposite.

Garbrecht and Rossel (2002) used state divisional monthly precipitation data from the US National Climatic Data Center to investigate the nature of precipitation throughout the US Great Plains from January 1895 through December 1999, finding that regions in the central and southern Great Plains experienced above-average precipitation over the last two decades of the twentieth century. This 20-year span of time was the longest and most intense wet period of the entire 105 years of record, and was primarily the result of a reduction in the number of dry years and an increase in the number of wet years. The number of very wet years, in the words of the authors, “did not increase as much and even showed a

decrease for many regions.” The northern and northwestern Great Plains also experienced a precipitation increase at the end of this 105-year interval, but it was primarily confined to the final decade of the twentieth century; and again, as Garbrecht and Rossel report, “fewer dry years over the last 10 years, as opposed to an increase in very wet years, were the leading cause of the observed wet conditions.”

Looking at the entire conterminous United States from 1895-1999, McCabe and Wolock (2002) evaluated and analyzed (1) values of annual precipitation minus annual potential evapotranspiration, (2) surplus water that eventually becomes streamflow, and (3) the water deficit that must be supplied by irrigation to grow vegetation at an optimum rate. Their work revealed that for the country as a whole, there was a statistically significant increase in the first two of these three parameters, while for the third there was no change. In describing the significance of these findings, McCabe and Wolock say “there is concern that increasing concentrations of atmospheric carbon dioxide and other radiatively active gases may cause global warming and ... adversely affect water resources.” The results of their analyses, however, reveal that over the past century of global warming, just the opposite has occurred, at least within the conterminous United States: moisture has become more available, while there has been no change in the amount of water required for optimum plant growth.

Also studying the conterminous United States were Kunkel *et al.* (2003), who analyzed a new data base of daily precipitation observations for the period 1895-2000. This effort indicated “heavy precipitation frequencies were relatively high during the late 19th/early 20th centuries, decreasing to a minimum in the 1920s and ‘30s, followed by a general increase into the 1990s.” More specifically, they note that “for 1-day duration events, frequencies during 1895-1905 are comparable in magnitude to frequencies in the 1980s and 1990s,” while “for 5- and 10-day duration events, frequencies during 1895-1905 are only slightly smaller than late 20th century values.”

In commenting on these findings, Kunkel *et al.* note that since enhanced greenhouse gas forcing of the climate system was very small in the early years of this record, the elevated extreme precipitation frequencies of that time “were most likely a consequence of naturally forced variability,” which further suggests, in their words, “the possibility that natural variability could be an important contributor

to the recent increases.” This is also the conclusion of Kunkel (2003), who in a review of this and other pertinent studies states that frequencies of extreme precipitation events in the United States in the late 1800s and early 1900s “were about as high as in the 1980s/1990s.” Consequently, he too concludes that “natural variability in the frequency of precipitation extremes is quite large on decadal time scales and cannot be discounted as the cause or one of the causes of the recent increases.”

Working with proxy data that extend much further back in time, Haston and Michaelsen (1997) developed a 400-year history of precipitation for 29 stations in coastal and near-interior California between San Francisco Bay and the U.S.-Mexican border using tree-ring chronologies. Their research revealed that although region-wide precipitation during the twentieth century was higher than what was experienced during the preceding three centuries, it was also “less variable compared to other periods in the past,” both of which characteristics are huge positive developments for both man and nature in this important region of California.

In a similar study, Gray *et al.* (2003) examined 15 tree ring-width series that had been used in previous reconstructions of drought for evidence of low-frequency variation in precipitation in five regional composite chronologies pertaining to the central and southern Rocky Mountains. They say “strong multidecadal phasing of moisture variation was present in all regions during the late 16th century megadrought,” and that “oscillatory modes in the 30-70 year domain persisted until the mid-19th century in two regions, and wet-dry cycles were apparently synchronous at some sites until the 1950s drought.” They also note that “severe drought conditions across consecutive seasons and years in the central and southern Rockies may ensue from coupling of the cold phase PDO [Pacific Decadal Oscillation] with the warm phase AMO [Atlantic Multidecadal Oscillation] (Cayan *et al.*, 1998; Barlow *et al.*, 2001; Enfield *et al.*, 2001),” something they envision happening in both the severe drought of the 1950s and the late sixteenth century megadrought.

Going back even further in time, Ni *et al.* (2002) developed a 1,000-year history of cool-season (November-April) precipitation for each climate division in Arizona and New Mexico from a network of 19 tree-ring chronologies. With respect to drought, they found “sustained dry periods comparable to the 1950s drought” occurred in “the late 1000s, the mid 1100s, 1570-97, 1664-70, the 1740s, the 1770s, and

the late 1800s.” They also note that the 1950s drought “was large in scale and severity, but it only lasted from approximately 1950 to 1956,” whereas the sixteenth century megadrought lasted more than four times longer. With respect to the opposite of drought, Ni *et al.* report that several wet periods comparable to the wet conditions seen in the early 1900s and after 1976 occurred in “1108-20, 1195-1204, 1330-45, the 1610s, and the early 1800s.” They also note that “the most persistent and extreme wet interval occurred in the 1330s.”

Regarding the causes of the different precipitation extremes, Ni *et al.* say that “the 1950s drought corresponds to La Niña/-PDO [Pacific Decadal Oscillation] and the opposite polarity [+PDO] corresponds to the post-1976 wet period,” which leads them to hypothesize that “the prominent shifts seen in the 1,000-year reconstructions in Arizona and New Mexico may also be linked to strong shifts of the coupled ENSO-PDO system.” For the particular part of the world covered by their study, therefore, there appears to be nothing unusual about the extremes of both wetness and dryness experienced during the twentieth century.

In another equally long study, but on the opposite side of the country, Cronin *et al.* (2000) measured and analyzed salinity gradients across sediment cores extracted from Chesapeake Bay, the largest estuary in the United States, in an effort to examine precipitation variability in the surrounding watershed over the past 1,000 years. They found a high degree of decadal and multidecadal variability between wet and dry conditions throughout the record, where regional precipitation totals fluctuated between 25 percent and 30 percent, often in “extremely rapid [shifts] occurring over about a decade.” Precipitation over the last two centuries, however, was on average greater than what it was during the previous eight centuries, with the exception of the Medieval Warm Period (AD 1250-1350), when the climate was judged to have been “extremely wet.” In addition, it was determined that this region, like the southwestern United States, had experienced several “mega-droughts,” lasting from 60-70 years in length, some of which Cronin *et al.* describe as being “more severe than twentieth century droughts.”

Cronin *et al.*'s work, like the study of Ni *et al.*, reveals nothing unusual about precipitation in the U.S. during the twentieth century, the latter two decades of which the IPCC claims comprise the warmest such period of the past two millennia. Cronin *et al.*'s work indicates, for example, that both wetter

and drier intervals occurred repeatedly in the past in the Chesapeake Bay watershed. There is reason to believe such intervals will occur in the future ... with or without any further global warming.

#### 4.3.7. Canada and Mexico

Kunkel (2003) reported that “several studies have argued that increasing greenhouse gas concentrations will result in an increase of heavy precipitation (Cubasch *et al.*, 2001; Yonetani and Gordon, 2001; Kharin and Zwiers, 2000; Zwiers and Kharin, 1998; Trenberth, 1998).” Consequently, Kunkel looked for such a signal in precipitation data from Canada that covered much of the past century. His search, however, was in vain, as the data indicated, in his words, that “there has been no discernible trend in the frequency of the most extreme events in Canada.”

Zhang *et al.* (2001) also studied the temporal characteristics of heavy precipitation events across Canada, using what they describe as “the most homogeneous long-term dataset currently available for Canadian daily precipitation.” Their efforts revealed that decadal-scale variability was a dominant feature of both the frequency and intensity of the

annual number of extreme precipitation events, but they found “no evidence of any significant long-term changes.” When the annual data were divided into seasonal data, however, an increasing trend in the number of extreme autumn snowfall events was noted; and an investigation into precipitation totals (extreme plus non-extreme events) revealed a slightly increasing trend that was attributed to increases in the number of non-heavy precipitation events. Zhang *et al.*'s overall conclusion was that “increases in the concentration of atmospheric greenhouse gases during the twentieth century have not been associated with a generalized increase in extreme precipitation over Canada.”

Taking a longer view of the subject was Lamoureux (2000), who analyzed varved lake sediments obtained from Nicolay Lake, Cornwall Island, Nunavut, Canada, and compared the results with rainfall events recorded at a nearby weather station over the period 1948-1978, which comparison enabled the reconstruction of a rainfall history for the location over the 487-year period from 1500 to 1987. This history was suggestive of a small, but statistically insignificant, increase in total rainfall over the course of the record. Heavy rainfall was most frequent during the seventeenth and nineteenth centuries, which were the coldest periods of the past 400 years in the Canadian High Arctic, as well as the Arctic as a whole. In addition, Lamoureux says that “more frequent extremes and increased variance in yield occurred during the 17th and 19th centuries, likely due to increased occurrences of cool, wet synoptic types during the coldest periods of the Little Ice Age.”

This study, like the others discussed above, contradicts the IPCC's claim that extreme precipitation events become more frequent and more severe with increasing temperature. Here in the Canadian High Arctic, in a part of the planet predicted to be most impacted by CO<sub>2</sub>-induced global warming, rising temperatures have been shown to *reduce* precipitation extremes, even in the face of a slight increase in total precipitation.

South of the United States, Diaz *et al.* (2002) created a 346-year history of winter-spring (November-April) precipitation for the Mexican state of Chihuahua, based on earlywood width chronologies of more than 300 Douglas fir trees growing at four locations along the western and southern borders of Chihuahua and at two locations in the United States just above Chihuahua's northeast border. This exercise revealed, in their words, that

“three of the 5 worst winter-spring drought years in the past three-and-a-half centuries are estimated to have occurred during the 20th century.” Although this fact makes it sound like the twentieth century was highly anomalous in this regard, it was not. Two of those three worst drought years occurred during a decadal period of average to slightly above-average precipitation, so the three years were not representative of long-term droughty conditions.

Diaz *et al.* additionally report that “the longest drought indicated by the smoothed reconstruction lasted 17 years (1948-1964),” which again makes the twentieth century look unusual in this regard. However, for several of the years of that interval, precipitation values were only slightly below normal; and there were four very similar dry periods interspersed throughout the preceding two-and-a-half centuries: one in the late 1850s and early 1860s, one in the late 1790s and early 1800s, one in the late 1720s and early 1730s, and one in the late 1660s and early 1670s.

With respect to the twentieth century alone, there was a long period of high winter-spring precipitation that stretched from 1905 to 1932; and following the major drought of the 1950s, precipitation remained at, or just slightly above, normal for the remainder of the record. Finally, with respect to the entire 346 years, there was no long-term trend in the data, nor was there any evidence of a significant departure from that trend over the course of the twentieth century. Consequently, Chihuahua’s precipitation history did not differ in any substantial way during the twentieth century from what it was over the prior quarter of a millennium, suggesting that neither twentieth century anthropogenic CO<sub>2</sub> emissions nor 20th-century warming—whether natural or human-induced—significantly impacted precipitation in that part of North America.

## 4.4. Streamflow

Model projections suggest that CO<sub>2</sub>-induced global warming will adversely impact earth’s water resources by inducing large changes in global streamflow characteristics. As a result, many scientists are examining proxy streamflow records in an effort to determine how temperature changes of the twentieth century may or may not have impacted this aspect of the planet’s hydrologic cycle. This is related to forecasts of droughts, floods, and precipitation variability, issues that are addressed in greater detail in Chapter 6.

A recent global study of this issue is Milliman *et al.* (2008), who computed temporal discharge trends for 137 rivers over the last half of the twentieth century that provide what they call a “reasonable

global representation,” as their combined drainage basins represent about 55 percent of the land area draining into the global ocean. In the words of the five researchers, “between 1951 and 2000 cumulative discharge for the 137 rivers remained statistically unchanged.” In addition, they report that “global on-land precipitation between 1951 and 2000 remained statistically unchanged.” Then, in a simple and straightforward conclusion, Milliman *et al.* write that “neither discharge nor precipitation changed significantly over the last half of the 20th century, offering little support to a global intensification of the hydrological cycle,” such as is generally claimed to be a consequence of CO<sub>2</sub>-induced global warming.

In the rest of this section we review studies for Eurasia and North America, seeking to discover if there have been any twentieth century changes in streamflow regimes that might reasonably have been caused by twentieth century changes in air temperature and atmospheric CO<sub>2</sub> concentration. Additional information on this topic, including reviews on streamflow not discussed here, can be found at [http://www.co2science.org/subject/s/subject\\_s.php](http://www.co2science.org/subject/s/subject_s.php) under the heading Streamflow.

### 4.4.1. Eurasia

Pederson *et al.* (2001) used tree-ring chronologies from northeastern Mongolia to develop annual precipitation and streamflow histories for the period 1651-1995. This work revealed, with respect to both standard deviations and five-year intervals of extreme wet and dry periods, that “variations over the recent period of instrumental data are not unusual relative to the prior record,” although they say that the reconstructions “appear to show more frequent extended wet periods in more recent decades.” Nevertheless, they state that this observation “does not demonstrate unequivocal evidence of an increase in precipitation as suggested by some climate models.” Spectral analysis of the data also revealed significant periodicities of 12 and 20-24 years, suggesting, in the researchers’ words, “possible

evidence for solar influences in these reconstructions for northeastern Mongolia.”

Working in another part of the same region, Davi *et al.* (2006) report that “absolutely dated tree-ring-width chronologies from five sampling sites in west-central Mongolia were used in precipitation models and an individual model was made using the longest of the five tree-ring records (1340-2002),” which effort led to a reconstruction of streamflow that extended from 1637 to 1997. In analyzing these data, the four researchers discovered there was “much wider variation in the long-term tree-ring record than in the limited record of measured precipitation,” which for the region they studied covered the period from 1937 to 2003. In addition, they report their streamflow history indicates that “the wettest 5-year period was 1764-68 and the driest period was 1854-58,” while “the most extended wet period [was] 1794-1802 and ... extended dry period [was] 1778-83.” For this part of Mongolia, therefore—which the researchers say “is representative of the central Asian region”—there is no evidence that the warming of the twentieth century has led to increased variability in precipitation and streamflow.

Pekarova *et al.* (2003) analyzed the annual discharge rates of selected large rivers of the world for recurring cycles of wet and dry periods. For those rivers with sufficiently long and accurate data series, they also derived long-term discharge rate trends. This latter analysis did not show “any significant trend change in long-term discharge series (1810-1990) in representative European rivers,” including the Goeta, Rhine, Neman, Loire, Wesaer, Danube, Elbe, Oder, Vistule, Rhone, and Po. These latter observations are most interesting, for they indicate that even over the 180-year time period that saw the demise of the Little Ice Age and the ushering in of the Current Warm Period, there were no long-term trends in the discharge rates of the major rivers of Europe.

In another study, Hisdal *et al.* (2001) performed a series of statistical analyses on more than 600 daily streamflow records from the European Water Archive to examine trends in the severity, duration, and frequency of drought over the following four time periods: 1962-1990, 1962-1995, 1930-1995, and 1911-1995. This protocol indicated that “despite several reports on recent droughts in Europe, there is no clear indication that streamflow drought conditions in Europe have generally become more severe or frequent in the time periods studied.” To the contrary, they report discovering that the number of trends pointing towards decreasing streamflow deficits or

fewer drought events exceeded the number of trends pointing towards increasing streamflow deficits or more drought events.

Looking back towards Asia, Cluis and Laberge (2001) utilized streamflow records stored in the databank of the Global Runoff Data Center at the Federal Institute of Hydrology in Koblenz (Germany) to see if there were any recent changes in river runoff of the type predicted by IPCC scenarios of global warming, such as increased streamflow and increases in streamflow variability that would lead to more floods and droughts. Spatially, their study encompassed 78 rivers said to be “geographically distributed throughout the whole Asia-Pacific region,” while temporally the mean start and end dates of the river flow records were  $1936 \pm 5$  years and  $1988 \pm 1$  year.

As a result of their analyses, the two researchers determined that mean river discharges were unchanged in 67 percent of the cases investigated; where trends did exist 69 percent of them were downward. Likewise, maximum river discharges were unchanged in 77 percent of the cases investigated; where trends did exist 72 percent of them were downward. Minimum river discharges, on the other hand, were unchanged in 53 percent of the cases investigated; where trends did exist, 62 percent of them were upward. All six metrics related to streamflow trends exhibit changes contrary to IPCC-promoted scenarios of climate change.

In another study, MacDonald *et al.* (2007) used “tree ring records from a network of sites extending across northern Eurasia to provide reconstructions [extending back to AD 1800] of annual discharge for the October to September water year for the major Eurasian rivers entering the Arctic Ocean (S. Dvina, Pechora, Ob’, Yenisey, Lena, and Kolyma).” Results indicated that annual discharges of the mid to late twentieth century previously reported are not significantly greater than discharges experienced over the preceding 200 years, and “are thus still within the range of long-term natural variability.” In addition, they say their “longer-term discharge records do not indicate a consistent positive significant correlation between discharge [and] Siberian temperature.” They report there are actually weak *negative* correlations between discharge and temperature on some of the rivers over the period of their study.

In a contemporaneous study, Smith *et al.* (2007) present “a first analysis of a new dataset of daily discharge records from 138 small to medium-sized unregulated rivers in northern Eurasia,” focusing on

providing “a first continental-scale assessment of low-flow trends since the 1930s.” Results indicate that “a clear result of this analysis is that, on balance, the monthly minimum values of daily discharge, or ‘low flows,’ have risen in northern Eurasia during the 20th century,” adding that “from 12 unusually complete records from 1935-2002 we see that the minimum flow increases are greatest since ~1985.”

Smith *et al.* reveals that over much of northern Eurasia, predictions of more drought seem rather off the mark, as daily low flows of the majority of northern Eurasian rivers have been *increasing*. Moreover, in the words of the five researchers, they have been increasing “in summer as well as winter and in non-permafrost as well as permafrost terrain,” with the greatest increases occurring “since ~1985.”

Writing about the Qinghai-Tibet Plateau, where they conducted their streamflow study, Cao *et al.* (2006) note that “both theoretical arguments and models suggest that net high-latitude precipitation increases in proportion to increases in mean hemispheric temperature (Houghton *et al.*, 2001; Rahmstorf and Ganopolski, 1999; Bruce *et al.*, 2002),” stating that in these scenarios “under global warming, mainly in the middle and west regions of northwest China, precipitation increases significantly,” so that “some researchers [have] even advanced the issue of [a] climatic shift from warm-dry to warm-wet in northwest China (Shi, 2003),” with the ultimate expectation that total river discharge within the region would significantly increase in response to global warming.

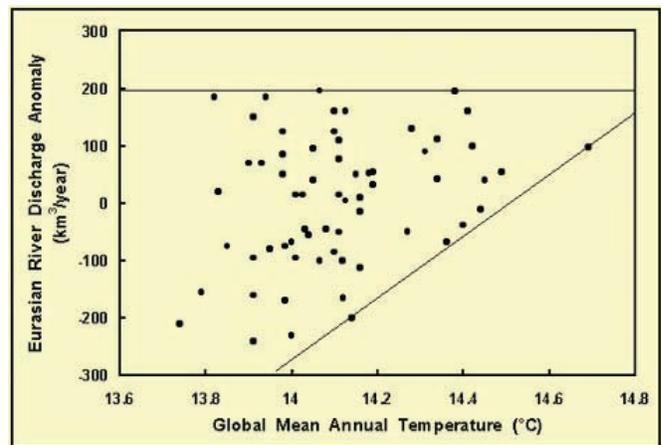

As a test of these climate-model predictions, Cao *et al.* analyzed annual discharge data for five large rivers of the Qinghai-Tibet Plateau over the period 1956-2000, using the Mann-Kendall nonparametric trend test; and in doing so, they found that over the period of their study, “river discharges in the Qinghai-Tibet Plateau, in general, have no obvious change with the increase of the Northern Hemisphere surface air temperature.” Because they could detect “no increase in the stream discharge in the Qinghai-Tibet Plateau with global warming,” Cao *et al.* concluded that their real-world findings are not “in accordance with the anticipated ideas” that led them to conduct their study. Indeed, the disconnect between streamflow and global warming in this and many other studies argues strongly against the claimed consequences of global warming, the claimed magnitude of global warming, or both of these standard claims.

Worried about the possibility that enhanced freshwater delivery to the Arctic ocean by increased river flow could shut down the ocean's thermohaline circulation, Peterson *et al.* (2002) plotted annual values of the combined discharge of the six largest Eurasian Arctic rivers (Yenisey, Lena, Ob', Pechora, Kolyma, and Severnaya Dvina)—which drain about two-thirds of the Eurasian Arctic landmass—against the globe's mean annual surface air temperature (SAT), after which they ran a simple linear regression through the data and determined that the combined discharge of the six rivers seems to rise by about 212 km<sup>3</sup>/year in response to a 1°C increase in mean global air temperature. Then, they calculated that for the high-end global warming predicted by the Intergovernmental Panel on Climate Change (IPCC) to occur by AD 2100, i.e., a temperature increase of 5.8°C, the warming-induced increase in freshwater discharge from the six rivers could rise by as much as 1260 km<sup>3</sup>/year (we calculate 5.8°C x 212 km<sup>3</sup>/year/°C = 1230 km<sup>3</sup>/year), which represents a 70 percent increase over the mean discharge rate of the past several years.

The link between this conclusion and the postulated shutting down of the thermohaline circulation of the world's oceans resides in the hypothesis that the delivery of such a large addition of freshwater to the North Atlantic Ocean may slow—or even stop—that location's production of new deep water, which constitutes one of the driving forces of the great oceanic “conveyor belt.” Although still discussed, this scenario is currently not as highly regarded as it was when Peterson *et al.* conducted their research, for a number of reasons. One that we have highlighted is the difficulty of accepting the tremendous extrapolation Peterson *et al.* make in extending their Arctic freshwater discharge vs. SAT relationship to the great length that is implied by the IPCC's predicted high-end warming of 5.8°C over the remainder of the current century. Consider, for example, that “over the period of the discharge record, global SAT increased by 0.4°C,” according to Peterson *et al.* It is implausible to extend the relationship they derived across that small temperature range fully 14-and-a-half times further, to 5.8°C.

Consider also the Eurasian river discharge anomaly vs. global SAT plot of Peterson *et al.* (their Figure 4), which we have replotted in Figure 4.4.1. Enclosing their data with simple straight-line upper and lower bounds, it can be seen that the upper bound of the data does not change over the entire range of

global SAT variability, suggesting the very real possibility that the upper bound corresponds to a maximum Eurasian river discharge rate that cannot be exceeded in the real world under its current geographic and climatic configuration. The lower bound, on the other hand, rises so rapidly with increasing global SAT that the two bounds intersect less than two-tenths of a degree above the warmest of Peterson *et al.*'s 63 data points, suggesting that 0.2°C beyond the temperature of their warmest data point may be all the further any relationship derived from their data may validly be extrapolated.

**Figure 4.4.1.** Annual Eurasian Arctic river discharge anomaly vs. annual global surface air temperature (SAT) over the period 1936 to 1999. Adapted from Peterson *et al.* (2002).

Clearly, real-world data do not support the hydrologic negativism the IPCC associates with both real-world and simulated global warming in Eurasia.

#### 4.4.2. North America

Brown *et al.* (1999) studied siliciclastic sediment grain size, planktonic foraminiferal and pteropod relative frequencies, and the carbon and oxygen isotopic compositions of two species of planktonic foraminifera in cored sequences of hemipelagic muds deposited over the past 5,300 years in the northern Gulf of Mexico for evidence of variations in Mississippi River outflow characteristics over this time period. The results of their research indicated the occurrence of large megafloods—which they describe as having been “almost certainly larger than historical floods in the Mississippi watershed”—at 4,700, 3,500, 3,000, 2,500, 2,000, 1,200, and 300 years before present. These fluvial events, in their estimation, were likely “episodes of multidecadal duration,” spawned by an export of extremely moist gulf air to midcontinental North America driven by naturally occurring same-time-scale oscillations in Gulf of Mexico ocean currents. These particular extreme events were in no way related to variations in atmospheric CO<sub>2</sub> concentration, as they occurred over a period of near-constancy in this atmospheric property.

Hidalgo *et al.* (2000) used a form of principal components analysis to reconstruct a history of streamflow in the Upper Colorado River Basin from information obtained from tree-ring data, after which they compared their results with the streamflow reconstruction of Stockton and Jacoby (1976). In doing so, they found their results were similar to those of the earlier 1976 study, but that their newer reconstruction responded with better fidelity to periods of below-average streamflow or regional drought, making it easier for them to see there had been “a near-centennial return period of extreme drought events in this region,” going all the way back to the early 1500s. Hidalgo *et al.*'s work provided additional evidence for the existence of past droughts that surpassed the worst of the twentieth century.

Woodhouse *et al.* (2006) generated updated proxy reconstructions of water-year streamflow for four key streamflow gauges in the Upper Colorado River Basin (Green River at Green River, Utah; Colorado near Cisco, Utah; San Juan near Bluff, Utah; and Colorado at Lees Ferry, Arizona), “using an expanded tree-ring network and longer calibration records than in previous efforts.” By these means they determined that the major drought of 2000-2004, “as measured by 5-year running means of water-year total flow at Lees Ferry ... is not without precedence in the tree ring

record,” and that “average reconstructed annual flow for the period 1844-1848 was lower.” They also report that “two additional periods, in the early 1500s and early 1600s, have a 25% or greater chance of being as dry as 1999-2004,” and that six other periods “have a 10% or greater chance of being drier.” Their work revealed that “longer duration droughts have occurred in the past,” and “the Lees Ferry reconstruction contains one sequence each of six, eight, and eleven consecutive years with flows below the 1906-1995 average.”

“Overall,” in the words of the three researchers, “these analyses demonstrate that severe, sustained droughts are a defining feature of Upper Colorado River hydroclimate.” They conclude that “droughts more severe than any 20th to 21st century event [have] occurred in the past.” This finding is just the opposite of what the IPCC would have us believe.

Woodhouse and Lukas (2006) developed “a network of 14 annual streamflow reconstructions, 300-600 years long, for gages in the Upper Colorado and South Platte River basins in Colorado generated from new and existing tree-ring chronologies.” The results indicated that “the 20th century gage record does not fully represent the range of streamflow characteristics seen in the prior two to five centuries.” The authors note that “paleoclimatic studies indicate that the natural variability in 20th century [streamflow] gage records is likely only a subset of the full range of natural variability,” while citing in support of this statement the studies of Stockton and Jacoby (1976), Smith and Stockton (1981), Meko *et al.* (2001), and Woodhouse (2001). Of greatest significance in this regard was probably the fact that “multi-year drought events more severe than the 1950s drought have occurred,” and that “the greatest frequency of extreme low flow events occurred in the 19th century,” with a “clustering of extreme event years in the 1840s and 1850s.”

Working in an adjacent region of the western United States, Carson and Munroe (2005) used tree-ring data collected by Stockton and Jacoby (1976) from the Uinta Mountains of Utah to reconstruct mean annual discharge in the Ashley Creek watershed for the period 1637 to 1970. Significant persistent departures from the long-term mean were noted throughout the 334-year record of reconstructed streamflow. The periods 1637-1691 and 1741-1897 experienced reduced numbers of extremely large flows and increased numbers of extremely small flows, indicative of persistent drought or near-drought conditions. By contrast, there was an overall

abundance of extremely large flows and relatively few extremely small flows during the periods 1692-1740 and 1898-1945, indicative of wetter conditions.

Lins and Slack (1999) analyzed secular trends in streamflow for 395 climate-sensitive stream gage stations (including data from more than 1,500 individual gages) located throughout the conterminous United States, some of which stations possessed datasets stretching all the way back to 1914. They found many more up-trends than down-trends in streamflow nationally, with slight decreases “only in parts of the Pacific Northwest and the Southeast.” These and other of their findings, as they describe them, indicate “the conterminous U.S. is getting wetter, but less extreme,” and it is difficult to conceive of a better result. As the world has warmed over the past century, the United States has gotten wetter in the mean, but less variable at the extremes, where floods and droughts occur.

Also studying the conterminous United States were McCabe and Wolock (2002), who for the period 1895-1999 evaluated (1) precipitation minus annual potential evapotranspiration, (2) the surplus water that eventually becomes streamflow, and (3) the water deficit that must be supplied by irrigation to grow vegetation at an optimum rate. This exercise revealed there was a statistically significant increase in the first two of these parameters, while for the third there was no change, indicative of the fact that water has actually become more available within the conterminous United States, and there has been no increase in the amount of water required for optimum plant growth.

Knox (2001) studied how conversion of the U.S. Upper Mississippi River Valley from prairie and forest to crop and pasture land by settlers in the early 1800s influenced subsequent watershed runoff and soil erosion rates. Initially, the conversion of the region’s natural landscape to primarily agricultural use boosted surface erosion rates to values three to eight times greater than those characteristic of pre-settlement times. In addition, the land-use conversion increased peak discharges from high-frequency floods by 200 to 400 percent. Since the late 1930s, however, surface runoff has been decreasing. The decrease “is not associated with climatic causes,” according to Knox, who reports that “an analysis of temporal variation in storm magnitudes for the same period showed no statistically significant trend.”

Other notable findings of Knox’s study include the observation that since the 1940s and early 1950s, the magnitudes of the largest daily flows have been

decreasing at the same time that the magnitude of the average daily baseflow has been increasing, indicating a trend toward fewer flood and drought conditions. Once again, we have a situation where global warming has coincided with a streamflow trend that is leading to the best of all possible worlds: one of greater water availability, but with fewer and smaller floods and droughts.

Molnar and Ramirez (2001) conducted a detailed watershed-based analysis of precipitation and streamflow trends for the period 1948-97 in a semiarid region of the southwestern United States, the Rio Puerco Basin of New Mexico. "At the annual timescale," as they describe it, "a statistically significant increasing trend in precipitation in the basin was detected." This trend was driven primarily by an increase in the number of rainy days in the moderate rainfall intensity range, with essentially no change at the high-intensity end of the spectrum. In the case of streamflow, there was no trend at the annual timescale; monthly totals increased in low-flow months and decreased in high-flow months.

Shifting to a study of snowmelt runoff (SMR), McCabe and Clark (2005) note that most prior studies of this phenomenon in the western United States have depended on trend analyses to identify changes in timing, but they indicate that "trend analyses are unable to determine if a trend is gradual or a step change." This fact is crucial, they say, because when "changes in SMR timing have been identified by linear trends, there is a tendency to attribute these changes to global warming because of large correlations between linear trends in SMR timing and the increasing trend in global temperature." Therefore, using daily streamflow data for 84 stations in the western U.S., each with complete water-year information for the period 1950-2003, they conducted a number of analyses that enabled them to determine each station's mean streamflow trend over the past half century, as well as any stepwise changes that may have occurred in each data series.

As others before them had previously learned, the two researchers found that "the timing of SMR for many rivers in the western United States has shifted to earlier in the snowmelt season." However, they discovered that "the shift to earlier SMR has not been a gradual trend, but appears to have occurred as a step change during the mid-1980s," which shift was "related to a regional step increase in April-July temperatures during the mid-1980s." As a result, and after discussing various other possible reasons for what they had discovered, McCabe and Clark

concluded that "the observed change in the timing of SMR in the western United States is a regional response to natural climatic variability and may not be related to global trends in temperature."

Over in Minnesota, Novotny and Stefan (2006) analyzed streamflow records (extending up to the year 2002, with lengths ranging from 53 to 101 years) obtained from 36 gauging stations in five major river basins of the state, deriving histories of seven annual streamflow statistics: "mean annual flow, 7-day low flow in winter, 7-day low flow in summer, peak flow due to snow melt runoff, peak flow due to rainfall, as well as high and extreme flow days (number of days with flow rates greater than the mean plus one or two standard deviations, respectively)." In doing so, they found significant trends in each of the seven streamflow statistics throughout the state, but that in most cases "the trends are not monotonic but periodic," and they determined, as might have been expected, that "the mean annual stream flow changes are well correlated with total annual precipitation changes."

Most significantly, they found that peak flood flows due to snowmelt runoff "are not changing at a significant rate throughout the state," but that seven-day low flows or base flows are "increasing in the Red River of the North, Minnesota River and Mississippi River basins during both the summer and winter"; that the "low flows are changing at a significant rate in a significant number of stations and at the highest rates in the past 20 years"; and that "this finding matches results of other studies which found low flows increasing in the upper Midwest region including Minnesota (Lins and Slack, 1999; Douglas *et al.*, 2000)."

The two researchers write that "an increase in mean annual streamflow in Minnesota would be welcome," as "it could provide more aquatic habitat, better water quality, and more recreational opportunities, among other benefits." Likewise, they say that "water quality and aquatic ecosystems should benefit from increases in low flows in both the summer and winter, since water quality stresses are usually largest during low flow periods." In addition, they say "other good news is that spring floods (from snowmelt), the largest floods in Minnesota, have not been increasing significantly."

Rood *et al.* (2005) performed an empirical analysis of streamflow trends for rivers fed by relatively pristine watersheds in the central Rocky Mountain Region of North America that extends from Wyoming in the United States through British

Columbia in Canada. They applied both parametric and non-parametric statistical analyses to assess nearly a century of annual discharge (ending about 2002) along 31 river reaches that drain this part of North America. These analyses revealed that river flows in this region *declined* over the past century by an average of 0.22 percent per year, with four of them exhibiting recent decline rates exceeding 0.5 percent per year. This finding, in the words of Rood *et al.*, “contrasts with the many current climate change predictions that [this] region will become warmer and wetter in the near-future.”

Working entirely in Canada, where about three-quarters of the country is drained by rivers that discharge their water into the Arctic and North Atlantic Oceans, Déry and Wood (2005) analyzed hydrometric data from 64 northern Canadian rivers that drain more than half of the country’s landmass for the period 1964-2003. Then, after assessing both variability and trends, they explored the influence of large-scale teleconnections as possible drivers of the trends they detected. This work indicated there was a statistically significant mean decline of approximately 10 percent in the discharge rates of the 64 rivers over the four decades of their study, which was nearly identical to the decline in precipitation falling over northern Canada between 1964 and 2000. These facts led the two scientists to conclude that the changes in river discharge they observed were driven “primarily by precipitation rather than evapotranspiration.” As for the *cause* of the precipitation/river discharge decline, statistically significant links were found between the decline and the Arctic Oscillation, the El Niño/Southern Oscillation, and the Pacific Decadal Oscillation. Consequently, the results of this study indicate there is nothing unusual about the four-decade-long trends in northern Canada river discharge rates, which means there is nothing in these trends that would suggest a global warming impact.

Also in Canada, Campbell (2002) analyzed the grain sizes of sediment cores obtained from Pine Lake, Alberta, to provide a non-vegetation-based high-resolution record of climate variability for this part of North America over the past 4,000 years. This research effort revealed the existence of periods of both increasing and decreasing grain size (a proxy for moisture availability) throughout the 4,000-year record at decadal, centennial, and millennial time scales. The most predominant departures included several-centuries-long epochs that corresponded to the Little Ice Age (about AD 1500-1900), the Medieval Warm Period (about AD 700-1300), the

Dark Ages Cold Period (about BC 100 to AD 700), and the Roman Warm Period (about BC 900-100). In addition, a standardized median grain-size history revealed that the highest rates of stream discharge during the past 4,000 years occurred during the Little Ice Age approximately 300-350 years ago. During this time, grain sizes were about 2.5 standard deviations above the 4,000-year mean. In contrast, the lowest rates of streamflow were observed around AD 1100, when median grain sizes were nearly 2 standard deviations below the 4,000-year mean, while most recently, grain size over the past 150 years has generally remained above average.

The Pine Lake sediment record convincingly demonstrates the reality of the non-CO<sub>2</sub>-induced millennial-scale climatic oscillation that has alternately brought several-century-long periods of dryness and wetness to the southern Alberta region of North America during concomitant periods of relative global warmth and coolness, respectively, revealing a relationship that was not evident in the prior streamflow studies reviewed here that did not stretch all the way back in time to the Medieval Warm Period. It also demonstrates there is nothing unusual about the region’s current moisture status.

In a final study from Canada, St. George (2007) begins by noting that the study of Burn (1994) suggested that a doubling of the air’s CO<sub>2</sub> content could increase the severity and frequency of droughts in the prairie provinces of Canada (Alberta, Saskatchewan, Manitoba), but that results from an ensemble of climate models suggest that runoff in the Winnipeg River region of southern Manitoba, as well as runoff in central and northern Manitoba, could increase 20-30 percent by the middle of the twenty-first century (Milly *et al.*, 2005). To help resolve this dichotomy, St. George obtained daily and monthly streamflow data from nine gauge stations within the Winnipeg River watershed from the Water Survey of Canada’s HYDAT data archive, plus precipitation and temperature data from Environment Canada’s Adjusted Historical Canadian Climate Data archive, and analyzed them for trends over the period 1924-2003.

This work revealed, in the words of St. George, that “mean annual flows have increased by 58% since 1924 ... with winter streamflow going up by 60-110%,” primarily because of “increases in precipitation during summer and autumn.” In addition, he notes that similar “changes in annual and winter streamflow are observed in records from both regulated and unregulated portions of the watershed,

which point to an underlying cause related to climate.” Countering these positive findings, however, St. George says there are “reports of declining flow for many rivers in the adjacent Canadian prairies,” citing the studies of Westmacott and Burn (1997), Yulianti and Burn (1998), Dery and Wood (2005), and Rood *et al.* (2005). Consequently, just as there are conflicting predictions about the future water status of portions of the prairie provinces of Canada, especially in Manitoba, so too are there conflicting reports about past streamflow trends in this region. It is anybody’s guess as to what will actually occur in the years and decades ahead, although based on the observed trends he discovered, St. George believes “the potential threats to water supply faced by the Canadian Prairie Provinces over the next few decades will not include decreasing streamflow in the Winnipeg River basin.”

Thus, we note there appear to be few real-world data that provide any significant support for the contention that CO<sub>2</sub>-induced global warming will lead to more frequent and/or more severe increases and decreases in streamflow that result in, or are indicative of, more frequent and/or more severe floods and droughts. In the vast majority of cases, observed trends appear to be just the opposite of what is predicted to occur. Not only are real-world observations nearly all not undesirable, they are positive, and typically extremely so.

Additional information on this topic, including reviews of newer publications as they become available, can be found at <http://www.co2science.org/subject/s/sfrtnorthamerica.php>.

## 4.5. Sea-level Rise

The possibility of large sea-level rises as a result of global warming is featured prominently in presentations of those, such as former U.S. Vice President Al Gore, who call for urgent action to “stop” global warming. In this section we examine historical trends in sea level to see if there is any indication of an increase in the mean rate-of-rise of the global ocean surface in response to the supposedly unprecedented warming of the planet over the course of the twentieth century. We then examine closely the various scenarios proposed whereby melting ice would cause sea levels to rise.

### 4.5.1 Mean Global Sea Levels

Cazenave *et al.* (2003) studied climate-related processes that cause variations in mean global sea level on interannual to decadal time scales, focusing on thermal expansion of the oceans and continental water mass balance. In doing so, they determined that the rate of thermal-induced sea-level rise over the past 40 years was about 0.5 mm/year. From early 1993 to the end of the twentieth century, however, analyses of TOPEX-Poseidon altimetry data and the global ocean temperature data of Levitus *et al.* (2000) yielded rates-of-rise that were approximately six times greater

than the mean four-decade rate, which suggested to them that “an acceleration took place in the recent past, likely related to warming of the world ocean.” However, as they alternatively note, “the recent rise may just correspond to the rising branch of a decadal oscillation.” In addition, they say that “satellite altimetry and *in situ* temperature data have their own uncertainties and it is still difficult to affirm with certainty that sea-level rise is indeed accelerating.” In fact, they cite the work of Nerem and Mitchum (2001) as indicating that “about 20 years of satellite altimetry data would be necessary to detect, with these data alone, any acceleration in sea-level rise.”

Mörner (2004) provided a more expansive setting for his analysis of the subject by noting that “prior to 5000-6000 years before present, all sea-level curves are dominated by a general rise in sea level in true glacial eustatic response to the melting of continental ice caps,” but that “sea-level records are now dominated by the irregular redistribution of water masses over the globe ... primarily driven by variations in ocean current intensity and in the atmospheric circulation system and maybe even in some deformation of the gravitational potential surface.” With respect to the last 150 years, he reports that “the mean eustatic rise in sea level for the period 1850-1930 was [on] the order of 1.0-1.1 mm/year,” but that “after 1930-40, this rise seems to have stopped (Pirazzoli *et al.*, 1989; Mörner, 1973, 2000).” This stasis, in his words, “lasted, at least, up to the mid-60s.” Thereafter, with the advent of the TOPEX/Poseidon mission, Mörner notes that “the record can be divided into three parts: (1) 1993-1996 with a clear trend of stability, (2) 1997-1998 with a high-amplitude rise and fall recording the ENSO event of these years and (3) 1998-2000 with an irregular record of no clear tendency.” Most important of all, in his words, Mörner states “there is a total absence of any recent ‘acceleration in sea-level rise’ as often claimed by IPCC and related groups,” and, therefore, “there is no fear of any massive future flooding as claimed in most global warming scenarios.”

Church *et al.* (2004) used TOPEX/Poseidon satellite altimeter data to estimate global empirical orthogonal functions, which they combined with historical tide gauge data, to estimate monthly distributions of large-scale sea-level variability and change over the period 1950-2000. Their resultant “best estimate” of the rate of globally averaged sea-level rise over the last half of the twentieth century was  $1.8 \pm 0.3$  mm/year. In addition, they noted that

“decadal variability in sea level is observed, but to date there is no detectable secular increase in the rate of sea-level rise over the period 1950-2000.” What is more, they reported that no increase in the rate of sea-level rise has been detected for the entire twentieth century, citing the work of Woodworth (1990) and Douglas (1992).

Cazenave and Nerem (2004) seemed to dismiss the caveats expressed in Cazenave *et al.* (2003) when they claimed that “the geocentric rate of global mean sea-level rise over the last decade (1993-2003) is now known to be very accurate,  $+2.8 \pm 0.4$  mm/year, as determined from TOPEX/Poseidon and Jason altimeter measurements,” and that “this rate is significantly larger than the historical rate of sea-level change measured by tide gauges during the past decades (in the range of 1-2 mm/year).” However, they then admit “the altimetric rate could still be influenced by decadal variations of sea level unrelated to long-term climate change, such as the Pacific Decadal Oscillation, and thus a longer time series is needed to rule this out.” They also noted that satellite altimetry had revealed a “non-uniform geographical distribution of sea-level change, with some regions exhibiting trends about 10 times the global mean.” In addition, they note that “for the past 50 years, sea-level trends caused by change in ocean heat storage also show high regional variability,” which fact “has led to questions about whether the rate of 20th-century sea-level rise, based on poorly distributed historical tide gauges, is really representative of the true global mean.” Consequently, and in spite of the many new instruments and techniques that are being used to search for a global warming signal in global sea-level data, Cazenave and Nerem report that “these tools seem to have raised more questions than they have answered.”

Noting that global climate models “show an increase in the rate of global average sea-level rise during the twentieth century,” but that several prior studies (Douglas, 1991, 1992; Maul and Martin, 1993; Church *et al.*, 2004; Holgate and Woodworth, 2004) had shown the measured rate of global sea-level rise to have been rather stable over the past hundred years, White *et al.* (2005) compared estimates of coastal and global averaged sea level for 1950 to 2000. Their results confirmed the earlier findings of “no significant increase in the rate of sea-level rise during this 51-year period.”

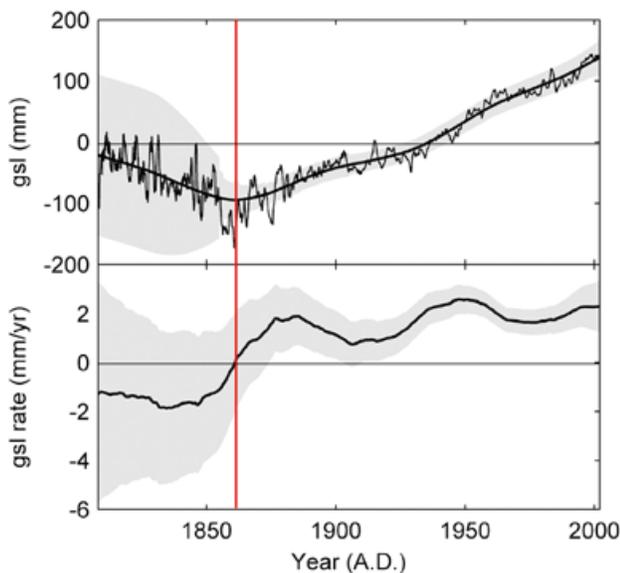

Lombard *et al.* (2005) investigated the thermosteric or temperature-induced sea-level change of the past 50 years using the global ocean

temperature data of Levitus *et al.* (2000) and Ishii *et al.* (2003). This work revealed that thermosteric sea-level variations are dominated by decadal oscillations of the planet’s chief ocean-atmosphere climatic perturbations (El Niño-Southern Oscillation, Pacific Decadal Oscillation, and North Atlantic Oscillation). In terms of the global mean, as they describe it, thermosteric trends computed over 10-year windows “show large fluctuations in time, with positive values (in the range 1 to 1.5 mm/year for the decade centered on 1970) and negative values (-1 to -1.5 mm/year for the decade centered on 1980).” In the mean, however, and over the full half-century period Lombard *et al.* investigated, there was a net rise in sea level due to the thermal expansion of sea water, but only because the record began at the bottom of a trough and ended at the top of a peak. In between these two points, there were both higher and lower values, so one cannot be sure what would be implied if earlier data were available or what will be implied as more data are acquired. Noting that sea-level trends derived from TOPEX/Poseidon altimetry over 1993-2003 are “mainly caused by thermal expansion” and are thus “very likely a non-permanent feature,” Lombard *et al.* conclude that “we simply cannot extrapolate sea level into the past or the future using satellite altimetry alone.” Even the 50 years of global ocean temperature data we possess are insufficient to tell us much about the degree of global warming that may have occurred over the past half-century, as any long-term increase in global sea level that may have been caused by the temperature increase is dwarfed by decadal-scale variability.

Carton *et al.* (2005) introduced their study of the subject by noting that “recent altimeter observations indicate an increase in the rate of sea-level rise during the past decade to 3.2 mm/year, well above the centennial estimate of 1.5-2 mm/year,” noting further that “this apparent increase could have resulted from enhanced melting of continental ice or from decadal changes in thermosteric and halosteric effects.” They explored these opposing options “using the new eddy-permitting Simple Ocean Data Assimilation version 1.2 reanalysis of global temperature, salinity, and sea level spanning the period 1968-2001.” They determined that “the effect on global sea-level rise of changing salinity is small except in subpolar regions.” However, they found that warming-induced steric effects “are enough to explain much of the observed rate of increase in the rate of sea-level rise in the last decade of the twentieth century without need to invoke acceleration of melting of continental ice.”

And as determined by Lombard *et al.*, as described in the preceding paragraph, the high thermosteric-induced rate-of-rise of global sea level over the past decade is likely “a non-permanent feature” of the global ocean’s transient thermal behavior. Consequently, and in harmony with the findings of Levitus *et al.* (2005) and Volkov and van Aken (2005), Carton *et al.* found no need to invoke the melting of land-based glacial ice to explain the observed increase in global sea-level rise of the past decade.

Even more revealing was the globally distributed sea-level time series study of Jevrejeva *et al.* (2006), who analyzed information contained in the Permanent Service for Mean Sea Level database using a method based on Monte Carlo Singular Spectrum Analysis and removed 2- to 30-year quasi-periodic oscillations to derive nonlinear long-term trends for 12 large ocean regions, which they combined to produce the mean global sea level (gsl) and gsl rate-of-rise (gsl rate) curves depicted in Figure 4.5.1.1.

**Figure 4.5.1.1.** Mean global sea level (top), with shaded 95 percent confidence interval, and mean gsl rate-of-rise (bottom), with shaded standard error interval, adapted from Jevrejeva *et al.* (2006).

The figure clearly shows no acceleration of sea-level rise since the end of the Little Ice Age. Jevrejeva *et al.* say “global sea-level rise is irregular and varies greatly over time,” but “it is apparent that rates in the 1920-1945 period are likely to be as large as today’s.” In addition, they report that their “global sea-level trend estimate of  $2.4 \pm 1.0$  mm/year for the period

from 1993 to 2000 matches the  $2.6 \pm 0.7$  mm/year sea-level rise found from TOPEX/Poseidon altimeter data.” With respect to what the four researchers describe as “the discussion on whether sea-level rise is accelerating,” their results pretty much answer the question in the negative.

The observations described above make us wonder why late twentieth century global warming—if it were as extreme as the IPCC claims it has been—cannot be detected in global sea-level data. The effects of the warming that led to the demise of the Little Ice Age—which the IPCC contends should have been considerably less dramatic than the warming of the late twentieth century—are readily apparent to the right of the vertical red line in the figure. Likewise, although the atmospheric CO<sub>2</sub> concentration experienced a dramatic increase in its rate-of-rise just after 1950 (shifting from a 1900-1950 mean rate-of-rise of 0.33 ppm/year to a 1950-2000 mean rate-of-rise of 1.17 ppm/year), the mean global sea-level rate-of-rise did not trend upwards after 1950, nor has it subsequently exceeded its 1950 rate-of-rise.

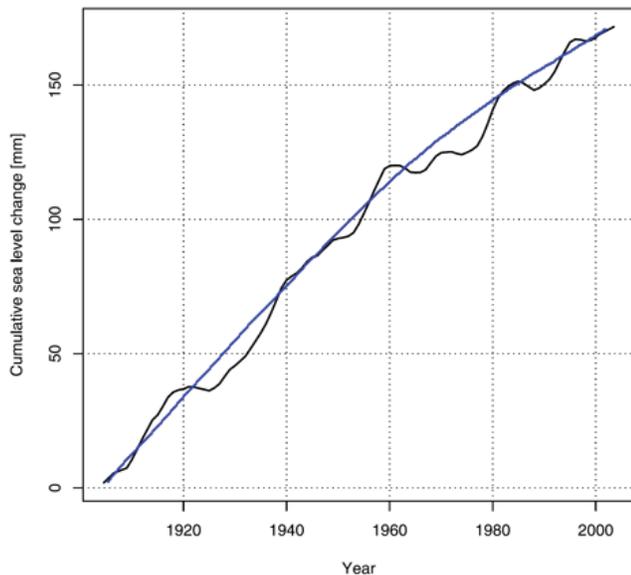

In concluding our examination of the peer-reviewed sea-level science, we report the findings of the most recent study of Holgate (2007). In a previous paper, Holgate and Woodworth (2004) derived a mean global sea-level history from 177 coastal tide gauge records that spanned the period 1955-1998. In an attempt to extend that record back in time another half-century, Holgate chose nine much longer high-quality records from around the world (New York, Key West, San Diego, Balboa, Honolulu, Cascais, Newlyn, Trieste, and Auckland) to see if their combined mean progression over the 1955-1998 period was similar enough to the concomitant mean sea-level history of the 177 stations to employ the mean nine-station record as a reasonable representation of mean global sea-level history for the much longer period stretching from 1904 to 2003.

In comparing the sea-level histories derived from the two datasets, Holgate found their mean rates-of-rise were indeed similar over the second half of the twentieth century; this observation thus implied, in Holgate’s words, that “a few high quality records from around the world can be used to examine large spatial-scale decadal variability as well as many gauges from each region are able to [do].”

As a result of this finding, Holgate constructed the nine-station-derived wavering line in Figure 4.5.1.2 as a reasonable best representation of the 1904-2003 mean global sea-level history of the world.

Based on that history, he calculated that the mean rate of global sea-level rise was “larger in the early part of the last century ( $2.03 \pm 0.35$  mm/year 1904-1953), in comparison with the latter part ( $1.45 \pm 0.34$  mm/year 1954-2003).”

Another way of thinking about the century-long sea-level history portrayed in Figure 4.5.1.2 is suggested by the curve we have fit to it, which indicates that mean global sea level may have been rising, in the mean, ever more slowly with the passage of time throughout the entire last hundred years.

**Figure 4.5.1.2.** Cumulative increase in mean global sea level (1904-2003) derived from nine high-quality tide gauge records from around the world. Adapted from Holgate (2007).

Whichever way one looks at the findings of Holgate—either as two successive linear trends (representative of the mean rates-of-rise of the first and last halves of the twentieth century) or as one longer continuous curve (such as we have drawn)—the nine select tide gauge records indicate that the mean rate of global sea-level rise has *not* accelerated over the recent past, and has probably fallen.

#### 4.5.2. Antarctica Contribution to Sea Level

Vaughn *et al.* (1999) used more than 1,800 published and unpublished *in situ* measurements of the surface mass balance of Antarctica to produce an assessment of yearly ice accumulation over the continent. Their results indicated that the "total net surface mass balance for the conterminous grounded ice sheet is 1811 Gton yr<sup>-1</sup> (149 kg m<sup>-2</sup> yr<sup>-1</sup>) and for the entire ice sheet including ice shelves and embedded ice rises, 2288 Gton yr<sup>-1</sup> (166 kg m<sup>-2</sup> yr<sup>-1</sup>)." These values, in their words, "are around 18% and 7% higher than the estimates widely adopted at present [1999]," which were derived about 15 years earlier. They suggest that net icefall on Antarctica may well have increased somewhat over that prior decade and a half. Nevertheless, because of uncertainties in the various numbers, Vaughn *et al.* say "we are still unable to

determine even the sign of the contribution of the Antarctic Ice Sheet to recent sea-level change."

In another review of the subject that was published about the same time, Reeh (1999) found a broad consensus for the conclusion that a 1°C warming would create but little net change in mean global sea level. Greenland's contribution would be a sea-level rise on the order of 0.30 to 0.77 millimeters per year, while Antarctica's contribution would be a fall on the order of 0.20 to 0.70 millimeters per year.

The following year, Wild and Ohmura (2000) studied the mass balance of Antarctica using two general circulation models developed at the Max Planck Institute for Meteorology in Hamburg, Germany: the older ECHAM3 and the new and improved ECHAM4. Under a doubled atmospheric CO<sub>2</sub> scenario, the two models were in close agreement in their mass balance projections, with both of them predicting increases in ice sheet growth, indicative of decreases in sea level.

Two years later, van der Veen (2002) addressed the problem again, noting that "for purposes of formulating policies, some of which could be unpopular or costly, it is imperative that probability density functions be derived for predicted values such as sea-level rise," further stating that with "greater societal relevance comes increased responsibility for geophysical modelers to demonstrate convincingly the veracity of their models to accurately predict future evolution of the earth's natural system or particular components thereof." In stepping forward to perform this task with respect to sea-level change, however, he was forced to conclude that "the validity of the parameterizations used by [various] glaciological modeling studies to estimate changes in surface accumulation and ablation under changing climate conditions has not been convincingly demonstrated." Van der Veen calculated, for example, that uncertainties in model parameters are sufficiently great to yield a 95 percent confidence range of projected meltwater contributions from Greenland and Antarctica that encompass global sea-level lowering as well as rise by 2100 A.D. for low, middle, and high warming scenarios. Hence, even for the worst of the IPCC warming projections, there could well be little to no change in mean global sea level due to the likely rise in the air's CO<sub>2</sub> content that may occur over the rest of this century. As a result, van der Veen concludes that the confidence level that can be placed in current ice sheet mass balance models "is quite low." Paraphrasing an earlier assessment of the subject, he says today's best models

“currently reside on the lower rungs of the ladder of excellence” and “considerable improvements are needed before accurate assessments of future sea-level change can be made.”

Wadhams and Munk (2004) attempted “an independent estimate of eustatic sea-level rise based on the measured freshening of the global ocean, and with attention to the contribution from melting of sea ice (which affects freshening but not sea level).” Their analysis produced “a eustatic rise of only 0.6 mm/year,” and when a steric contribution of 0.5 mm/year is added to the eustatic component, “a total of 1.1 mm/year, somewhat less than IPCC estimates,” is the final result. Perhaps the most interesting finding of their analysis, however, is that the continental runoff which is “allowed,” after subtracting the effect of sea ice melt, “is considerably lower than current estimates of sub-polar glacial retreat, suggesting a negative contribution from polar ice sheets (Antarctica plus Greenland) or from other non-glacial processes.” In this regard, they assert “we do not have good estimates of the mass balance of the Antarctic ice sheet, which could make a much larger positive *or* negative contribution.”

The bottom line of Wadhams and Munk’s analysis, as well as the other studies we have reviewed, is that there is considerable uncertainty associated with a number of basic parameters related to the water balance of the world’s oceans and the meltwater contribution of Antarctica. Until these uncertainties are satisfactorily resolved, we cannot be confident that we know what is happening at the bottom of the world in terms of phenomena related to sea level.

### 4.5.3. West Antarctic Ice Sheet

#### 4.5.3.1. Collapse and Disintegration

The West Antarctic Ice Sheet (WAIS) is often described as the world’s most unstable large ice sheet. As Hillenbrand *et al.* (2002) report, “it was speculated, from observed fast grounding-line retreat and thinning of a glacier in Pine Island Bay (Rignot, 1998; Shepherd *et al.*, 2001), from the timing of late Pleistocene-Holocene deglaciation in the Ross Sea (Bindschadler, 1998; Conway *et al.*, 1999), and from predicted activity of ice-stream drainage in response to presumed future global warming (Oppenheimer, 1998), that the WAIS may disappear in the future, causing the sea-level to rise at a rate of 1 to 10 mm/year (Bindschadler, 1998; Oppenheimer, 1998).”

Cofaigh *et al.* (2001) analyzed five sediment cores from the continental rise west of the Antarctic Peninsula and six from the Weddell and Scotia Seas for their ice rafted debris (IRD) content, in an attempt to see if there are Antarctic analogues of the Heinrich layers of the North Atlantic Ocean, which testify of the repeated collapse of the eastern margin of the Laurentide Ice Sheet and the concomitant massive discharge of icebergs. If such IRD layers exist around Antarctica, the researchers reasoned, they would be evidence of “periodic, widespread catastrophic collapse of basins within the Antarctic Ice Sheet,” which could obviously occur again. However, after carefully studying their data, they concluded that “the ice sheet over the Antarctic Peninsula did not undergo widespread catastrophic collapse along its western margin during the late Quaternary,” and they say this evidence “argues against pervasive, rapid ice-sheet collapse around the Weddell embayment over the last few glacial cycles.” If there was no dramatic break-up of the WAIS over the last few glacial cycles, there’s a very good chance there will be none before the current interglacial ends, especially since the data of

Petit *et al.* (1999) indicate that the peak temperatures of each of the previous four interglacials were warmer than the peak temperature of the current interglacial by an average of more than 2°C.

Hillenbrand *et al.* (2002) studied the nature and history of glaciomarine deposits contained in sediment cores recovered from the West Antarctic continental margin in the Amundsen Sea to “test hypotheses of past disintegration of the WAIS.” In doing so, they found that all proxies regarded as sensitive to a WAIS collapse changed markedly during the global climatic cycles of the past 1.8 million years, but they “do not confirm a complete disintegration of the WAIS during the Pleistocene” at a place where “dramatic environmental changes linked to such an event should be documented.” They say their results “suggest relative stability rather than instability of the WAIS during the Pleistocene climatic cycles,” and they note that this conclusion is “consistent with only a minor reduction of the WAIS during the last interglacial period,” citing the work of Huybrechts (1990), Cuffey and Marshall (2000) and Huybrechts (2002).

In another paper that addresses the subject of possible WAIS collapse, O’Neill and Oppenheimer (2002) say the ice sheet “may have disintegrated in the past during periods only modestly warmer (~2°C global mean) than today,” and they thus claim that setting “a limit of 2°C above the 1990 global average temperature”—above which the mean temperature of the globe should not be allowed to rise—“is justified.” In fact, a 2°C warming of the globe would likely have little to no impact on the stability of the WAIS. The average Antarctic peak temperature of all four of the world’s prior interglacials was at least 2°C greater than the Antarctic peak temperature of the current interglacial; yet, in the words of the scientists who developed the pertinent temperature record (Petit *et al.*, 1999), the evidence contained in the core “makes it unlikely that the West Antarctic ice sheet collapsed during the past 420,000 years,” pretty much the same conclusion that was drawn by Cofaigh *et al.*

In addition, we know from the Vostok ice core record that the peak Antarctic temperature of the most recent prior interglacial was fully 3°C warmer than the peak Antarctic temperature of the interglacial in which we presently live, yet the WAIS still did not disintegrate then. Furthermore, we know that throughout the long central portion of the current interglacial (when the most recent peak Antarctic temperature was reached), it was much warmer than it was in 1990, which is the year from which O’Neill

and Oppenheimer’s critical 2°C warming increment is measured; and this fact raises the 3°C temperature elevation of the last interglacial relative to the global temperature of 1990 to something on the order of 4° or 5°C, for which, again, there was no evidence of even a partial WAIS disintegration.

Finally, and in spite of the current interglacial’s current relative coolness, the Vostok ice core data indicate that the current interglacial has been by far the longest stable warm period of the entire 420,000-year record, which suggests we are probably long overdue for the next ice age to begin, and that we may not have the “5 to 50 centuries” that O’Neill and Oppenheimer suggest could be needed to bring about the WAIS disintegration subsequent to the attainment of whatever temperature in excess of 4° or 5°C above the current global mean would be needed to initiate the process.

Additional information on this topic, including reviews of newer publications as they become available, can be found at <http://www.co2science.org/subject/w/waiscollapse.php>.

#### 4.5.3.2. Dynamics

The supposedly imminent demise of the West Antarctic Ice Sheet (WAIS) is what Al Gore apparently had in mind when warned that if “half of Antarctica melted or broke up and slipped into the sea, sea levels worldwide would increase by between 18 and 20 feet” (Gore 2006). A few scientists, as reported by Ackert (2003), believe we are witnessing the CO<sub>2</sub>-induced “early stages of rapid ice sheet collapse, with potential near-term impacts on the world’s coastlines.” However, studies of the dynamics of various components of the WAIS suggest this is highly unlikely.

Bindschadler and Vornberger (1998) utilized satellite imagery taken since 1963 to examine spatial and temporal changes of Ice Stream B, which flows into the Ross Ice Shelf. The data indicated that since that time, the ice stream’s width had increased by nearly 4 kilometers, at a rate that was, in their words, an “order of magnitude faster than models have predicted.” However, they reported that the flow speed of the ice stream had decreased over this time period by about 50 percent, noting that “such high rates of change in velocity greatly complicate the calculation of mass balance of the ice sheet,” and that such changes “do not resolve the overriding question of the stability of the West Antarctic Ice Sheet.”

Bindschadler (1998) reviewed what was known about the WAIS and analyzed its historical retreat in terms of its grounding line and ice front. This work revealed that from the time of the Last Glacial

Maximum to the present, the retreat of the WAIS’s grounding line had been faster than that of its ice front, which resulted in an expanding Ross Ice Shelf. In fact, Bindschadler reported that “the ice front now appears to be nearly stable,” although its grounding line appeared to be retreating at a rate that suggested complete dissolution of the WAIS in another 4,000 to 7,000 years. Such a retreat would indeed result in a sustained sea-level rise of 8 to 13 cm per century. However, even the smallest of these sea-level rates-of-rise would require, according to Bindschadler, “a large negative mass balance for all of West Antarctica,” and there were no broad-based data to support that scenario.

Oppenheimer (1998) reviewed 122 studies that dealt with the stability of the WAIS and its effects on global sea level, concluding that “human-induced climate change may play a significant role in controlling the long-term stability of the West Antarctic Ice Sheet and in determining its contribution to sea-level change in the near future.” Other of his statements, however, detract from this conclusion. He noted, for example, that the Intergovernmental Panel on Climate Change (IPCC) “estimated a zero Antarctic contribution to sea-level rise over the past century, and projected a small negative (about -1 cm) contribution for the twenty-first century.” With respect to the state and behavior of the atmosphere and ocean above and around Antarctica, he acknowledged that “measurements are too sparse to enable the observed changes to be attributed to any such [human-induced] global warming.” And in the case of sea-ice extent, he admitted “the IPCC assessment is that no trend has yet emerged.”

Oppenheimer concluded his review with four scenarios of the future based upon various assumptions. One was that the WAIS will experience a sudden collapse that causes a 4-6 m sea-level rise within the coming century. However, he stated that this scenario “may be put aside for the moment, because no convincing model of it has been presented.” A second scenario had the WAIS gradually disintegrating and contributing to a slow sea-level rise over two centuries, followed by a more rapid disintegration over the following 50 to 200 years. Once again, however, he noted that “progress on understanding [the] WAIS over the past two decades has enabled us to lower the relative likelihood of [this] scenario.”

In another scenario, the WAIS takes 500-700 years to disappear, as it raises sea-level by 60-120 cm

per century. Oppenheimer assesses the relative likelihood of this scenario to be the highest of all, “but with low confidence,” as he puts it. Last is what occurs if ice streams slow, as a result of internal ice sheet readjustments, and the discharge of grounded ice decreases, which could well happen even if ice shelves thin and major fast-moving glaciers do not slow. In such a situation, he notes that “the Antarctic contribution to sea-level rise turns increasingly negative,” i.e., sea level *falls*. And in commenting upon the suite of scenarios just described, Oppenheimer emphatically states that “it is not possible to place high confidence in any specific prediction about the future of WAIS.”

Also writing in *Nature*, Bell *et al.* (1998) used aerogeophysical data to investigate processes that govern fast-moving ice streams on the WAIS. In conjunction with various models, these data suggested a close correlation between the margins of various ice streams and the underlying sedimentary basins, which appeared to act as lubricants for the overlying ice. The seven scientists suggested that the positions of ice-stream margins and their onsets were controlled by features of the underlying sedimentary basins. They concluded that “geological structures beneath the West Antarctic Ice Sheet have the potential to dictate the evolution of the dynamic ice system, modulating the influence of changes in the global climate system,” although their work did not indicate what effect, if any, a modest rise in near-surface air temperature might have on this phenomenon.

Rignot (1998) reported on satellite radar measurements of the grounding line of Pine Island Glacier from 1992 to 1996, which were studied to determine whether or not this major ice stream in remote West Antarctica was advancing or retreating. The data indicated that the glacier’s grounding line had retreated inland at a rate of  $1.2 \pm 0.3$  kilometers per year over the four-year period of the study; Rignot suggested that this retreat may have been the result of a slight increase in ocean water temperature. Because the study had utilized only four years of data, however, questions concerning the long-term stability of the WAIS, in the words of the researcher, “cannot be answered at present.” In addition, although the glacier’s grounding line had been found to be retreating, subsequent satellite images suggested that the location of the ice front had remained stable.

Also in the journal *Science*, Conway *et al.* (1999) examined previously reported research, while conducting some of their own, dealing with the retreat of the WAIS since its maximum glacial extent some

20,000 years ago. In doing so, they determined that the ice sheet’s grounding line remained near its maximum extent until about 10,000 years ago, whereupon it began to retreat at a rate of about 120 meters per year. This work also indicated that at the end of the twentieth century it was retreating at about the same rate, which suggests that if it continues to behave as it has in the past, complete deglaciation of the WAIS will occur in about 7,000 years. The researchers concluded that the modern-day grounding-line retreat of the WAIS is part of an ongoing recession that has been underway since the early to mid-Holocene, and that “it is not a consequence of anthropogenic warming or recent sea-level rise.”

Stenoien and Bentley (2000) mapped the catchment region of Pine Island Glacier using radar altimetry and synthetic aperture radar interferometry, which they used to develop a velocity map that revealed a system of tributaries that channel ice from the catchment area into the fast-flowing glacier. Then, by combining the velocity data with information on ice thickness and snow accumulation rates, they were able to calculate, within an uncertainty of 30 percent, that the mass balance of the catchment region was not significantly different from zero.

One year later, Shepherd *et al.* (2001) used satellite altimetry and interferometry to determine the rate of change of the ice thickness of the entire Pine Island Glacier drainage basin between 1992 and 1999. This work revealed that the grounded glacier thinned by up to 1.6 meters per year between 1992 and 1999. Of this phenomenon, the researchers wrote that “the thinning cannot be explained by short-term variability in accumulation and must result from glacier dynamics,” and since glacier dynamics typically respond to phenomena operating on time scales of hundreds to thousands of years, this observation would argue against twentieth century warming being a primary cause of the thinning. Shepherd *et al.* additionally say they could “detect no change in the rate of ice thinning across the glacier over a 7-year period,” which also suggests that a long-term phenomenon of considerable inertia must be at work in this particular situation.

But what if the rate of glacier thinning, which sounds pretty dramatic, were to continue unabated? The researchers state that “if the trunk continues to lose mass at the present rate it will be entirely afloat within 600 years.” And if that happens, they “estimate the net contribution to eustatic sea level to be 6 mm,” which means that over each century, we could expect

global sea level to rise by about one millimeter, about the thickness of a paper clip.

Publishing in the same year were Pudsey and Evans (2001), who studied ice-rafted debris obtained from four cores in Prince Gustav Channel, which until 1995 was covered by floating ice shelves. Their efforts indicated that the ice shelves had also retreated in mid-Holocene time, but that, in their words, “colder conditions after about 1.9 ka allowed the ice shelf to reform.” Although they concluded that the ice shelves are sensitive indicators of regional climate change, they were careful to state that “we should not view the recent decay as an unequivocal indicator of anthropogenic climate change.” Indeed, the disappearance of the ice shelves was not unique; it had happened before without our help, and it could well have happened again on its own. In fact, the breakup of the Prince Gustav Channel ice shelves was likely nothing more than the culmination of the Antarctic Peninsula’s natural recovery from the cold conditions of Little Ice Age.

Raymond (2002) presented a brief appraisal of the status of the world’s major ice sheets. His primary conclusions relative to the WAIS were that (1) “substantial melting on the upper surface of WAIS would occur only with considerable atmospheric warming,” (2) of the three major WAIS drainages, the ice streams that drain northward to the Amundsen Sea have accelerated, widened, and thinned “over substantial distances back into the ice sheet,” but that “the eastward drainage toward the Weddell Sea is close to mass balance.” And (3) of the westward drainage into the Ross Ice Shelf, “over the last few centuries, margins of active ice streams migrated inward and outward,” while the “overall mass balance has changed from loss to gain,” as “a currently active ice stream (Whillans) has slowed by about 20% over recent decades.”

In a summary statement that takes account of these observations, Raymond says that “the total mass of today’s ice sheets is changing only slowly, and even with climate warming increases in snowfall should compensate for additional melting,” such as might possibly occur for the WAIS if the planet’s temperature continues its post-Little Ice Age rebound.

Stone *et al.* (2003)—working on western Marie Byrd Land—report how they determined cosmogenic <sup>10</sup>Be exposure dates of glacially transported cobbles in elevation transects on seven peaks of the Ford Ranges between the ice sheet’s present grounding line and the Clark Mountains some 80 km inland. Based on these ages and the elevations at which the cobbles

were found, they reconstructed a history of ice-sheet thinning over the past 10,000-plus years. This history showed, in their words, that “the exposed rock in the Ford Ranges, up to 700 m above the present ice surface, was deglaciated within the past 11,000 years,” and that “several lines of evidence suggest that the maximum ice sheet stood considerably higher than this.”

Stone *et al.* additionally report that the consistency of the exposure age versus elevation trends of their data “indicates steady deglaciation since the first of these peaks emerged from the ice sheet some time before 10,400 years ago,” and that the mass balance of the region “has been negative throughout the Holocene.” The researchers also say their results “add to the evidence that West Antarctic deglaciation continued long after the disappearance of the Northern Hemisphere ice sheets and may still be under way,” noting that the ice sheet in Marie Byrd Land “shows the same pattern of steady Holocene deglaciation as the marine ice sheet in the Ross Sea,” where ice “has thinned and retreated since 7000 years ago,” adding that “there is strong evidence that the limit of grounded ice in both regions—and in Pine Island Bay—is still receding.”

The work of Stone *et al.* convincingly demonstrates that the current thinning and retreat of the WAIS are merely manifestations of a slow but steady deglaciation that has been going on ever since the beginning-of-the-end of the last great ice age. Stone *et al.* say “the pattern of recent change is consistent with the idea that thinning of the WAIS over the past few thousand years is continuing,” while Ackert (2003) makes the point even plainer when he says “recent ice sheet dynamics appear to be dominated by the ongoing response to deglacial forcing thousands of years ago, rather than by a recent anthropogenic warming or sea-level rise.”

#### 4.5.3.2. Mass Balance

Is the West Antarctic Ice Sheet (WAIS) growing or shrinking? In what follows, we briefly review the findings of several researchers who have focused their attention on the mass balance of the WAIS.

Anderson and Andrews (1999) analyzed grain size and foraminiferal contents of radiometrically dated sediment cores collected from the eastern Weddell Sea continental shelf and the western Weddell Sea deep-sea floor in an attempt to better

understand the behavior of both the East and West Antarctic ice sheets. In doing so, their data led them to conclude that “significant deglaciation of the Weddell Sea continental shelf took place prior to the last glacial maximum,” and that the ice masses that border the Weddell Sea today “are more extensive than they were during the previous glacial minimum.” They concluded “that the current interglacial setting is characterized by a more extensive ice margin and larger ice shelves than existed during the last glacial minimum, and that the modern West and East Antarctic ice sheets have not yet shrunk to their minimum.” It is thus to be expected—independent of what global air temperature may currently be doing, because of the great inertial forces at work over much longer time scales—that the modern East and West Antarctic Ice Sheets may well continue to shrink and release more icebergs to the Southern Ocean over the coming years, decades and centuries, thereby slowly raising global sea level.

Also studying the combined ice sheets of East and West Antarctica were Wingham *et al.* (1998), who used satellite radar altimeter measurements from 1992 to 1996 to estimate the rate of change of the thickness of nearly two-thirds of the grounded portion of the entire Antarctic Ice Sheet, while using snowfall variability data obtained from ice cores to ultimately calculate the mass balance of the interior of the continental ice sheet over the past century. Their results showed that, at most, the interior of the Antarctic Ice Sheet has been “only a modest source or sink of sea-level mass this century.” As a result, Wingham *et al.* concluded that “a large century-scale imbalance for the Antarctic interior is unlikely,” noting that this conclusion is in harmony with a body of relative sea-level and geodetic evidence “supporting the notion that the grounded ice has been in balance at the millennial scale.” This full set of findings thus suggests that both portions of the Antarctic Ice Sheet may be rather impervious to climate changes of the magnitude characteristic of the Medieval Warm Period and Little Ice Age, which is the type of change most likely to occur—if there is any change at all—in response to the ongoing rise in the air’s CO<sub>2</sub> content.

Davis and Ferguson (2004) evaluated elevation changes of the entire Antarctic ice sheet over the five-year period June 1995 to April 2000, based on more than 123 million elevation change measurements made by the European Space Agency’s European Remote Sensing 2 satellite radar altimeter. They determined the east Antarctic ice sheet had a five-year

trend of  $1.0 \pm 0.6$  cm/year, the west Antarctic ice sheet had a five-year trend of  $-3.6 \pm 1.0$  cm/year, and the entire Antarctic continent (north of  $81.6^\circ\text{S}$ ) had a five-year trend of  $0.4 \pm 0.4$  cm/year. In addition, the Pine Island, Thwaites, DeVicq, and Land glaciers of West Antarctica exhibited five-year trends ranging from -26 to—135 cm/year.

In discussing their findings, Davis and Ferguson noted that the strongly negative trends of the coastal glacier outlets “suggest that the basin results are due to dynamic changes in glacier flow,” and that recent observations “indicate strong basal melting, caused by ocean temperature increases, is occurring at the grounding lines of these outlet glaciers.” They concluded “there is good evidence that the strongly negative trends at these outlet glaciers, the mass balance of the corresponding drainage basins, and the overall mass balance of the west Antarctic ice sheet may be related to increased basal melting caused by ocean temperature increases.” Nevertheless, driven by the significantly positive trend of the much larger east Antarctic ice sheet, the ice volume of the entire continent grew ever larger over the last five years of the twentieth century, the majority of which increase, according to Davis and Ferguson, was due to increased snowfall.

One year later, in an “editorial essay” (i.e., not a peer-reviewed submission) published in the journal *Climatic Change*, Oppenheimer and Alley (2005) discussed “the degree to which warming can affect the rate of ice loss by altering the mass balance between precipitation rates on the one hand, and melting and ice discharge to the ocean through ice streams on the other,” with respect to the WAIS and Greenland Ice Sheet (GIS). After a brief overview of the topic, they noted that “the key questions with respect to both WAIS and GIS are: What processes limit ice velocity, and how much can warming affect those processes?” In answer to these questions, they said that “no consensus has emerged about these issues nor, consequently, about the fate of either ice sheet, a state of affairs reflecting the weakness of current models and uncertainty in paleoclimatic reconstructions.”

After a cursory review of the science related to these two key questions, Oppenheimer and Alley say their review “leads to a multitude of questions with respect to the basic science of the ice sheets,” which we list below. However, instead of listing them in their original question form, we post them in the form of statements that address what we do not know about the various sub-topics mentioned, which is obviously

what prompts the questions in the first place and validates the content of the statements.

(1) We do not know if the apparent response of glaciers and ice streams to surface melting and melting at their termini (e.g., ice shelves) could occur more generally over the ice sheets.

(2) We do not know if dynamical responses are likely to continue for centuries and propagate further inland or if it is more likely that they will be damped over time.

(3) We do not know if surface melting could cause rapid collapse of the Ross or Filchner-Ronne ice shelves, as occurred for the smaller Larsen ice shelf.

(4) We do not know if ice sheets made a significant net contribution to sea-level rise over the past several decades.

(5) We do not know what might be useful paleoclimate analogs for sea level and ice sheet behavior in a warmer world.

(6) We do not know the reliability of Antarctic and Southern Ocean temperatures (and polar amplification) that are projected by current GCMs, nor do we know why they differ so widely among models, nor how these differences might be resolved.

(7) We do not know the prospects for expanding measurements and improving models of ice sheets nor the timescales involved.

(8) We do not know if current uncertainties in future ice sheet behavior can be expressed quantitatively.

(9) We do not know what would be useful early warning signs of impending ice sheet disintegration nor when these might be detectable.

(10) We do not know, given current uncertainties, if our present understanding of the vulnerability of either the WAIS or GIS is potentially useful in defining “dangerous anthropogenic interference” with earth’s climate system.

(11) We do not know if the concept of a threshold temperature is useful.

(12) We do not know if either ice sheet seems more vulnerable and thus may provide a more immediate measure of climate “danger” and a more pressing target for research.

(13) We do not know if any of the various temperatures proposed in the literature as demarking danger of disintegration for one or the other ice sheet are useful in contributing to a better understanding of “dangerous anthropogenic interference.”

(14) We do not know on what timescale future learning might affect the answers to these questions.

Oppenheimer and Alley describe this list of deficiencies in our knowledge of things related to the WAIS as “gaping holes in our understanding” that “will not be closed unless governments provide adequate resources for research.” Nevertheless, they claim that “if emissions of the greenhouse gases are not reduced while uncertainties are being resolved, there is a risk of making ice-sheet disintegration nearly inevitable.” Obviously, their own analysis contradicts so dire a warning. Given the degree of deficiency in our knowledge of the matter, it is perhaps as likely as not that a continuation of the planet’s recovery from the relative cold of the Little Ice Age will lead to a buildup of polar ice.

The following year also saw the publication of another paper that mixed “gaping holes in our understanding” with warnings of dire-sounding WAIS mass losses. Velicogna and Wahr (2006) used measurements of time-variable gravity from the Gravity Recovery and Climate Experiment (GRACE) satellites to determine mass variations of the Antarctic ice sheet for the 34 months between April 2002 and August 2005. The two researchers concluded that “the ice sheet mass decreased significantly, at a rate of  $152 \pm 80 \text{ km}^3/\text{year}$  of ice, equivalent to  $0.4 \pm 0.2 \text{ mm/year}$  of global sea-level rise,” all of which mass loss came from the WAIS, since they calculated that the East Antarctic Ice Sheet mass balance was  $0 \pm 56 \text{ km}^3/\text{year}$ .

Velicogna and Wahr admit there is “geophysical contamination ... caused by signals outside Antarctica,” including “continental hydrology ... and ocean mass variability.” The first of these confounding factors, according to them, “is estimated using monthly, global water storage fields from the Global Land Data Assimilation system,” while “the ocean contamination is estimated using a JPL version of the Estimating Circulation and Climate of the Ocean (ECCO) general circulation model.”

The two researchers note that the GRACE mass solutions “do not reveal whether a gravity variation over Antarctica is caused by a change in snow and ice on the surface, a change in atmospheric mass above Antarctica, or post-glacial rebound (PGR: the viscoelastic response of the solid Earth to glacial unloading over the last several thousand years).”

To adjust for the confounding effect of the variable atmospheric mass above Antarctica, Velicogna and Wahr utilized European Centre for Medium-Range Weather Forecasts (ECMWF) meteorological fields, but they acknowledge that “there are errors in those fields,” so they “estimate the

secular component of those errors by finding monthly differences between meteorological fields from ECMWF and from the National Centers for Environmental Prediction.”

With respect to post-glacial rebound, Velicogna and Wahr say “there are two important sources of error in PGR estimates: the ice history and Earth’s viscosity profile.” To deal with this problem, they “estimate the PGR contribution and its uncertainties using two ice history models.”

All of these estimates and adjustments are convoluted and complex, as well as highly dependent upon various models. Velicogna and Wahr acknowledge that “the PGR contribution is much larger than the uncorrected GRACE trend.” In fact, their calculations indicate that the PGR contribution exceeds that of the signal being sought by nearly a factor of five. And they are forced to admit “a significant ice mass trend does not appear until the PGR contribution is removed.”

Finally, Velicogna and Wahr’s study covered less than a three-year period. Much more likely to be representative of the truth with respect to the WAIS’s mass balance are the findings of Zwally *et al.* (2005), who determined Antarctica’s contribution to mean global sea level over a recent nine-year period to be only  $0.08 \text{ mm/year}$  compared to the five-times-greater value of  $0.4 \text{ mm/year}$  calculated by Velicogna and Wahr.

In a contemporaneous study, van de Berg *et al.* (2006) compared results of model-simulated Antarctic surface mass balance (SMB)—which they derived from a regional atmospheric climate model for the time period 1980 to 2004 that used ERA-40 fields as lateral forcings—with “all available SMB observations from Antarctica (N=1900)” in a recalibration process that ultimately allowed them “to construct a best estimate of contemporary Antarctic SMB,” where the many real-world observations employed in this process came from the studies of Vaughan *et al.* (1999), van den Broeke *et al.* (1999), Frezzotti *et al.* (2004), Karlof *et al.* (2000), Kaspari *et al.* (2004), Magand *et al.* (2004), Oerter *et al.* (1999, 2000), Smith *et al.* (2002), and Turner *et al.* (2002). Observations were derived by a number of different measurement techniques, including stake arrays, bomb horizons, and chemical analyses of ice cores that covered time periods ranging from a few years to more than a century.

As a result of this effort, van de Berg *et al.* determined that “the SMB integrated over the grounded ice sheet ( $171 \pm 3 \text{ mm per year}$ ) exceeds

previous estimates by as much as 15%,” with the largest differences between their results and those of others being “up to one meter per year higher in the coastal zones of East and West Antarctica,” concluding that “support or falsification of this result can only be found in new SMB observations from poorly covered high accumulation regions in coastal Antarctica.”

In the same year, Wingham *et al.* (2006) “analyzed  $1.2 \times 10^8$  European remote sensing satellite altimeter echoes to determine the changes in volume of the Antarctic ice sheet from 1992 to 2003,” which survey, in their words, “covers 85% of the East Antarctic ice sheet and 51% of the West Antarctic ice sheet,” which together comprise “72% of the grounded ice sheet.” In doing so, they found that “overall, the data, corrected for isostatic rebound, show the ice sheet growing at  $5 \pm 1$  mm per year.” To calculate the ice sheet’s change in mass, however, “requires knowledge of the density at which the volume changes have occurred,” and when the researchers’ best estimates of regional differences in this parameter were used, they found that “72% of the Antarctic ice sheet is gaining  $27 \pm 29$  Gt per year, a sink of ocean mass sufficient to *lower* [their italics] global sea levels by 0.08 mm per year.” This net *extraction* of water from the global ocean, according to Wingham *et al.*, occurs because “mass gains from accumulating snow, particularly on the Antarctic Peninsula and within East Antarctica, exceed the ice dynamic mass loss from West Antarctica.”

Ramillien *et al.* (2006) derived new estimates of the mass balances of the East and West Antarctic ice sheets from GRACE data for the period July 2002 to March 2005: a loss of  $107 \pm 23$  km<sup>3</sup>/year for West Antarctica and a gain of  $67 \pm 28$  km<sup>3</sup>/year for East Antarctica, which results yielded a net ice loss for the entire continent of 40 km<sup>3</sup>/year (which translates to a mean sea-level rise of 0.11 mm/year). This is of the same order of magnitude as the 0.08 mm/year Antarctic-induced mean sea-level rise calculated by Zwally *et al.* (2005), which was derived from elevation changes based on nine years of satellite radar altimetry data obtained from the European Remote-sensing Satellites ERS-1 and -2. Even at that, the GRACE approach is still laden with a host of potential errors, as we noted in our discussion of the Velicogna and Wahr paper, and as both they and Ramillien *et al.* readily admit. In addition, as the latter researchers note in their closing paragraph, “the GRACE data time series is still very short and these results must be considered as preliminary since we

cannot exclude that the apparent trends discussed in this study only reflect interannual fluctuations.”

Remy and Frezzotti (2006) reviewed “the results given by three different ways of estimating mass balance, first by measuring the difference between mass input and output, second by monitoring the changing geometry of the continent, and third by modeling both the dynamic and climatic evolution of the continent.” In describing their findings, the two researchers state that “the East Antarctica ice sheet is nowadays more or less in balance, while the West Antarctica ice sheet exhibits some changes likely to be related to climate change and is in negative balance.” In addition, they report that “the current response of the Antarctica ice sheet is dominated by the background trend due to the retreat of the grounding line, leading to a sea-level rise of 0.4 mm/yr over the short-time scale,” which they describe in terms of centuries. However, they note that “later, the precipitation increase will counterbalance this residual signal, leading to a thickening of the ice sheet and thus a decrease in sea level.”

Van den Broeke *et al.* (2006) employed a regional atmospheric climate model (RACMO2), with snowdrift-related processes calculated offline, to calculate the flux of solid precipitation (Ps), surface sublimation (SU), sublimation from suspended (drifting/saltating) snow particles, horizontal snow drift transport, and surface melt (ME). In doing so, they found that “even without snowdrift-related processes, modeled (Ps-SU-ME) from RACMO2 strongly correlates with 1900 spatially weighted quality-controlled in situ SSMB observations,” which result they describe as “remarkable,” given that the “model and observations are completely independent.” Then, to deal with a remaining systematic elevation bias in the model results, they applied a set of empirical corrections (at 500-m intervals) that “largely eliminated” this final deviation from reality. And after analyzing all of the data-driven results for trends over the period 1980-2004, the four Dutch researchers report that “no trend is found in any of the Antarctic SSMB components, nor in the size of ablation areas.”

Krinner *et al.* (2007) used the LMDZ4 atmospheric general circulation model (Hourdin *et al.*, 2006) to simulate Antarctic climate for the periods 1981-2000 (to test the model’s ability to adequately simulate present conditions) and 2081-2100 (to see what the future might hold for the mass balance of the Antarctic Ice Sheet and its impact on global sea level). This work revealed, first, that “the

simulated present-day surface mass balance is skilful on continental scales,” which gave them confidence that their results for the end of the twenty-first century would be reasonably accurate as well. Of that latter period a full century from now, they determined that “the simulated Antarctic surface mass balance increases by 32 mm water equivalent per year,” which corresponds “to a sea-level decrease of 1.2 mm per year by the end of the twenty-first century,” which would in turn “lead to a cumulated sea-level decrease of about 6 cm.” This result, in their words, occurs because the simulated temperature increase “leads to an increased moisture transport towards the interior of the continent because of the higher moisture holding capacity of warmer air,” where the extra moisture falls as precipitation, causing the continent’s ice sheet to grow.

The results of this study—based on sea surface boundary conditions taken from IPCC Fourth Assessment Report simulations (Dufresne *et al.*, 2005) that were carried out with the IPSL-CM4 coupled atmosphere-ocean general circulation model (Marti *et al.*, 2005), of which the LMDZ4 model is the atmospheric component—argue strongly against predictions of future catastrophic sea-level rise due to mass wastage of the Antarctic Ice Sheet. In fact, they suggest just the opposite, i.e., that CO<sub>2</sub>-induced global warming would tend to buffer the world against such an outcome. That seems to be the message of most of the other major studies of the subject.

Additional information on this topic, including reviews of newer publications as they become available, can be found at <http://www.co2science.org/subject/w/waisbalance.php>.

#### 4.5.3.3. West Antarctic Ice Sheet and Sea Level

Many of the studies of the West Antarctic Ice Sheet (WAIS) cited in the previous sections of this report address its past and future effects on sea level. In this final section on the WAIS, we bring this body of research together in one place and add other research summaries.

Bindschadler (1998) analyzed the WAIS's historical retreat in terms of its grounding line and ice front. This work revealed that from the time of the Last Glacial Maximum to the present, the retreat of the ice sheet's grounding line had been faster than that of its ice front, which resulted in an expanding Ross Ice Shelf. Although Bindschadler wrote that "the ice front now appears to be nearly stable," there were indications that its grounding line was retreating at a rate that suggested complete dissolution of the WAIS in another 4,000 to 7,000 years. Such a retreat was calculated to result in a sustained sea-level rise of 8-13 cm per century. However, even the smallest of these rates-of-rise would require, in Bindschadler's words, "a large negative mass balance for all of West Antarctica," and there were no broad-based data that supported that scenario.

A year later, Reeh (1999) reviewed what was known about the mass balances of both the Greenland and Antarctic ice sheets, concluding that the future contribution of the Greenland and Antarctic ice sheets to global sea level depends upon their past climate and dynamic histories as much as it does upon future climate. With respect to potential climate change, Reeh determined there was a broad consensus that the effect of a 1°C climatic warming on the Antarctic ice sheet would be a *fall* in global sea level on the order of 0.2 to 0.7 millimeters per year.

The following year, Cuffey and Marshall (2000) reevaluated previous model estimates of the Greenland ice sheet's contribution to sea-level rise during the last interglacial, based on a recalibration of oxygen-isotope-derived temperatures from central Greenland ice cores. Their results suggested that the Greenland ice sheet was much smaller during the last interglacial than previously thought, with melting of

the ice sheet contributing somewhere between four and five-and-a-half meters to sea-level rise. According to Hvidberg (2000), this finding suggests that “high sea levels during the last interglacial should not be interpreted as evidence for extensive melting of the West Antarctic Ice Sheet, and so challenges the hypothesis that the West Antarctic is particularly sensitive to climate change.”

Oppenheimer and Alley (2005) discussed “the degree to which warming can affect the rate of ice loss by altering the mass balance between precipitation rates on the one hand, and melting and ice discharge to the ocean through ice streams on the other,” with respect to both the West Antarctic and Greenland Ice Sheets. Their review of the subject led them to conclude that we simply do not know if these ice sheets had made a significant contribution to sea-level rise over the past several decades.

One year later, however, the world was exposed to a different view of the issue when Velicogna and Wahr (2006) used measurements of time-variable gravity from the Gravity Recovery and Climate Experiment (GRACE) satellites to determine mass variations of the Antarctic ice sheet for the 34 months between April 2002 and August 2005. The two researchers concluded that “the ice sheet mass decreased significantly, at a rate of  $152 \pm 80 \text{ km}^3/\text{year}$  of ice, equivalent to  $0.4 \pm 0.2 \text{ mm/year}$  of global sea-level rise,” all of which mass loss came from the WAIS, since they calculated that the East Antarctic Ice Sheet mass balance was  $0 \pm 56 \text{ km}^3/\text{year}$ .

The many estimates and adjustments used by Velicogna and Wahr to reach this conclusion were described in Section 4.5.3.2. For example, the adjustment for post-glacial rebound alone exceeded the signal being sought by nearly a factor of five. Moreover, the study covers less than a three-year period, which compares poorly with the findings of Zwally *et al.* (2005), who determined Antarctica’s contribution to mean global sea level over a recent nine-year period to be only  $0.08 \text{ mm/year}$ .

Ramillien *et al.* (2006) also used GRACE data to derive estimates of the mass balances of the East and West Antarctic ice sheets for the period July 2002 to March 2005, obtaining a loss of  $107 \pm 23 \text{ km}^3/\text{year}$  for West Antarctica and a gain of  $67 \pm 28 \text{ km}^3/\text{year}$  for East Antarctica, which results yielded a net ice loss for the entire continent of only  $40 \text{ km}^3/\text{year}$  (which translates to a mean sea-level rise of  $0.11 \text{ mm/year}$ ), as opposed to the  $152 \text{ km}^3/\text{year}$  ice loss calculated by Velicogna and Wahr (which translates to a nearly four times larger mean sea-level rise of

$0.40 \text{ mm/year}$ ). Ramillien *et al.* note in their closing paragraph, “the GRACE data time series is still very short and these results must be considered as preliminary since we cannot exclude that the apparent trends discussed in this study only reflect interannual fluctuations.” That caveat also applies to the Velicogna and Wahr analysis.

About the same time, Wingham *et al.* (2006) analyzed European remote sensing satellite altimeter echoes to determine the changes in volume of the Antarctic ice sheet from 1992 to 2003. They found that “72% of the Antarctic ice sheet is gaining  $27 \pm 29 \text{ Gt}$  per year, a sink of ocean mass sufficient to *lower* [their italics] global sea levels by  $0.08 \text{ mm}$  per year.” This net extraction of water from the global ocean, according to Wingham *et al.*, occurs because “mass gains from accumulating snow, particularly on the Antarctic Peninsula and within East Antarctica, exceed the ice dynamic mass loss from West Antarctica.”

Remy and Frezzotti (2006) reviewed “the results given by three different ways of estimating mass balance, first by measuring the difference between mass input and output, second by monitoring the changing geometry of the continent, and third by modeling both the dynamic and climatic evolution of the continent.” They report that “the current response of the Antarctica ice sheet is dominated by the background trend due to the retreat of the grounding line, leading to a sea-level rise of  $0.4 \text{ mm/yr}$  over the short-time scale,” which they describe in terms of *centuries*. However, they note that “later, the precipitation increase will counterbalance this residual signal, leading to a thickening of the ice sheet and thus a decrease in sea level.”

Krinner *et al.* (2007), in a study summarized in Section 5.6.3.3., used the LMDZ4 atmospheric general circulation model of Hourdin *et al.* (2006) to simulate Antarctic climate for the periods 1981-2000 (to test the model’s ability to adequately simulate present conditions) and 2081-2100 (to see what the future might hold for the mass balance of the Antarctic Ice Sheet and its impact on global sea level). They determined that “the simulated Antarctic surface mass balance increases by  $32 \text{ mm}$  water equivalent per year,” which corresponds “to a sea-level decrease of  $1.2 \text{ mm}$  per year by the end of the twenty-first century,” which would in turn “lead to a cumulated sea-level decrease of about  $6 \text{ cm}$ .” This result occurs because the simulated temperature increase “leads to an increased moisture transport towards the interior of the continent because of the

higher moisture holding capacity of warmer air,” where the extra moisture falls as precipitation, causing the continent’s ice sheet to grow.

There has been very little change in global sea level due to wastage of the WAIS over the past few decades, and there will probably be little change in both the near and far future. What wastage might occur along the coastal area of the ice sheet over the long term would likely be countered, or more than countered, by greater inland snowfall. In the case of the latter possibility, the entire Antarctic Ice Sheet could well compensate for any long-term wastage of the Greenland Ice Sheet that might occur.

Additional information on this topic, including reviews of newer publications as they become available, can be found at <http://www.co2science.org/subject/w/waissealevel.php>.

### 4.5.4. Greenland Ice Cap

Studies of the growth and decay of polar ice sheets are of great importance because of the relationships of these phenomena to global warming and the impacts they can have on sea level. In this section, we review a number of such studies that pertain to the Greenland Ice Sheet.

In the March 24, 2006 issue of *Science*, several commentaries heralded accelerating discharges of glacial ice from Greenland and Antarctica, while dispensing dire warnings of an imminent large, rapid, and accelerating sea-level rise (Bindschadler, 2006; Joughin, 2006; Kerr, 2006; Kennedy and Hanson, 2006). This distressing news was based largely on three reports published in the same issue (Ekstrom *et al.*, 2006; Otto-Bliesner *et al.*, 2006; Overpeck *et al.*, 2006), wherein the unnerving phenomena were attributed to anthropogenic-induced global warming.

Consider the report of Ekstrom *et al.*, who studied “glacial earthquakes” caused by sudden sliding motions of glaciers on Greenland. Over the period from January 1993 to October 2005, they determined that (1) *all* of the best-recorded quakes were

associated with major outlet glaciers on the east and west coasts of Greenland between approximately 65 and 76°N latitude, (2) “a clear increase in the number of events is seen starting in 2002,” and (3) “to date in 2005, twice as many events have been detected as in any year before 2002.”

With respect to the reason for the recent increase in glacial activity on Greenland, Clayton Sandell of ABC News on March 23, 2006 quoted Ekstrom as saying “I think it is very hard not to associate this with global warming,” which sentiment appears to be shared by almost all of the authors of the seven *Science* articles. Unwilling to join that conclusion, however, was Joughin, who in the very same issue presented histories of summer temperature at four coastal Greenland stations located within the same latitude range as the sites of the glacial earthquakes, which histories suggest that it was warmer in this region back in the 1930s than it was over the period of Ekstrom *et al.*'s analysis.

Based on these data, Joughin concluded that the recent warming in Greenland “is too short to determine whether it is an anthropogenic effect or natural variability,” a position that is supported by many scientists cited previously in this chapter, and more in the discussion that follows.

A study based on mean monthly temperatures of 37 Arctic and seven sub-Arctic stations and temperature anomalies of 30 grid-boxes from the updated dataset of Jones by Przybylak (2000) found (1) “in the Arctic, the highest temperatures since the beginning of instrumental observation occurred clearly in the 1930s,” (2) “even in the 1950s the temperature was higher than in the last 10 years,” (3) “since the mid-1970s, the annual temperature shows no clear trend,” and (4) “the level of temperature in Greenland in the last 10-20 years is similar to that observed in the 19th century.” These findings led him to conclude that the meteorological record “shows that the observed variations in air temperature in the real Arctic are in many aspects not consistent with the projected climatic changes computed by climatic models for the enhanced greenhouse effect,” because, in his words, “the temperature predictions produced by numerical climate models significantly differ from those actually observed.”

In light of these several other studies of real-world observations, it is clear that the recent upswing in glacial activity on Greenland likely has had nothing to do with anthropogenic-induced global warming, as temperatures there have yet to rise either as fast or as high as they did during the great warming of the

1920s, which was clearly a natural phenomenon. It is also important to recognize the fact that coastal glacial discharge represents only half of the equation relating to sea-level change, the other half being inland ice accumulation derived from precipitation; and when the mass balance of the entire Greenland ice sheet was recently assessed via satellite radar altimetry, quite a different result was obtained than that suggested by the seven *Science* papers.

Zwally *et al.* (2005) found that although “the Greenland ice sheet is thinning at the margins,” it is “growing inland with a small overall mass gain.” In fact, for the 11-year period 1992-2003, Johannessen *et al.* (2005) found that “below 1500 meters, the elevation-change rate is [a negative]  $2.0 \pm 0.9$  cm/year, in qualitative agreement with reported thinning in the ice-sheet margins,” but that “an increase of  $6.4 \pm 0.2$  cm/year is found in the vast interior areas above 1500 meters.” Spatially averaged over the bulk of the ice sheet, the net result, according to the latter researchers, was a mean increase of  $5.4 \pm 0.2$  cm/year, “or ~60 cm over 11 years, or ~54 cm when corrected for isostatic uplift.” Consequently, the Greenland Ice Sheet would appear to have experienced no net loss of mass over the last decade for which data are available. To the contrary, it was likely host to a net accumulation of ice, which Zwally *et al.* found to be producing a  $0.03 \pm 0.01$  mm/year decline in sea-level.

In an attempt to downplay the significance of these inconvenient findings, Kerr quoted Zwally as saying he believes that “right now” the Greenland Ice Sheet is experiencing a net loss of mass. Why? Kerr says Zwally's belief is “based on his gut feeling about the most recent radar and laser observations.” Gut feelings are a poor substitute for comprehensive real-world measurements, and even if Zwally's intestines are ultimately found to be correct, their confirmation would only demonstrate just how rapidly the Greenland environment can change. We would have to wait and see how long the mass losses prevailed in order to assess their significance within the context of the CO<sub>2</sub>-induced global warming debate. For the present and immediate future, therefore, we have no choice but to stick with what existent data and analyses suggest; i.e., that cumulatively since the early 1990s and conservatively (since the balance is likely still positive), there has been no net loss of mass from the Greenland Ice Sheet.

The recent study by Eldrett *et al.* (2007) provides further evidence that the IPCC's view of melting sea ice is wrong. The five researchers from the School of

Ocean and Earth Science of the National Oceanography Centre of the University of Southampton in the UK report they “have generated a new stratigraphy for three key Deep Sea Drilling Project/Ocean Drilling Program sites by calibrating dinocyst events to the geomagnetic polarity timescale.” In doing so, they say their detailed core observations revealed evidence for “extensive ice-rafted debris, including macroscopic dropstones, in late Eocene to early Oligocene sediments from the Norwegian-Greenland Sea that were deposited between about 38 and 30 million years ago.” They further report that their data “indicate sediment rafting by glacial ice, rather than sea ice, and point to East Greenland as the likely source,” and they conclude that their data thus suggest “the existence of (at least) isolated glaciers on Greenland about 20 million years earlier than previously documented.”

What is particularly interesting about this finding, as Eldrett *et al.* describe it, is that it indicates the presence of glacial ice on Greenland “at a time when temperatures and atmospheric carbon dioxide concentrations were substantially higher.” How much higher? According to graphs the researchers present, ocean bottom-water temperatures were 5-8°C warmer, while atmospheric CO<sub>2</sub> concentrations were as much as four times greater than they are today.

The problem these observations provide for those who hold to the view that global warming will melt the Greenland Ice Sheet, to quote Eldrett *et al.*, is that “palaeoclimate model experiments generate substantial ice sheets in the Northern Hemisphere for the Eocene only in runs where carbon dioxide levels are lower (approaching the pre-anthropogenic level) than suggested by proxy records,” which records indicate atmospheric CO<sub>2</sub> concentrations fully two to seven times greater than the pre-anthropogenic level during the time of the newly detected ice sheets.

“Regardless,” as the researchers say, their data “provide the first stratigraphically extensive evidence for the existence of continental ice in the Northern Hemisphere during the Palaeogene,” which “is about 20 million years earlier than previously documented, at a time when global deep water temperatures and, by extension, surface water temperatures at high latitude, were much warmer.” Therefore—and also “by extension”—we now have evidence of a much warmer period of time that failed to melt the Greenland Ice Sheet.

Continuing, Krabill *et al.* (2000) used data obtained from aircraft laser-altimeter surveys over northern Greenland in 1994 and 1999, together with

previously reported data from southern Greenland, to evaluate the mass balance of the Greenland Ice Sheet. Above an elevation of 2,000 meters they found areas of both thinning and thickening; and these phenomena nearly balanced each other, so that in the south there was a net thinning of  $11 \pm 7$  mm/year, while in the north there was a net thickening of  $14 \pm 7$  mm/year. Altogether, the entire region exhibited a net thickening of  $5 \pm 5$  mm/year; but in correcting for bedrock uplift, which averaged 4 mm/year in the south and 5 mm/year in the north, the average thickening rate decreased to practically nothing. The word used by Krabill *et al.* to describe the net balance was “zero.”

At lower elevations, thinning was found to predominate along approximately 70 percent of the coast. Here, however, flight lines were few and far between; so few and far between, in fact, that the researchers said that “in order to extend our estimates to the edge of the ice sheet in areas not bounded by our surveys, we calculated a hypothetical thinning rate on the basis of the coastal positive degree day anomalies.” Then, they interpolated between this calculated coastal thinning rate and the nearest observed elevation changes to obtain their final answer: a total net reduction in ice volume of 51 km<sup>3</sup>/year.

Unfortunately, it is difficult to know what estimates derived from interpolations based on calculations of a hypothetical thinning rate mean. We question their significance; and the researchers themselves do the same. They note that they do not have a “satisfactory explanation” for the “widespread thinning at elevations below 2000 m,” which suggests that the reason this phenomenon is unexplainable is that it may not be real. The authors further note that even if the thinning was real, it could not be due to global or regional warming, since Greenland temperature records indicate “the 1980s and early 1990s were about half a degree cooler than the 96-year mean.”

After discussing some other factors that could be involved, Krabill *et al.* state they are left with changes in ice dynamics as the most likely cause of the hypothetical ice sheet thinning. But they admit in their final sentence that “we have no evidence for such changes, and we cannot explain why they should apply to many glaciers in different parts of Greenland.” It would seem logical to admit this study resolves almost nothing about the mass balance of the coastal regions of the Greenland Ice Sheet and nothing about the subject of global warming and its

effect or non-effect upon this hypothetical phenomenon.

In a preliminary step required to better understand the relationship of glacier dynamics to climate change in West Greenland, Taurisano *et al.* (2004) described the temperature trends of the Nuuk fjord area during the past century. This analysis of all pertinent regional data led them to conclude that “at all stations in the Nuuk fjord, both the annual mean and the average temperature of the three summer months (June, July and August) exhibit a pattern in agreement with the trends observed at other stations in south and west Greenland (Humlum 1999; Hanna and Cappelen, 2003).” As they describe it, the temperature data “show that a warming trend occurred in the Nuuk fjord during the first 50 years of the 1900s, followed by a cooling over the second part of the century, when the average annual temperatures decreased by approximately 1.5°C.” Coincident with this cooling trend there was also what they describe as “a remarkable increase in the number of snowfall days (+59 days).” What is more, they report that “not only did the cooling affect the winter months, as suggested by Hanna and Cappelen (2002), but also the summer mean,” noting that “the summer cooling is rather important information for glaciological studies, due to the ablation-temperature relations.” Finally, they report there was no significant trend in annual precipitation. In their concluding discussion, Taurisano *et al.* remark that the temperature data they studied “reveal a pattern which is common to most other stations in Greenland.”

Rignot and Kanagaratnam (2005) used satellite radar interferometry observations of Greenland to detect what they described as “widespread glacier acceleration.” Calculating that this phenomenon had led to a doubling of the ice sheet mass deficit in the past decade and, therefore, a comparable increase in Greenland’s contribution to rising sea levels, they went on to claim that “as more glaciers accelerate ... the contribution of Greenland to sea-level rise will continue to increase.”

With respect to these contentions, we have no problem with what the two researchers have observed with respect to Greenland’s glaciers; but we feel compelled to note that what they have calculated with respect to the mass balance of Greenland’s Ice Sheet and what they say it implies about sea level are contradicted by more inclusive real-world data. One reason for this discrepancy is that instead of relying on measurements for this evaluation, Rignot and Kanagaratnam relied on the calculations of Hanna *et*

*al.* (2005), who used meteorological models “to retrieve annual accumulation, runoff, and surface mass balance.” When actual measurements of the ice sheet via satellite radar altimetry are employed, a decidedly different perspective is obtained, as indicated by the work of Zwally *et al.* (2005) and Johannessen *et al.* (2005), which we cited earlier. Consequently, and contrary to the claim of Rignot and Kanagaratnam, Greenland would appear to have experienced no ice sheet mass deficit in the past decade.

Shepherd and Wingham (2007) reviewed what is known about sea-level contributions arising from wastage of the Antarctic and Greenland Ice Sheets, concentrating on the results of 14 satellite-based estimates of the imbalances of the polar ice sheets that have been derived since 1998. These studies have been of three major types—standard mass budget analyses, altimetry measurements of ice-sheet volume changes, and measurements of the ice sheets’ changing gravitational attraction—and they have yielded a diversity of values, ranging from a sea-level-rise-equivalent of 1.0 mm/year to a sea-level-fall-equivalent of 0.15 mm/year. The two researchers conclude that the current “best estimate” of the contribution of polar ice wastage (from both Greenland and Antarctica) to global sea-level change is a rise of 0.35 millimeters per year, which over a century amounts to only 35 millimeters.

Even this unimpressive sea-level increase may be too large an estimate, for although two of Greenland’s largest outlet glaciers doubled their rates of mass loss in less than a year in 2004—causing the IPCC to claim the Greenland Ice Sheet was responding much more rapidly to global warming than anyone had ever expected—Howat *et al.* (2007) report that the two glaciers’ rates of mass loss “decreased in 2006 to near the previous rates.” And these observations, in their words, “suggest that special care must be taken in how mass-balance estimates are evaluated, particularly when extrapolating into the future, because short-term spikes could yield erroneous long-term trends.”

In conclusion, the part of the Northern Hemisphere that holds the lion’s share of the hemisphere’s ice has been cooling for the past half-century, and at a very significant rate, making it unlikely that its frozen water will be released to the world’s oceans. In addition, because the annual number of snowfall days over much of Greenland has increased so dramatically over the same time period, it is possible that enhanced accumulation of snow on

its huge ice sheet may be compensating for the melting of many of the world's mountain glaciers and keeping global sea level in check for this reason too. Lastly, Greenland's temperature trend of the past half-century has been just the opposite—and strikingly so—of that which is claimed for the Northern Hemisphere and the world by the IPCC.

Additional information on this topic, including reviews of newer publications as they become available, can be found at <http://www.co2science.org/subject/s/sealevelgreenland.php>.

### Introduction

The Intergovernmental Panel on Climate Change (IPCC) claims “most of the observed increase in global average temperatures since the mid-20th century is *very likely* due to the observed increase in anthropogenic greenhouse gas concentrations [italics in the original]” (IPCC, 2007-I, p. 10). The IPCC’s authors even tell us they have decided there is a better-than-90-percent probability that their shared opinion is true. But as we demonstrated in Chapter 1, the general circulation models upon which the IPCC rests its case are notoriously unreliable. In Chapter 2 we documented feedback factors and forcings that the IPCC clearly overlooked. In Chapters 3 and 4 we showed that observations do not confirm the temperatures and weather trends the IPCC said should exist if its theory were true.

In this chapter we set out evidence in favor of an alternative theory of climate change that holds that variations in the sun’s output and magnetic field, mediated by cosmic ray fluxes and changes in global cloud cover, play a larger role in regulating the earth’s temperature, precipitation, droughts, floods, monsoons, and other climate features than any past or expected human activities, including projected increases in GHG emissions. Unlike the IPCC, we do

not invent a measure of our confidence in this theory, nor do we confuse it with a forecast of future weather patterns. Rather, we make the case for this alternative theory to demonstrate how much we *don’t* know about earth’s climate, and therefore how wrong it is to assume that human activity is responsible for any variability in the climate that we cannot explain by pointing to already known forcings or feedbacks.

According to the IPCC, “changes in solar irradiance since 1750 are estimated to cause a radiative forcing of +0.12 [+0.06 to +0.30] W m<sup>-2</sup>,” which is an order of magnitude smaller than their estimated net anthropogenic forcing of +1.66 W m<sup>-2</sup> from CO<sub>2</sub> over the same time period (pp. 3,4). However, the studies summarized in this chapter suggest the IPCC has got it backwards, that it is the sun’s influence that is responsible for most climate change during the past century and beyond.

In the spirit of genuine scientific inquiry, in contrast to the IPCC’s agenda-driven focus on making its case against GHG, we examine some research that is truly on the frontiers of climate research today. We begin with a discussion of cosmic rays, followed by research on irradiance, and then survey the evidence linking solar variability to climate phenomena both ancient and recent.

### 5.1. Cosmic Rays

The study of extraterrestrial climatic forcing factors is primarily a study of phenomena related to the sun. Historically, this field of inquiry began with the work of Milankovitch (1920, 1941), who linked the cyclical glaciations of the past million years to the receipt of solar radiation at the surface of the earth as modulated by variations in earth's orbit and rotational characteristics. Subsequent investigations implicated a number of other solar phenomena that operate on both shorter and longer timescales; in this summary we review the findings of the subset of those studies that involve galactic cosmic rays.

We begin with the review paper of Svensmark (2007), Director of the Center for Sun-Climate Research of the Danish National Space Center, who starts by describing how he and his colleagues experimentally determined that electrons released to the atmosphere by galactic cosmic rays act as catalysts that significantly accelerate the formation of ultra-small clusters of sulfuric acid and water molecules that constitute the building blocks of cloud condensation nuclei. He then discusses how, during periods of greater solar magnetic activity, greater shielding of the earth occurs, resulting in less cosmic rays penetrating to the lower atmosphere, resulting in fewer cloud condensation nuclei being produced, resulting in fewer and less reflective low-level clouds occurring, which leads to more solar radiation being absorbed by the surface of the earth, resulting in increasing near-surface air temperatures and global warming.

Svensmark provides support for key elements of this scenario with graphs illustrating the close correspondence between global low-cloud amount and cosmic-ray counts over the period 1984-2004, as well as by the history of changes in the flux of galactic cosmic rays since 1700, which correlates well with earth's temperature history over the same time period, starting from the latter portion of the Maunder

Minimum (1645-1715), when Svensmark says "sunspots were extremely scarce and the solar magnetic field was exceptionally weak," and continuing on through the twentieth century, over which last hundred-year interval, as noted by Svensmark, "the sun's coronal magnetic field doubled in strength."

Svensmark cites the work of Bond *et al.* (2001), who in studying ice-rafted debris in the North Atlantic Ocean determined, in Svensmark's words, that "over the past 12,000 years, there were many icy intervals like the Little Ice Age" that "alternated with warm phases, of which the most recent were the Medieval Warm Period (roughly AD 900-1300) and the Modern Warm Period (since 1900)." And as Bond's 10-member team clearly indicates, "over the last 12,000 years virtually every centennial time-scale increase in drift ice documented in our North Atlantic records was tied to a solar minimum."

In another expansion of timescale—this one highlighting the work of Shaviv (2002, 2003) and Shaviv and Veizer (2003)—Svensmark presents plots of reconstructed sea surface temperature anomalies and relative cosmic ray flux over the last 550 million years, during which time the solar system experienced four passages through the spiral arms of the Milky Way galaxy, with the climatic data showing "rhythmic cooling of the earth whenever the sun crossed the galactic midplane, where cosmic rays are locally most intense." In addition, he notes that the "Snowball Earth" period of some 2.3 billion years ago "coincided with the highest star-formation rate in the Milky Way since the earth was formed, in a mini-starburst 2400-2000 million years ago," when, of course, the cosmic ray flux would have been especially intense. In light of these many diverse observations, Svensmark concludes that "stellar winds and magnetism are crucial factors in the origin and viability of life on wet earth-like planets," as are "ever-changing galactic environments and star-formation rates."

Several studies conducted over the past 10 years have uncovered evidence for several of the linkages described by Svensmark in his overview of what we could call the cosmic ray-climate connection. We start with the work of Lockwood *et al.* (1999), who examined measurements of the near-earth interplanetary magnetic field to determine the total magnetic flux leaving the sun since 1868. In doing so, they were able to show that the total magnetic flux from the sun rose by a factor of 1.41 over the period 1964-1996, while surrogate measurements of the

interplanetary magnetic field previous to this time indicate that this parameter had risen by a factor of 2.3 since 1901, which observations led the three researchers to state that the variation in the total solar magnetic flux they found “stresses the importance of understanding the connections between the sun’s output and its magnetic field and between terrestrial global cloud cover, cosmic ray fluxes and the heliospheric field.” The results of this study lead one to wonder just how much of the 0.8°C global temperature rise of the last century might have been a result of the more than two-fold increase in the total magnetic solar flux over that period.

Next, Parker (1999) noted that the number of sunspots had also doubled over the prior 100 years, and that one consequence of the latter phenomenon would have been “a much more vigorous sun” that was slightly brighter. Parker pointed out that spacecraft measurements suggest that the brightness (B) of the sun varies by an amount  $\Delta B/B = 0.15\%$ , in step with the 11-year magnetic cycle. He then pointed out that during times of much reduced activity of this sort (such as the Maunder Minimum of 1645-1715) and much increased activity (such as the twelfth century Mediaeval Maximum), brightness variations on the order of  $\Delta B/B = 0.5\%$  typically occur, after which he noted the mean temperature (T) of the northern portion of the earth varied by 1 to 2°C in association with these variations in solar activity, stating finally that “we cannot help noting that change in  $T/T = \text{change in } B/B$ .”

Knowing that sea surface temperatures are influenced by the brightness of the sun, and that they had risen since 1900, Parker wrote that “one wonders to what extent the solar brightening [of the past century] has contributed to the increase in atmospheric temperature and CO<sub>2</sub>” over that period. It was Parker’s “inescapable conclusion” that “we will have to know a lot more about the sun and the terrestrial atmosphere before we can understand the nature of the contemporary changes in climate.”

Digging deeper into the subject, Feynman and Ruzmaikin (1999) investigated twentieth century changes in the intensity of cosmic rays incident upon the earth’s magnetopause and their transmission through the magnetosphere to the upper troposphere. This work revealed “the intensity of cosmic rays incident on the magnetopause has decreased markedly during this century” and “the pattern of cosmic ray precipitation through the magnetosphere to the upper troposphere has also changed.”

With respect to the first and more basic of these changes, they noted that “at 300 MeV the difference between the proton flux incident on the magnetosphere at the beginning of the century and that incident now is estimated to be a factor of 5 decrease between solar minima at the beginning of the century and recent solar minima,” and that “at 1 GeV the change is a factor of 2.5.” With respect to the second phenomenon, they noted that the part of the troposphere open to cosmic rays of all energies increased by a little over 25 percent and shifted equatorward by about 6.5° of latitude. And with the great decrease in the intensity of cosmic rays incident on earth’s magnetosphere over the twentieth century, one would have expected to see a progressive decrease in the presence of low-level clouds and, therefore, an increase in global air temperature, as has indeed been observed.

A number of other pertinent papers also appeared at this time. Black *et al.* (1999) conducted a high-resolution study of sediments in the southern Caribbean that were deposited over the past 825 years, finding substantial variability of both a decadal and centennial nature, which suggested that such climate regime shifts are a natural aspect of Atlantic variability; and relating these features to other records of climate variability, they concluded that “these shifts may play a role in triggering changes in the frequency and persistence of drought over North America.” Another of their findings was a strong correspondence between the changes in North Atlantic climate and similar changes in <sup>14</sup>C production; and they concluded that this finding “suggests that small changes in solar output may influence Atlantic variability on centennial time scales.”

Van Geel *et al.* (1999) reviewed what was known at the time about the relationship between variations in the abundances of the cosmogenic isotopes <sup>14</sup>C and <sup>10</sup>Be and millennial-scale climate oscillations during the Holocene and portions of the last great ice age. This exercise indicated “there is mounting evidence suggesting that the variation in solar activity is a cause for millennial scale climate change,” which is known to operate independently of the glacial-interglacial cycles that are forced by variations in the earth’s orbit about the sun. They also reviewed the evidence for various mechanisms by which the postulated solar-climate connection might be implemented, finally concluding that “the climate system is far more sensitive to small variations in solar activity than generally believed” and that “it

could mean that the global temperature fluctuations during the last decades are partly, or completely explained by small changes in solar radiation.”

Noting that recent research findings in both palaeoecology and solar science “indicate a greater role for solar forcing in Holocene climate change than has previously been recognized,” Chambers *et al.* (1999) reviewed the subject and found much evidence for solar-driven variations in earth-atmosphere processes over a range of timescales stretching from the 11-year solar cycle to century-scale events. They acknowledged, however, that absolute solar flux variations associated with these phenomena are rather small; but they identified a number of “multiplier effects” that can operate on solar rhythms in such a way that, as they describe it, “minor variations in solar activity can be reflected in more significant variations within the earth’s atmosphere.” They also noted that such nonlinear amplifier responses to solar variability are inadequately represented in the global climate models used by the IPCC to predict future greenhouse gas-induced global warming, even though that organization employs other amplifier effects to model well-known glacial/interglacial cycles of temperature change of the past, as well as the hypothesized CO<sub>2</sub>-induced warming of the future.

Noting that “solar magnetic activity exhibits chaotically modulated cycles ... which are responsible for slight variations in solar luminosity and modulation of the solar wind,” Tobias and Weiss (2000) attacked the solar forcing of climate problem by means of a model in which the solar dynamo and earth’s climate are represented by low-order systems, each of which in isolation supports chaotic oscillations but which when run together sometimes resonate. By this means they determined that “solutions oscillate about either of two fixed points, representing warm and cold states, flipping sporadically between them.” They also discovered that a weak nonlinear input from the solar dynamo “has a significant effect when the ‘typical frequencies’ of each system are in resonance.” “It is clear,” they say, “that the resonance provides a powerful mechanism for amplifying climate forcing by solar activity.”

Contemporaneously, Solanki *et al.* (2000) developed a model of the long-term evolution of the sun’s large-scale magnetic field and compared its predictions against two proxy measures of this parameter. The model proved successful in reproducing the observed century-long doubling of the strength of the part of the sun’s magnetic field that

reaches out from the sun’s surface into interplanetary space. It also indicated there is a direct connection between the length of the 11-year sunspot cycle and secular variations in solar activity that occur on timescales of centuries, such as the Maunder Minimum of the latter part of the seventeenth century, when sunspots were few in number and earth was in the midst of the Little Ice Age.

In discussing their findings, the solar scientists say their modeled reconstruction of the solar magnetic field “provides the major parameter needed to reconstruct the secular variation of the cosmic ray flux impinging on the terrestrial atmosphere,” because, as they continue, a stronger solar magnetic field “more efficiently shields the earth from cosmic rays,” and “cosmic rays affect the total cloud cover of the earth and thus drive the terrestrial climate.”

One year later, using cosmic ray data recorded by ground-based neutron monitors, global precipitation data from the Climate Predictions Center Merged Analysis of Precipitation project, and estimates of monthly global moisture from the National Centers for Environmental Prediction reanalysis project, Kniveton and Todd (2001) set out to evaluate whether there is empirical evidence to support the hypothesis that solar variability (represented by changes in cosmic ray flux) is linked to climate change (manifested by changes in precipitation and precipitation efficiency) over the period 1979-1999. In doing so, they determined there is “evidence of a statistically strong relationship between cosmic ray flux, precipitation and precipitation efficiency over ocean surfaces at mid to high latitudes,” since variations in both precipitation and precipitation efficiency for mid to high latitudes showed a close relationship in both phase and magnitude with variations in cosmic ray flux, varying 7-9 percent during the solar cycle of the 1980s, while other potential forcing factors were ruled out due to poorer statistical relationships.

Also in 2001, Bond *et al.* (2001) published the results of their study of ice-rafted debris found in three North Atlantic deep-sea sediment cores and cosmogenic nuclides sequestered in the Greenland ice cap (<sup>10</sup>Be) and Northern Hemispheric tree rings (<sup>14</sup>C). Based on arduous analyses of deep-sea sediment cores that yielded the variable-with-depth amounts of three proven proxies for the prior presence of overlying drift-ice, the scientists were able to discern and, with the help of an accelerator mass spectrometer, date a number of recurring alternate periods of relative cold and warmth that wended their

way through the entire 12,000-year expanse of the Holocene. The mean duration of the several complete climatic cycles thus delineated was 1,340 years, the cold and warm nodes of the latter of which oscillations, in the words of Bond *et al.*, were “broadly correlative with the so called ‘Little Ice Age’ and ‘Medieval Warm Period’.”

The signal accomplishment of the scientists’ study was the linking of these millennial-scale climate oscillations—and their embedded centennial-scale oscillations—with similar-scale oscillations in cosmogenic nuclide production, which are known to be driven by contemporaneous oscillations in solar activity. In fact, Bond *et al.* were able to report that “over the last 12,000 years virtually every centennial time-scale increase in drift ice documented in our North Atlantic records was tied to a solar minimum.” In light of this observation they thus concluded that “a solar influence on climate of the magnitude and consistency implied by our evidence could not have been confined to the North Atlantic,” suggesting that the cyclical climatic effects of the variable solar inferno are experienced throughout the world.

At this point in their paper, the international team of scientists cited additional evidence in support of the implications of their work. With respect to the global extent of the climatic impact of the solar radiation variations they detected, they reference studies conducted in Scandinavia, Greenland, the Netherlands, the Faroe Islands, Oman, the Sargasso Sea, coastal West Africa, the Cariaco Basin, equatorial East Africa, and the Yucatan Peninsula, demonstrating thereby that “the footprint of the solar impact on climate we have documented extend[s] from polar to tropical latitudes.” They note “the solar-climate links implied by our record are so dominant over the last 12,000 years ... it seems almost certain that the well-documented connection between the Maunder solar minimum and the coldest decades of the Little Ice Age could not have been a coincidence,” further noting that their findings supported previous suggestions that both the Little Ice Age and Medieval Warm Period “may have been partly or entirely linked to changes in solar irradiance.”

Another point reiterated by Bond *et al.* is that the oscillations in drift-ice they studied “persist across the glacial termination and well into the last glaciation, suggesting that the cycle is a pervasive feature of the climate system.” At two of their coring sites, they identified a series of such cyclical variations that extended throughout all of the previous interglacial and were “strikingly similar to those of the

Holocene.” Here they could also have cited the work of Oppo *et al.* (1998), who observed similar climatic oscillations in a sediment core that covered the span of time from 340,000 to 500,000 years before present, and that of Raymo *et al.* (1998), who pushed back the time of the cycles’ earliest known occurrence to well over one million years ago.

How do the small changes in solar radiation inferred from the cosmogenic nuclide variations bring about such significant and pervasive shifts in earth’s global climate? Bond *et al.* described a scenario whereby solar-induced changes high in the stratosphere are propagated downward through the atmosphere to the earth’s surface, where they envisioned them provoking changes in North Atlantic deep water formation that alter the thermohaline circulation of the global ocean. In light of the plausibility of this particular scenario, they suggested that “the solar signals thus may have been transmitted through the deep ocean as well as through the atmosphere, further contributing to their amplification and global imprint.”

Concluding their landmark paper, the researchers wrote that the results of their study “demonstrate that the earth’s climate system is highly sensitive to extremely weak perturbations in the sun’s energy output,” noting their work “supports the presumption that solar variability will continue to influence climate in the future.”

The following year, Carlsaw *et al.* (2002) began an essay on “Cosmic Rays, Clouds, and Climate” by noting that the intensity of cosmic rays varies by about 15 percent over a solar cycle, due to changes in the strength of the solar wind, which carries a weak magnetic field into the heliosphere that partially shields the earth from low-energy galactic charged particles. When this shielding is at a minimum, allowing more cosmic rays to impinge upon the planet, more low clouds have been observed to cover the earth, producing a tendency for lower temperatures to occur. When the shielding is maximal, on the other hand, fewer cosmic rays impinge upon the planet and fewer low clouds form, which produces a tendency for the earth to warm.

The three researchers further noted that the total variation in low cloud amount over a solar cycle is about 1.7 percent, which corresponds to a change in the planet’s radiation budget of about one watt per square meter ( $1 \text{ Wm}^{-2}$ ). This change, they say, “is highly significant when compared ... with the estimated radiative forcing of  $1.4 \text{ Wm}^{-2}$  from anthropogenic  $\text{CO}_2$  emissions.” However, because of

the short length of a solar cycle (11 years), the large thermal inertia of the world's oceans dampens the much greater global temperature change that would have occurred as a result of this radiative forcing if it had been spread out over a much longer period of time, so that the actual observed warming is something a little less than 0.1°C.

Much of Carslaw *et al.*'s review focuses on mechanisms by which cosmic rays might induce the synchronous low cloud cover changes that have been observed to accompany their intensity changes. They begin by briefly describing the three principal mechanisms that have been suggested to function as links between solar variability and changes in earth's weather: (1) changes in total solar irradiance that provide variable heat input to the lower atmosphere, (2) changes in solar ultraviolet radiation and its interaction with ozone in the stratosphere that couple dynamically to the lower atmosphere, and (3) changes in cloud processes having significance for condensation nucleus abundances, thunderstorm electrification and thermodynamics, and ice formation in cyclones.

Focusing on the third of these mechanisms, the researchers note that cosmic rays provide the sole source of ions away from terrestrial sources of radioisotopes. Hence, they further refine their focus to concentrate on ways by which cosmic-ray-produced ions may affect cloud droplet number concentrations and ice particles. Here, they concentrate on two specific topics: what they call the ion-aerosol clear-air mechanism and the ion-aerosol near-cloud mechanism. Their review suggests that what we know about these subjects is very much less than what we *could* know about them. Many scientists, as they describe it, believe "it is inconceivable that the lower atmosphere can be globally bombarded by ionizing radiation without producing an effect on the climate system."

Carslaw *et al.* point out that cosmic ray intensity declined by about 15 percent during the last century "owing to an increase in the solar open magnetic flux by more than a factor of 2." They further report that "this 100-year change in intensity is about the same magnitude as the observed change over the last solar cycle." In addition, we note that the cosmic ray intensity was already much lower at the start of the twentieth century than it was just after the start of the nineteenth century, when the Esper *et al.* (2002) record indicates the planet began its nearly two-century-long recovery from the chilly depths of the Little Ice Age.

These observations strongly suggest that solar-mediated variations in the intensity of cosmic rays bombarding the earth are indeed responsible for the temperature variations of the past three centuries. They provide a much better fit to the temperature data than do atmospheric CO<sub>2</sub> data; and as Carslaw *et al.* remark, "if the cosmic ray-cloud effect is real, then these long-term changes of cosmic ray intensity could substantially influence climate." It is this possibility, they say, that makes it "all the more important to understand the cause of the cloudiness variations," which is basically the message of their essay; i.e., that we must work hard to deepen our understanding of the cosmic ray-cloud connection, as it may well hold the key to resolving what they call this "fiercely debated geophysical phenomenon."

One year later, and noting that Svensmark and Friis-Christensen (1997), Marsh and Svensmark (2000), and Palle Bago and Butler (2000) had derived positive relationships between global cosmic ray intensity and low-cloud amount from infrared cloud data contained in the International Satellite Cloud Climatology Project (ISCCP) database for the years 1983-1993, Marsden and Lingenfelter (2003) used the ISCCP database for the expanded period 1983-1999 to see if a similar relationship could be detected via cloud amount measurements made in the visible spectrum. This work revealed that there was indeed, in their words, "a positive correlation at low altitudes, which is consistent with the positive correlation between global low clouds and cosmic ray rate seen in the infrared."

That same year, Shaviv and Veizer (2003) suggested that from two-thirds to three-fourths of the variance in earth's temperature (T) over the past 500 million years may be attributable to cosmic ray flux (CRF) variations due to solar system passages through the spiral arms of the Milky Way galaxy. This they did after presenting several half-billion-year histories of T, CRF, and atmospheric CO<sub>2</sub> concentrations derived from various types of proxy data, and after finding that none of the CO<sub>2</sub> curves showed any clear correlation with the T curves, suggesting to them that "CO<sub>2</sub> is not likely to be the principal climate driver." On the other hand, they discovered that the T trends displayed a dominant cyclic component on the order of  $135 \pm 9$  million years, and that "this regular pattern implies that we may be looking at a reflection of celestial phenomena in the climate history of earth."

That such is likely the case is borne out by their identification of a similar CRF cycle of  $143 \pm 10$

million years, together with the fact that the large cold intervals in the T records “appear to coincide with times of high CRF,” which correspondence is what would be expected from the likely chain of events: high CRF ==> more low-level clouds ==> greater planetary albedo ==> colder climate, as described by Svensmark and Friis-Christensen (1997), Marsh and Svensmark (2000), Palle Bago and Butler (2000), and Marsden and Lingefelter (2003).

What do these findings suggest about the role of atmospheric CO<sub>2</sub> variations with respect to global temperature change? Shaviv and Veizer began their analysis of this question by stating that the conservative approach is to assume that the entire residual variance not explained by measurement error is due to CO<sub>2</sub> variations. And when this was done, they found that a doubling of the air’s CO<sub>2</sub> concentration could account for only about a 0.5°C increase in T.

This result differs considerably, in their words, “from the predictions of the general circulation models, which typically imply a CO<sub>2</sub> doubling effect of ~1.5-5.5°C,” but they say it is “consistent with alternative lower estimates of 0.6-1.6°C (Lindzen, 1997).” We note also, in this regard, that Shaviv and Veizer’s result is even more consistent with the results of the eight empirically based “natural experiments” of Idso (1998), which yield an average warming of about 0.4°C for a 300 to 600 ppm doubling of the atmosphere’s CO<sub>2</sub> concentration.

In another important test of a critical portion of the cosmic ray-climate connection theory, Usoskin *et al.* (2004b) compared the spatial distributions of low cloud amount (LCA) and cosmic ray-induced ionization (CRII) over the globe for the period 1984-2000. They used observed LCA data obtained from the ISCCP-D2 database limited to infrared radiances, while they employed CRII values calculated by Usoskin *et al.* (2004a) at 3 km altitude, which corresponds roughly to the limiting altitude below which low clouds form. This work revealed that “the LCA time series can be decomposed into a long-term slow trend and inter-annual variations, the latter depicting a clear 11-year cycle in phase with CRII.” In addition, they found there was “a one-to-one relation between the relative variations of LCA and CRII over the latitude range 20-55°S and 10-70°N,” and that “the amplitude of relative variations in LCA was found to increase polewards, in accordance with the amplitude of CRII variations.” These findings of the five-member team of Finnish, Danish, and Russian scientists provide substantial evidence for a

solar-cosmic ray linkage (the 11-year cycle of CRII) and a cosmic ray-cloud linkage (the in-phase cycles of CRII and CLA), making the full solar activity/cosmic ray/low cloud/climate change hypothesis appear to be rather robust.

In a review of the temporal variability of various solar phenomena conducted the following year, Lean (2005) made the following important but disturbing point about climate models and the sun-climate connection: “a major enigma is that general circulation climate models predict an immutable climate in response to decadal solar variability, whereas surface temperatures, cloud cover, drought, rainfall, tropical cyclones, and forest fires show a definite correlation with solar activity (Haigh, 2001, Rind, 2002).”

Lean begins her review by noting that the beginning of the Little Ice Age “coincided with anomalously low solar activity (the so-called Sporer and Maunder minima),” and that “the latter part coincided with both low solar activity (the Dalton minimum) and volcanic eruptions.” Then, after discussing the complexities of this potential relationship, she muses about another alternative: “Or might the Little Ice Age be simply the most recent cool episode of millennial climate-oscillation cycles?” Lean cites evidence that reveals the sensitivity of drought and rainfall to solar variability, stating that climate models are unable to reproduce the plethora (her word) of sun-climate connections. She notes that simulations with climate models yield decadal and centennial variability even in the absence of external forcing, stating that “arguably, this very sensitivity of the climate system to unforced oscillation and stochastic noise predisposes it to nonlinear responses to small forcings such as by the sun.”

Lean reports that “various high-resolution paleoclimate records in ice cores, tree rings, lake and ocean sediment cores, and corals suggest that changes in the energy output of the sun itself may have contributed to sun-earth system variability,” citing the work of Verschuren *et al.* (2000), Hodell *et al.* (2001), and Bond *et al.* (2001). She notes that “many geographically diverse records of past climate are coherent over time, with periods near 2400, 208 and 90 years that are also present in the <sup>14</sup>C and <sup>10</sup>Be archives,” which isotopes (produced at the end of a complex chain of interactions that are initiated by galactic cosmic rays) contain information about various aspects of solar activity (Bard *et al.*, 1997).

Veretenenko *et al.* (2005) examined the potential influence of galactic cosmic rays (GCR) on the long-

term variation of North Atlantic sea-level pressure over the period 1874-1995. Their comparisons of long-term variations in cold-season (October-March) sea-level pressure with different solar/geophysical indices revealed that increasing sea-level pressure coincided with a secular rise in solar/geomagnetic activity that was accompanied by a decrease in GCR intensity, whereas long-term decreases in sea-level pressure were observed during periods of decreasing solar activity and rising GCR flux. Spectral analysis further supported a link between sea-level pressure, solar/geomagnetic activity and GCR flux, as similar spectral characteristics (periodicities) were present among all datasets at time scales from approximately 10 to 100 years.

These results support a link between long-term variations in cyclonic activity and trends in solar activity/GCR flux in the extratropical latitudes of the North Atlantic. Concerning how this relationship works, Veretenenko *et al.* hypothesize that GCR-induced changes in cloudiness alter long-term variations in solar and terrestrial radiation receipt in this region, which in turn alters tropospheric temperature gradients and produces conditions more favorable for cyclone formation and development. Although we are still far from possessing a complete understanding of many solar/GCR-induced climatic influences, this study highlights the ever-growing need for such relationships to be explored. As it and others have shown, small changes in solar output can indeed induce significant changes in earth's climate.

Also working in the North Atlantic region, Macklin *et al.* (2005) developed what they call "the first probability-based, long-term record of flooding in Europe, which spans the entire Holocene and uses a large and unique database of  $^{14}\text{C}$ -dated British flood deposits," after which they compared their reconstructed flood history "with high-resolution proxy-climate records from the North Atlantic region, northwest Europe and the British Isles to critically test the link between climate change and flooding." By these means they determined that "the majority of the largest and most widespread recorded floods in Great Britain have occurred during cool, moist periods," and that "comparison of the British Holocene palaeoflood series ... with climate reconstructions from tree-ring patterns of subfossil bog oaks in northwest Europe also suggests that a similar relationship between climate and flooding in Great Britain existed during the Holocene, with floods being more frequent and larger during relatively cold, wet periods." In addition, they say that

"an association between flooding episodes in Great Britain and periods of high or increasing cosmogenic  $^{14}\text{C}$  production suggests that centennial-scale solar activity may be a key control of non-random changes in the magnitude and recurrence frequencies of floods."

Another intriguing study from this time period, Usoskin *et al.* (2005), noted that "the variation of the cosmic ray flux entering earth's atmosphere is due to a combination of solar modulation and geomagnetic shielding, the latter adding a long-term trend to the varying solar signal," while further noting that "the existence of a geomagnetic signal in the climate data would support a direct effect of cosmic rays on climate." They evaluated this proposition by reproducing 1,000-year reconstructions of two notable solar-heliospheric indices derived from cosmogenic isotope data, i.e., the sunspot number and the cosmic ray flux (Usoskin *et al.*, 2003; Solanki *et al.*, 2004), and by creating a new 1,000-year air temperature history of the Northern Hemisphere by computing annual means of six different thousand-year surface air temperature series: those of Jones *et al.* (1998), Mann *et al.* (1999), Briffa (2000), Crowley (2000), Esper *et al.* (2002), and Mann and Jones (2003).

In comparing these three series (solar activity, cosmic ray, and air temperature), Usoskin *et al.* found that they "indicate higher temperatures during times of more intense solar activity (higher sunspot number, lower cosmic ray flux)." In addition, they report that three different statistical tests "consistently indicate that the long-term trends in the temperature correlate better with cosmic rays than with sunspots," which suggests that something in addition to solar activity must have been influencing the cosmic ray flux, in order to make the cosmic ray flux the better correlate of temperature.

Noting that earth's geomagnetic field strength would be a natural candidate for this "something," Usoskin *et al.* compared their solar activity, cosmic ray, and temperature reconstructions with two long-term reconstructions of geomagnetic dipole moment that they obtained from the work of Hongre *et al.* (1998) and Yang *et al.* (2000). This effort revealed that between AD 1000 and 1700, when there was a substantial downward trend in air temperature associated with a less substantial downward trend in solar activity, there was also a general downward trend in geomagnetic field strength. As a result, Usoskin *et al.* suggested that the substantial upward trend of cosmic ray flux that was needed to sustain

the substantial rate of observed cooling (which was more than expected in light of the slow decline in solar activity) was likely due to the positive effect on the cosmic ray flux that was produced by the decreasing geomagnetic field strength.

After 1700, the geomagnetic field strength continued to decline, but air temperature did a dramatic turnabout and began to rise. The reason for this “parting of company” between the two parameters, according to Usoskin *et al.*, was that “the strong upward trend of solar activity during that time overcompensate[d] [for] the geomagnetic effect,” leading to a significant warming. In addition, a minor portion of the warming of the last century or so (15–20 percent) may have been caused by the concomitant increase in the atmosphere’s CO<sub>2</sub> content, which would have complemented the warming produced by the upward trending solar activity and further decoupled the upward trending temperature from the declining geomagnetic field strength.

In their totality, these several observations tend to strengthen the hypothesis that cosmic ray variability was the major driver of changes in earth’s surface air temperature over the past millennium, and that this forcing was primarily driven by variations in solar activity, modulated by the more slowly changing geomagnetic field strength of the planet, which sometimes strengthened the solar forcing and sometimes worked against it. Once again, however, the results leave room for only a small impact of anthropogenic CO<sub>2</sub> emissions on twentieth century global warming.

Publishing in the same year, Versteegh (2005) reviewed what we know about past climatic responses to solar forcing and their geographical coherence based upon proxy records of temperature and the cosmogenic radionuclides <sup>10</sup>Be and <sup>14</sup>C, which provide a measure of magnetized plasma emissions from the sun that impact earth’s exposure to galactic cosmic rays, thereby altering cloud formation and climate. As a result of this exercise, it was concluded that “proxy records provide ample evidence for climate change during the relatively stable and warm Holocene,” and that “all frequency components attributed to solar variability re-occur in proxy records of environmental change,” emphasizing in this regard “the ~90 years Gleisberg and ~200 years Suess cycles in the <sup>10</sup>Be and <sup>14</sup>C records,” as well as “the ~1500 years Bond cycle which occurs in several proxy records [and] could originate from the interference between centennial-band solar cycles.” As a result, Versteegh concludes that “long-term

climate change during the preindustrial [era] seems to have been dominated by solar forcing,” and that the long-term response to solar forcing “greatly exceeds unforced variability.”

Delving further into the subject, Harrison and Stephenson (2005) introduce their contribution by noting that because the net global effect of clouds is cooling (Hartman, 1993), any widespread increase in the amount of overcast days could reduce air temperature globally, while local overcast conditions could do so locally. They compared the ratio of diffuse to total solar radiation (the diffuse fraction, DF)—which had been measured daily at 0900 UT at Whiteknights, Reading (UK) from 1997–2004—with the traditional subjective determination of cloud amount made simultaneously by a human observer, as well as with daily average temperature. They then compared the diffuse fraction measured at Jersey between 1968 and 1994 with corresponding daily mean neutron count rates measured at Climax, Colorado (USA), which provide a globally representative indicator of the galactic cosmic ray flux. The result, as they describe it, was that “across the UK, on days of high cosmic ray flux (which occur 87% of the time on average) compared with low cosmic ray flux, (i) the chance of an overcast day increases by 19% ± 4%, and (ii) the diffuse fraction increases by 2% ± 0.3%.” In addition, they found that “during sudden transient reductions in cosmic rays (e.g. Forbush events), simultaneous decreases occur in the diffuse fraction.”

As for the implications of their findings, the two researchers note that the latter of these observations indicates that diffuse radiation changes are “unambiguously due to cosmic rays.” They also report that “at Reading, the measured sensitivity of daily average temperatures to DF for overcast days is -0.2 K per 0.01 change in DR.” Consequently, they suggest that the well-known inverse relationship between galactic cosmic rays and solar activity will lead to cooling at solar minima, and that “this might amplify the effect of the small solar cycle variation in total solar irradiance, believed to be underestimated by climate models (Stott *et al.*, 2003) which neglect a cosmic ray effect.” In addition, although the effect they detect is small, they say it is “statistically robust,” and that the cosmic ray effect on clouds likely “will emerge on long time scales with less variability than the considerable variability of daily cloudiness.”

Next, Shaviv (2005) identified six periods of earth’s history (the entire Phanerozoic, the

Cretaceous, the Eocene, the Last Glacial Maximum, the twentieth century, and the 11-year solar cycle as manifest over the last three centuries) for which he was able to derive reasonably sound estimates of different time-scale changes in radiative forcing, temperature, and cosmic ray flux. From these sets of data he derived probability distribution functions of whole-earth temperature sensitivity to radiative forcing for each time period and combined them to obtain a mean planetary temperature sensitivity to radiative forcing of  $0.28^{\circ}\text{C}$  per  $\text{Wm}^{-2}$ . Then, noting that the IPCC (2001) had suggested that the increase in anthropogenic radiative forcing over the twentieth century was about  $0.5 \text{ Wm}^{-2}$ , Shaviv calculated that the anthropogenic-induced warming of the globe over this period was approximately  $0.14^{\circ}\text{C}$  ( $0.5 \text{ Wm}^{-2} \times 0.28^{\circ}\text{C}$  per  $\text{Wm}^{-2}$ ). This result harmonizes perfectly with the temperature increase ( $0.10^{\circ}\text{C}$ ) that was calculated by Idso (1998) to be due solely to the twentieth century increase in the air's  $\text{CO}_2$  concentration (75 ppm), which would have been essentially indistinguishable from Shaviv's result if the warming contributions of the twentieth century concentration increases of all greenhouse gases had been included in the calculation.

Based on information that indicated a solar activity-induced increase in radiative forcing of  $1.3 \text{ Wm}^{-2}$  over the twentieth century (by way of cosmic ray flux reduction), plus the work of others (Hoyt and Schatten, 1993; Lean *et al.*, 1995; Solanki and Fligge, 1998) that indicated a globally averaged solar luminosity increase of approximately  $0.4 \text{ Wm}^{-2}$  over the same period, Shaviv calculated an overall and ultimately solar activity-induced warming of  $0.47^{\circ}\text{C}$  ( $1.7 \text{ Wm}^{-2} \times 0.28^{\circ}\text{C}$  per  $\text{Wm}^{-2}$ ) over the twentieth century. Added to the  $0.14^{\circ}\text{C}$  of anthropogenic-induced warming, the calculated total warming of the twentieth century thus came to  $0.61^{\circ}\text{C}$ , which was noted by Shaviv to be very close to the  $0.57^{\circ}\text{C}$  temperature increase that was said by the IPCC to have been observed over the past century. Consequently, both Shaviv's and Idso's analyses, which mesh well with real-world data of both the recent and distant past, suggest that only 15-20 percent ( $0.10^{\circ}\text{C}/0.57^{\circ}\text{C}$ ) of the observed warming of the twentieth century can be attributed to the rise in the air's  $\text{CO}_2$  content.

Usoskin *et al.* (2006) note that many solar scientists believe changes in solar activity have been responsible for significant changes in climate, but that to demonstrate that such is truly the case, a record of past variations in solar activity is required. They write

that "long-term solar activity in the past is usually estimated from cosmogenic isotopes,  $^{10}\text{Be}$  or  $^{14}\text{C}$ , deposited in terrestrial archives such as ice cores and tree rings," because "the production rate of cosmogenic isotopes in the atmosphere is related to the cosmic ray flux impinging on earth," which "is modulated by the heliospheric magnetic field and is thus a proxy of solar activity." A nagging concern, however, is that the isotope records may suffer from what the five scientists call "uncertainties due to the sensitivity of the data to several *terrestrial* [our italics] processes." Consequently, they devised a plan to attempt to resolve this issue.

Noting that the activity of a cosmogenic isotope in a meteorite represents "the time integrated cosmic ray flux over a period determined by the mean life of the radioisotope," Usoskin *et al.* reasoned that (1) "by measuring abundance of cosmogenic isotopes in meteorites which fell through the ages, one can evaluate the variability of the cosmic ray flux, since the production of cosmogenic isotopes ceases after the fall of the meteorite," and that (2) if they could develop such a meteoritic-based cosmogenic isotope record they could use it "to constrain [other] solar activity reconstructions using cosmogenic  $^{44}\text{Ti}$  activity in meteorites *which is not affected by terrestrial processes* [our italics]."

The researchers' choice of  $^{44}\text{Ti}$  for this purpose was driven by the fact that it has a half-life of about 59 years and is thus "relatively insensitive to variations of the cosmic ray flux on decadal or shorter time scales, but is very sensitive to the level of the cosmic ray flux and its variations on a centennial scale." Hence, they compared the results of different long-term  $^{10}\text{Be}$ - and  $^{14}\text{C}$ -based solar activity reconstruction models with measurements of  $^{44}\text{Ti}$  in 19 stony meteorites (chondrites) that fell between 1766 and 2001, as reported by Taricco *et al.* (2006); in doing so, they ultimately determined that "most recent reconstructions of solar activity, in particular those based on  $^{10}\text{Be}$  data in polar ice (Usoskin *et al.*, 2003, 2004c; McCracken *et al.*, 2004) and on  $^{14}\text{C}$  in tree rings (Solanki *et al.*, 2004), are consistent with the  $^{44}\text{Ti}$  data." Consequently, the results of this study give ever more credence to the findings of the many studies that have reported strong correlations between various climatic changes and  $^{10}\text{Be}$ - and  $^{14}\text{C}$ -based reconstructions of solar activity.

Dergachev *et al.* (2006) reviewed "direct and indirect data on variations in cosmic rays, solar activity, geomagnetic dipole moment, and climate from the present to 10-12 thousand years ago, [as]

registered in different natural archives (tree rings, ice layers, etc.).” They found that “galactic cosmic ray levels in the earth’s atmosphere are inversely related to the strength of the helio- and geomagnetic fields,” and they conclude that “cosmic ray flux variations are apparently the most effective natural factor of climate changes on a large time scale.” More specifically, they note that “changes in cloud processes under the action of cosmic rays, which are of importance for abundance of condensation nuclei and for ice formation in cyclones, can act as a connecting link between solar variability and changes in weather and climate,” and they cite numerous scientific studies that indicate that “cosmic rays are a substantial factor affecting weather and climate on time scales of hundreds to thousands of years.”

Voiculescu *et al.* (2006) observed “there is evidence that solar activity variations can affect the cloud cover at Earth. However, it is still unclear which solar driver plays the most important role in the cloud formation. Here, we use partial correlations to distinguish between the effects of two solar drivers (cosmic rays and the UV irradiance) and the mutual relations between clouds at different altitudes.” They found “a strong solar signal in the cloud cover” and that “low clouds are mostly affected by UV irradiance over oceans and dry continental areas and by cosmic rays over some mid-high latitude oceanic areas and moist lands with high aerosol concentration. High clouds respond more strongly to cosmic ray variations, especially over oceans and moist continental areas. These results provide observational constraints on related climate models.”

Gallet and Genevey (2007) documented what they call a “good temporal coincidence” between “periods of geomagnetic field intensity increases and cooling events,” as measured in western Europe, where cooling events were “marked by glacier advances on land and increases in ice-rafted debris in [North Atlantic] deep-sea sediments.” Their analyses revealed “a succession of three cooling periods in western Europe during the first millennium AD,” the ages of which were “remarkably coincident with those of the main discontinuities in the history of Maya civilization,” confirming the earlier similar work of Gallet *et al.* (2005), who had found a “good temporal coincidence in western Europe between cooling events recovered from successive advances of Swiss glaciers over the past 3000 years and periods of rapid increases in geomagnetic field intensity,” the latter of which were “nearly coeval with abrupt changes, or hairpin turns, in magnetic field direction.”

Gallet and Genevey concluded that “the most plausible mechanism linking geomagnetic field and climate remains a geomagnetic impact on cloud cover,” whereby “variations in morphology of the earth’s magnetic field could have modulated the cosmic ray flux interacting with the atmosphere, modifying the nucleation rate of clouds and thus the albedo and earth surface temperatures (Gallet *et al.*, 2005; Courtillot *et al.*, 2007).” These observations clearly suggest a global impact on climate, which is further suggested by the close relationship that has been found to exist between “cooling periods in the North Atlantic and aridity episodes in the Middle East,” as well as by the similar relationship demonstrated by Gallet and Genevey to have prevailed between periods of aridity over the Yucatan Peninsula and well-documented times of crisis in Mayan civilization.

In another study that took a look at the *really* big picture, painted by rhythmically interbedded limestone and shale or limestone and chert known as *rhythmites*, Elrick and Hinnov (2007) “(1) review the persistent and widespread occurrence of Palaeozoic *rhythmites* across North America, (2) demonstrate their primary depositional origin at millennial time scales, (3) summarize the range of paleo-environmental conditions that prevailed during *rhythmite* accumulation, and (4) briefly discuss the implications primary Palaeozoic *rhythmites* have on understanding the origin of pervasive late Neogene-Quaternary millennial-scale climate variability.” They concluded that “millennial-scale climate changes occurred over a very wide spectrum of paleoceanographic, paleogeographic, paleoclimatic, tectonic, and biologic conditions and over time periods from the Cambrian to the Quaternary,” and that given this suite of observations, “it is difficult to invoke models of internally driven thermohaline oceanic oscillations or continental ice sheet instabilities to explain their origin.” Consequently, they suggest that “millennial-scale paleoclimate variability is a more permanent feature of the earth’s ocean-atmosphere system, which points to an external driver such as solar forcing.”

Kirkby (2008) reports that “diverse reconstructions of past climate change have revealed clear associations with cosmic ray variations recorded in cosmogenic isotope archives, providing persuasive evidence for solar or cosmic ray forcing of the climate.” He discusses two different classes of microphysical mechanisms that have been proposed to connect cosmic rays with clouds, which interact

significantly with fluxes of both solar and thermal radiation and, therefore, climate: “firstly, an influence of cosmic rays on the production of cloud condensation nuclei and, secondly, an influence of cosmic rays on the global electrical circuit in the atmosphere and, in turn, on ice nucleation and other cloud microphysical processes.” Kirkby observes that “considerable progress on understanding ion-aerosol-cloud processes has been made in recent years, and the results are suggestive of a physically plausible link between cosmic rays, clouds and climate” and “with new experiments planned or underway, such as the CLOUD facility at CERN, there are good prospects that we will have some firm answers to this question within the next few years.”

In one final review paper, Lu (2009) showed that in the period of 1980–2007, two full 11-year cosmic ray cycles clearly correlated with ozone depletion, especially the polar ozone loss (hole) over Antarctica. The temporal correlation is also supported by a strong spatial correlation because the ozone hole is located in the lower polar stratosphere at ~18 km, exactly where the ionization rate of cosmic rays producing electrons is the strongest. The results provide strong evidence that the cosmic ray-driven electron-induced reaction of halogenated molecules plays the dominant role in causing the ozone hole. Changes in ozone then have a global impact on climate.

In conclusion, and as Kirkby (2008) rightly notes, “the question of whether, and to what extent, the climate is influenced by solar and cosmic ray variability remains central to our understanding of the anthropogenic contribution to present climate change.” Clearly, carbon dioxide is not the all-important dominating factor in earth’s climatic history. Within the context of the Holocene, the only time CO<sub>2</sub> moved in concert with air temperature was over the period of earth’s recovery from the global chill of the Little Ice Age (the past century or so), and it does so then only quite imperfectly. The flux of galactic cosmic rays, on the other hand, appears to have influenced ups and downs in both temperature and precipitation over the entire 10-12 thousand years of the Holocene, making it the prime candidate for “prime determinant” of earth’s climatic state.

## 5.2. Irradiance

We begin this section of our review of the potential effects of solar activity on earth's climate with the study of Karlén (1998), who examined proxy climate data related to changes in summer temperatures in Scandinavia over the past 10,000 years. This temperature record—derived from analyses of changes in the size of glaciers, changes in the altitude

of the alpine tree-limit, and variations in the width of annual tree rings—was compared with contemporaneous solar irradiance data derived from  $^{14}\text{C}$  anomalies measured in tree rings. The former record revealed both long- and short-term temperature fluctuations; it was noted by Karlén that during warm periods the temperature was “about  $2^\circ\text{C}$  warmer than at present.” In addition, the temperature fluctuations were found to be “closely related” to the  $^{14}\text{C}$ -derived changes in solar irradiation, leading him to conclude that “the similarity between solar irradiation changes and climate indicate a solar influence on the Scandinavian and Greenland climates.” This association led him to further conclude that “the frequency and magnitude of changes in climate during the Holocene [i.e., the current interglacial] do not support the opinion that the climatic change of the last 100 years is unique.” He bluntly stated that “there is no evidence of a human influence so far.”

Also writing just before the turn of the century, Lockwood *et al.* (1999) analyzed measurements of the near-earth interplanetary magnetic field to determine the total magnetic flux leaving the sun since 1868. Based on their analysis, they were able to show that the total magnetic flux leaving the sun rose by a factor of 1.41 over the period 1964-1996, while surrogate measurements of the interplanetary magnetic field previous to this time indicated that this parameter had increased by a factor of 2.3 since 1901. These findings and others linking changes in solar magnetic activity with terrestrial climate change led the authors to state that “the variation [in the total solar magnetic flux] found here stresses the importance of understanding the connections between the sun’s output and its magnetic field and between terrestrial global cloud cover, cosmic ray fluxes and the heliospheric field.”

Parker (1999) noted that the number of sunspots also doubled over the same time period, and that one consequence of this phenomenon is a much more vigorous sun that is slightly brighter. Parker also drew attention to the fact that NASA spacecraft measurements had revealed that the brightness (B) of the sun varies by an amount “change in  $B/B = 0.15\%$ , in step with the 11-year magnetic cycle.” He then pointed out that during times of much reduced activity of this sort (such as the Maunder Minimum of 1645-1715) and much increased activity (such as the twelfth century Mediaeval Maximum), brightness variations on the order of change in  $B/B = 0.5\%$  typically occur, after which he indicated that the mean temperature (T) of the northern portion of the earth

varied by 1 to  $2^\circ\text{C}$  in association with these variations in solar activity, stating finally that “we cannot help noting that change in  $T/T = \text{change in } B/B$ .”

Also in 1999, Chambers *et al.* noted that recent research findings in both palaeoecology and solar science “indicate a greater role for solar forcing in Holocene climate change than has previously been recognized,” which subject they then proceeded to review. In doing so, they found much evidence within the Holocene for solar-driven variations in earth-atmosphere processes over a range of timescales stretching from the 11-year solar cycle to century-scale events. They acknowledge that the absolute solar flux variations associated with these phenomena are rather small; but they identify a number of “multiplier effects” that can operate on solar rhythms in such a way that “minor variations in solar activity can be reflected in more significant variations within the earth’s atmosphere.”

The three researchers also noted, in this regard, that nonlinear responses to solar variability are inadequately represented (in fact, they are essentially ignored) in the global climate models used by the IPCC to predict future  $\text{CO}_2$ -induced global warming, while at the same time other amplifier effects are used to model the hypothesized  $\text{CO}_2$ -induced global warming of the future, where  $\text{CO}_2$  is only an initial perturber of the climate system which, according to the IPCC, sets other more powerful forces in motion that produce the bulk of the warming.

At the start of the new millennium, Bard *et al.* (2000) listed some of the many different types of information that have been used to reconstruct past solar variability, including “the envelope of the SSN [sunspot number] 11-year cycle (Reid, 1991), the length and decay rate of the solar cycle (Hoyt and Schatten, 1993), the structure and decay rate of individual sunspots (Hoyt and Schatten, 1993), the mean level of SSN (Hoyt and Schatten, 1993; Zhang *et al.*, 1994; Reid, 1997), the solar rotation and the solar diameter (Nesme-Ribes *et al.*, 1993), and the geomagnetic aa index (Cliver *et al.*, 1998).” They also noted that “Lean *et al.* (1995) proposed that the irradiance record could be divided into 2 superimposed components: an 11-year cycle based on the parameterization of sunspot darkening and facular brightening (Lean *et al.*, 1992), and a slowly varying background derived separately from studies of sun-like stars (Baliunas and Jastrow, 1990),” and that Solanki and Fligge (1998) had developed an even more convoluted technique. Bard *et al.*, however, used an entirely different approach.

Rather than directly characterize some aspect of solar variability, they assessed certain consequences of that variability. Specifically, they noted that magnetic fields of the solar wind deflect portions of the primary flux of charged cosmic particles in the vicinity of the earth, leading to reductions in the creation of cosmogenic nuclides in earth's atmosphere. Consequently, they reasoned that histories of the atmospheric concentrations of  $^{14}\text{C}$  and  $^{10}\text{Be}$  can be used as proxies for solar activity, as noted many years earlier by Lal and Peters (1967).

In employing this approach to the problem, the four researchers first created a 1,200-year history of cosmogenic production in earth's atmosphere from  $^{10}\text{Be}$  measurements of South Pole ice (Raisbeck *et al.*, 1990) and the atmospheric  $^{14}\text{C}/^{12}\text{C}$  record as measured in tree rings (Bard *et al.*, 1997). This record was then converted to total solar irradiance (TSI) values by "applying a linear scaling using the TSI values published previously for the Maunder Minimum," when cosmogenic production was 30-50 percent above the modern value.

This approach resulted in an extended TSI record that suggests, in their words, that "solar output was significantly reduced between AD 1450 and 1850, but slightly higher or similar to the present value during a period centered around AD 1200." "It could thus be argued," they say, "that irradiance variations may have contributed to the so-called 'little ice age' and 'medieval warm period'."

In discussing this idea, Bard *et al.* downplay their own suggestion, because, as they report, "some researchers have concluded that the 'little ice age' and/or 'medieval warm period' [were] regional, rather than global events." Noting the TSI variations they developed from their cosmogenic data "would tend to force global effects," they felt they could not associate this global impetus for climate change with what other people were calling regional climatic anomalies. With respect to these thoughts, we refer the reader to Section 3.2 of this report, where it is demonstrated that the Little Ice Age and Medieval Warm Period were truly global in extent.

Rozelot (2001) conducted a series of analyses designed to determine whether phenomena related to variations in the radius of the sun may have influenced earth's climate over the past four centuries. The results of these analyses revealed, in the words of the researcher, that "at least over the last four centuries, warm periods on the earth correlate well with smaller apparent diameter of the Sun and colder ones with a bigger sun." Although the results

of this study were correlative and did not identify a physical mechanism capable of inducing significant climate change on earth, Rozelot reports that the changes in the sun's radius are "of such magnitude that significant effects on the earth's climate are possible."

Rigozo *et al.* (2001) created a history of sunspot numbers for the last 1,000 years "using a sum of sine waves derived from spectral analysis of the time series of sunspot number  $R_Z$  for the period 1700-1999," and from this record they derived the strengths of a number of parameters related to various aspects of solar variability. In describing their results, the researchers say that "the 1000-year reconstructed sunspot number reproduces well the great maximums and minimums in solar activity, identified in cosmogenic variation records, and, specifically, the epochs of the Oort, Wolf, Sporer, Maunder, and Dalton Minimums, as well [as] the Medieval and Modern Maximums," the latter of which they describe as "starting near 1900." The mean sunspot number for the Wolf, Sporer, and Maunder Minimums was 1.36. For the Oort and Dalton Minimums it was 25.05; for the Medieval Maximum it was 53.00; and for the Modern Maximum it was 57.54. Compared to the average of the Wolf, Sporer, and Maunder Minimums, therefore, the mean sunspot number of the Oort and Dalton Minimums was 18.42 times greater; that of the Medieval Maximum was 38.97 times greater; and that of the Modern Maximum was 42.31 times greater. Similar strength ratios for the solar radio flux were 1.41, 1.89, and 1.97, respectively. For the solar wind velocity the corresponding ratios were 1.05, 1.10, and 1.11; while for the southward component of the interplanetary magnetic field they were 1.70, 2.54, and 2.67. In comparing these numbers, both the Medieval and Modern Maximums in sunspot number and solar variability parameters stand out above all other periods of the past thousand years, with the Modern Maximum slightly besting the Medieval Maximum.

Noting that a number of different spacecraft have monitored total solar irradiance (TSI) for the past 23 years, with at least two of them operating simultaneously at all times, and that TSI measurements made from balloons and rockets supplement the satellite data, Frohlich and Lean (2002) compared the composite TSI record with an empirical model of TSI variations based on known magnetic sources of irradiance variability, such as sunspot darkening and brightening, after which they described how "the TSI record may be extrapolated

back to the seventeenth century Maunder Minimum of anomalously lower solar activity, which coincided with the coldest period of the Little Ice Age.” This exercise, as they have described it, “enables an assessment of the extent of post-industrial climate change that may be attributable to a varying sun, and how much the sun might influence future climate change.”

In reporting their results, Frolich and Lean state that “warming since 1650 due to the solar change is close to 0.4°C, with pre-industrial fluctuations of 0.2°C that are seen also to be present in the temperature reconstructions.” From this study, therefore, it would appear that solar variability can explain a significant portion of the warming experienced by the earth in recovering from the global chill of the Little Ice Age, with a modicum of positive feedback accounting for the rest. With respect to the future, however, the two solar scientists say that “solar forcing is unlikely to compensate for the expected forcing due to the increase of anthropogenic greenhouse gases which are projected to be about a factor of 3-6 larger.” The magnitude of that anthropogenic forcing, however, has been computed by many different approaches to be much smaller than the value employed by Frohlich and Lean in making this comparison (Idso, 1998).

Contemporaneously, Douglass and Clader (2002) used multiple regression analysis to separate surface and atmospheric temperature responses to solar irradiance variations over the past two-and-a-half solar cycles (1979-2001) from temperature responses produced by variations in ENSO and volcanic activity. Based on the satellite-derived lower tropospheric temperature record, they evaluated the sensitivity ( $k$ ) of temperature ( $T$ ) to solar irradiance ( $I$ ), where temperature sensitivity to solar irradiance is defined as  $k = \Delta T / \Delta I$ , obtaining the result of  $k = 0.11 \pm 0.02^\circ\text{C}/(\text{W}/\text{m}^2)$ . Similar analyses based on the radiosonde temperature record of Parker *et al.* (1997) and the surface air temperature records of Jones *et al.* (2001) and Hansen and Lebedeff (1987, with updates) produced  $k$  values of 0.13, 0.09, and  $0.11^\circ\text{C}/(\text{W}/\text{m}^2)$ , respectively, with the identical standard error of  $\pm 0.02^\circ\text{C}/(\text{W}/\text{m}^2)$ . In addition, they reported that White *et al.* (1997) derived a decadal timescale solar sensitivity of  $0.10 \pm 0.02^\circ\text{C}/(\text{W}/\text{m}^2)$  from a study of upper ocean temperatures over the period 1955-1994 and that Lean and Rind (1998) derived a value of  $0.12 \pm 0.02^\circ\text{C}/(\text{W}/\text{m}^2)$  from a paleo-reconstructed temperature record spanning the period 1610-1800. They concluded that “the close agreement of these

various independent values with our value of  $0.11 \pm 0.02 [^\circ\text{C}/(\text{W}/\text{m}^2)]$  suggests that the sensitivity  $k$  is the same for both decadal and centennial time scales and for both ocean and lower tropospheric temperatures.” They further suggest that if these values of  $k$  hold true for centennial time scales, which appears to be the case, their high-end value implies a surface warming of  $0.2^\circ\text{C}$  over the last 100 years in response to the  $1.5 \text{ W}/\text{m}^2$  increase in solar irradiance inferred by Lean (2000) for this period. This warming represents approximately one-third of the total increase in global surface air temperature estimated by Parker *et al.* (1997),  $0.55^\circ\text{C}$ , and Hansen *et al.* (1999),  $0.65^\circ\text{C}$ , for the same period. It does not, however, include potential indirect effects of more esoteric solar climate-affecting phenomena, such as those discussed in Section 5.1 of this report, that could also have been operative over this period.

Foukal (2002) analyzed the findings of spaceborne radiometry and reported that “variations in total solar irradiance,  $S$ , measured over the past 22 years, are found to be closely proportional to the difference in projected areas of dark sunspots,  $AS$ , and of bright magnetic plage elements,  $APN$ , in active regions and in enhanced network,” plus the finding that “this difference varies from cycle to cycle and is not simply related to cycle amplitude itself,” which facts suggest there is “little reason to expect that  $S$  will track any of the familiar indices of solar activity.” On the other hand, he notes that “empirical modeling of spectro-radiometric observations indicates that the variability of solar ultraviolet flux,  $FUV$ , at wavelengths shorter than approximately 250 nm, is determined mainly by  $APN$  alone.”

Building upon this conceptual foundation, and using daily data from the Mt. Wilson Observatory that covered the period 1905-1984, plus partially overlapping data from the Sacramento Peak Observatory that extended through 1999, Foukal derived time series of both total solar and UV irradiances between 1915 and 1999, which he then compared with global temperature data for the same time period. This work revealed, in his words, that “correlation of our time series of UV irradiance with global temperature,  $T$ , accounts for only 20% of the global temperature variance during the 20<sup>th</sup> century,” but that “correlation of our total irradiance time series with  $T$  accounts *statistically* for 80% of the variance in global temperature over that period.”

The UV findings of Foukal were not impressive, but the results of his total solar irradiance analysis were, leading him to state that “the possibility of

significant driving of twentieth century climate by total irradiance variation cannot be dismissed.” Although the magnitude of the total solar effect was determined to be “a factor 3-5 lower than expected to produce a significant global warming contribution based on present-day climate model sensitivities,” what Foukal calls the “high correlation between S and T” strongly suggests that changes in S largely determine changes in T, the confirmation of which suggestion likely merely awaits what he refers to as an “improved understanding of possible climate sensitivity to relatively small total irradiance variation.”

In the following year, Willson and Mordvinov (2003) analyzed total solar irradiance (TSI) data obtained from different satellite platforms over the period 1978-2002, attempting to resolve various small but important inconsistencies among them. In doing so, they came to the realization that “construction of TSI composite databases will not be without its controversies for the foreseeable future.” Nevertheless, their most interesting result, in the estimation of the two researchers, was their confirmation of a +0.05%/decade trend between the minima separating solar cycles 21-22 and 22-23, which they say “appears to be significant.”

Willson and Mordvinov say the finding of the 0.05 percent/decade minimum-to-minimum trend “means that TSI variability can be caused by unknown mechanisms other than the solar magnetic activity cycle,” which means that “much longer time scales for TSI variations are therefore a possibility,” which they say “has obvious implications for solar forcing of climate.” Specifically, it means there could be undiscovered long-term variations in total solar irradiance of a magnitude that could possibly explain centennial-scale climate variability, which Bond *et al.* (2001) have already demonstrated to be related to solar activity, as well as the millennial-scale climatic oscillation that pervades both glacial and interglacial periods for essentially as far back in time as paleoclimatologists can see (Oppo *et al.*, 1998; Raymo *et al.*, 1998).

Like Willson and Mordvinov, Foukal (2003) acknowledged that “recent evidence from ocean and ice cores suggests that a significant fraction of the variability in northern hemisphere climate since the last Ice Age correlates with solar activity (Bond *et al.*, 2001),” while additionally noting that “a recent reconstruction of S [total solar irradiance] from archival images of spots and faculae obtained daily from the Mt. Wilson Observatory in California since

1915 shows remarkable agreement with smoothed global temperature in the 20<sup>th</sup> century,” citing his own work of 2002. However, he was forced to acknowledge that the observed variations in S between 1978 and 2002 were not large enough to explain the observed temperature changes on earth within the context of normal radiative forcing. Hence, he proceeded to review the status of research into various subjects that might possibly be able to explain this dichotomy. Specifically, he presented an overview of then-current knowledge relative to the idea that “the solar impact on climate might be driven by other variable solar outputs of ultraviolet radiation or plasmas and fields via more complex mechanisms than direct forcing of tropospheric temperature.” As could have been expected, the article contained no grand revelations; when all was said and done, Foukal returned pretty much to where he had started, concluding that “we cannot rule out multi-decadal variations in S sufficiently large to influence climate, yet overlooked so far through limited sensitivity and time span of our present observational techniques.”

The following year, Damon and Laut (2004) reported what they described as errors made by Friis-Christensen and Lassen (1991), Svensmark and Friis-Christensen (1997), Svensmark (1998) and Lassen and Friis-Christensen (2000) in their presentation of solar activity data, correlated with terrestrial temperature data. The Danish scientists’ error, in the words of Damon and Laut, was “adding to a heavily smoothed (‘filtered’) curve, four additional points covering the period of global warming, which were only partially filtered or not filtered at all.” This in turn led to an apparent dramatic increase in solar activity over the last quarter of the twentieth century that closely matched the equally dramatic rise in temperature manifest by the Northern Hemispheric temperature reconstruction of Mann *et al.* (1998, 1999) over the same period. With the acquisition of additional solar activity data in subsequent years, however, and with what Damon and Laut called the proper handling of the numbers, the late twentieth century dramatic increase in solar activity totally disappears.

This new result, to quote Damon and Laut, means that “the sensational agreement with the recent global warming, which drew worldwide attention, has totally disappeared.” In reality, however, it is only the agreement with the last quarter-century of the discredited Mann *et al.* “hockey stick” temperature history that has disappeared. This new disagreement is most welcome, for the Mann *et al.* temperature

reconstruction is likely in error over this stretch of time. (See Section 3.2.)

Using a nonlinear non-stationary time series technique called empirical mode decomposition, Coughlin and Tung (2004) analyzed monthly mean geopotential heights and temperatures—obtained from Kalnay *et al.* (1996)—from 1000 hPa to 10 hPa over the period January 1958 to December 2003. This work revealed the existence of five oscillations and a trend in both datasets. The fourth of these oscillations has an average period of 11 years and indicates enhanced warming during times of maximum solar radiation. As the two researchers describe it, “the solar flux is positively correlated with the fourth modes in temperature and geopotential height almost everywhere [and] the overwhelming picture is that of a positive correlation between the solar flux and this mode throughout the troposphere.”

Coughlin and Tung concluded that “the atmosphere warms during the solar maximum almost everywhere over the globe.” And the unfailing omnipresent impact of this small forcing (a 0.1 percent change in the total energy output of the sun from cycle minimum to maximum) suggests that any longer-period oscillations of the solar inferno could well be causing the even greater centennial- and millennial-scale oscillations of temperature that are observed in paleotemperature data from various places around the world.

Additional light on the subject has been provided by widespread measurements of the flux of solar radiation received at the surface of the earth that have been made since the late 1950s. Nearly all of these measurements reveal a sizeable decline in the surface receipt of solar radiation that was not reversed until the mid-1980s, as noted by Wild *et al.* (2005). During this time, there was also a noticeable dip in earth’s surface air temperature, after which temperatures rose at a rate and to a level of warmth that the IPCC claims were both without precedent over the past one to two millennia, which phenomena they attribute to similarly unprecedented increases in greenhouse gas concentrations, the most notable, of course, being CO<sub>2</sub>.

This reversal of the decline in the amount of solar radiation incident upon the earth’s surface, in the words of Wild *et al.*, “is reconcilable with changes in cloudiness and atmospheric transmission and may substantially affect surface climate.” They say, for example, that “whereas the decline in solar energy could have counterbalanced the increase in downwelling longwave energy from the enhanced

greenhouse effect before the 1980s, the masking of the greenhouse effect and related impacts may no longer have been effective thereafter, enabling the greenhouse signals to become more evident during the 1990s.” Qualitatively, this scenario sounds reasonable; but when the magnitude of the increase in the surface-received flux of solar radiation over the 1990s is considered, the statement is seen to be rather disingenuous.

Over the range of years for which high-quality data were available to them (1992-2002), Wild *et al.* determined that the mean worldwide increase in clear-sky insolation averaged 0.68 Wm<sup>-2</sup> per year, which increase they found to be “comparable to the increase under all-sky conditions.” Consequently, for that specific 10-year period, these real-world data suggest that the total increase in solar radiation received at the surface of the earth should have been something on the order of 6.8 Wm<sup>-2</sup>, which is not significantly different from what is implied by the satellite and “earthshine” data of Palle *et al.* (2004), although the satellite data of Pinker *et al.* (2005) suggest an increase only about a third as large for this period.

Putting these numbers in perspective, Charlson *et al.* (2005) report that the longwave radiative forcing provided by all greenhouse gas increases since the beginning of the industrial era has amounted to only 2.4 Wm<sup>-2</sup>, citing the work of Anderson *et al.* (2003), while Palle *et al.* say that “the latest IPCC report argues for a 2.4 Wm<sup>-2</sup> increase in CO<sub>2</sub> longwave forcing since 1850.” Consequently, it can be readily appreciated that the longwave forcing of greenhouse gases over the 1990s would have been but a fraction of a fraction of the observed increase in the contemporary receipt of solar radiation at the surface of the earth. To thus suggest, as Wild *et al.* do, that the increase in insolation experienced at the surface of the earth over the 1990s may have enabled anthropogenic greenhouse gas signals of that period to become more evident, seems incongruous, as their suggestion implies that the bulk of the warming of that period was due to increases in greenhouse gas concentrations, when the solar component of the temperature forcing was clearly much greater. And this incongruity is made all the worse by the fact that methane concentrations rose ever more slowly over this period, apparently actually stabilizing near its end (see Section 2.6. Methane). Consequently, a much more logical conclusion would be that the primary driver of the global warming of the 1990s was the large increase in global surface-level insolation.

A final paper of note from 2005 was that of Soon (2005), who explored the question of which variable was the dominant driver of twentieth century temperature change in the Arctic—rising atmospheric CO<sub>2</sub> concentrations or variations in solar irradiance—by examining what roles the two variables may have played in decadal, multi-decadal, and longer-term variations in surface air temperature (SAT). He performed a number of statistical analyses on (1) a composite Arctic-wide SAT record constructed by Polyakov *et al.* (2003), (2) global CO<sub>2</sub> concentrations taken from estimates given by the NASA GISS climate modeling group, and (3) a total solar irradiance (TSI) record developed by Hoyt and Schatten (1993, updated by Hoyt in 2005) over the period 1875-2000.

The results of these analyses indicated a much stronger statistical relationship between SATs and TSI, as opposed to SATs and CO<sub>2</sub>. Solar forcing generally explained well over 75 percent of the variance in decadal-smoothed seasonal and annual Arctic SATs, while CO<sub>2</sub> forcing explained only between 8 and 22 percent of the variance. Wavelet analysis further supported the case for solar forcing of the SAT record, revealing similar time-frequency characteristics for annual and seasonally averaged temperatures at decadal and multi-decadal time scales. By contrast, wavelet analysis gave little to no indication of a CO<sub>2</sub> forcing of Arctic SSTs. Based on these data and analyses, therefore, it would appear that the sun, not atmospheric CO<sub>2</sub>, has been the driving force for temperature change in the Arctic.

Lastovicka (2006) summarized recent advancements in the field, saying “new results from various space and ground-based experiments monitoring the radiative and particle emissions of the sun, together with their terrestrial impact, have opened an exciting new era in both solar and atmospheric physics,” stating that “these studies clearly show that the variable solar radiative and particle output affects the earth’s atmosphere and climate in many fundamental ways.” That same year, Bard and Frank (2006) examined “changes on different time scales, from the last million years up to recent decades,” and in doing so critically assessed recent claims that “the variability of the sun has had a significant impact on global climate.” “Overall,” in the judgment of the two researchers, the role of solar activity in causing climate change “remains unproven.” However, as they state in the concluding sentence of their abstract, “the weight of evidence suggests that solar changes have contributed to small

climate oscillations occurring on time scales of a few centuries, similar in type to the fluctuations classically described for the last millennium: the so-called Medieval Warm Period (AD 900-1400) followed on by the Little Ice Age (AD 1500-1800).”

In another study from 2006, which also reviewed the scientific literature, Beer *et al.* (2006) explored what we know about solar variability and its possible effects on earth’s climate, focusing on two types of variability in the flux of solar radiation incident on the earth. The first type, in their words, “is due to changes in the orbital parameters of the earth’s position relative to the sun induced by the other planets,” which arises from gravitational perturbations that “induce changes with characteristic time scales in the eccentricity (~100,000 years), the obliquity (angle between the equator and the orbital plane, ~40,000 years) and the precession of the earth’s axis (~20,000 years),” while the second type is due to variability within the sun itself.

With respect to the latter category, the three researchers report that direct observations of total solar irradiance above the earth’s atmosphere have been made only over the past quarter-century, while observations of sunspots have been made and recorded for approximately four centuries. In between the time scales of these two types of measurements fall neutron count rates and aurora counts. Therefore, <sup>10</sup>Be and other cosmogenic radionuclides (such as <sup>14</sup>C)—stored in ice, sediment cores, and tree rings—currently provide our only means of inferring solar irradiance variability on a millennial time scale. These cosmogenic nuclides “clearly reveal that the sun varies significantly on millennial time scales and most likely plays an important role in climate change,” especially within this particular time domain. In reference to their <sup>10</sup>Be-based derivation of a 9,000-year record of solar modulation, Beer *et al.* note that its “comparison with paleoclimatic data provides strong evidence for a causal relationship between solar variability and climate change.”

We have now reached the work of Nicola Scafetta, a research scientist in the Duke University physics department, and Bruce West, chief scientist in the mathematical and information science directorate of the U.S. Army Research Office in Research Triangle Park, North Carolina. To better follow the arc of their work, we’ll temporarily abandon our chronological ordering of this literature review.

Scafetta and West (2006a) developed “two distinct TSI reconstructions made by merging in 1980 the annual mean TSI proxy reconstruction of Lean *et*

*al.* (1995) for the period 1900-1980 and two alternative TSI satellite composites, ACRIM (Willson and Mordvinov, 2003), and PMOD (Frohlich and Lean, 1998), for the period 1980-2000,” and then used a climate sensitivity transfer function to create twentieth century temperature histories. The results suggested that the sun contributed some 46 to 49 percent of the 1900-2000 global warming of the earth. Considering that there may have been uncertainties of 20 to 30 percent in their sensitivity parameters, the two researchers suggested the sun may have been responsible for as much as 60 percent of the twentieth century temperature rise.

Scafetta and West say the role of the sun in twentieth century global warming has been significantly underestimated by the climate modeling community, with various energy balance models producing estimates of solar-induced warming over this period that are “two to ten times lower” than what they found. The two researchers say “the models might be inadequate because of the difficulty of modeling climate in general and a lack of knowledge of climate sensitivity to solar variations in particular.” They also note that “theoretical models usually acknowledge as solar forcing only the direct TSI forcing,” thereby ignoring “possible additional climate effects linked to solar magnetic field, UV radiation, solar flares and cosmic ray intensity modulations.” In this regard, we additionally note that some of these phenomena may to some degree be independent of, and thereby add to, the simple TSI forcing Scafetta and West employed, which suggests that the totality of solar activity effects on climate may be even greater than what they calculated.

In a second study published in the same year, Scafetta and West (2006b) begin by noting that nearly all attribution studies begin with pre-determined forcing and feedback mechanisms in the models they employ. “One difficulty with this approach,” according to Scafetta and West, “is that the feedback mechanisms and alternative solar effects on climate, since they are only partially known, might be poorly or not modeled at all.” Consequently, “to circumvent the lack of knowledge in climate physics,” they adopt “an alternative approach that attempts to evaluate the total direct plus indirect effect of solar changes on climate by comparing patterns in the secular temperature and TSI reconstructions,” where “a TSI reconstruction is not used as a radiative forcing, but as a proxy [for] the entire solar dynamics.” They then proceed on the assumption that “the secular climate sensitivity to solar change can be phenomenologically

estimated by comparing ... solar and temperature records during the pre-industrial era, when, reasonably, only a negligible amount of anthropogenic-added climate forcing was present,” and when “the sun was the only realistic force affecting climate on a secular scale.”

Scafetta and West used the Northern Hemispheric temperature reconstruction of Moberg *et al.* (2005), three alternative TSI proxy reconstructions developed by Lean *et al.* (1995), Lean (2000), and Wang *et al.* (2005), and a scale-by-scale transfer model of climate sensitivity to solar activity changes created by themselves (Scafetta and West, 2005, 2006a) and found what they called a “good correspondence between global temperature and solar induced temperature curves during the pre-industrial period, such as the cooling periods occurring during the Maunder Minimum (1645-1715) and the Dalton Minimum (1795-1825).” In addition, they note that since the time of the seventeenth century solar minimum, “the sun has induced a warming of  $\Delta T \sim 0.7$  K,” and that “this warming is of the same magnitude [as] the cooling of  $\Delta T \sim 0.7$  K from the medieval maximum to the 17<sup>th</sup> century minimum,” which finding, in their words, “suggests the presence of a millenarian solar cycle, with ... medieval and contemporary maxima, driving the climate of the last millennium,” as was first suggested fully three decades ago by Eddy (1976) in his seminal study of the Maunder Minimum.

Scafetta and West say their work provides substantive evidence for the likelihood that “solar change effects are greater than what can be explained by several climate models,” citing Stevens and North (1996), the Intergovernmental Panel on Climate Change (2001), Hansen *et al.* (2002), and Foukal *et al.* (2004); and they note that a solar change “might trigger several climate feedbacks and alter the greenhouse gas (H<sub>2</sub>O, CO<sub>2</sub>, CH<sub>4</sub>, etc.) concentrations, as 420,000 years of Antarctic ice core data would also suggest (Petit *et al.*, 1999),” once again reiterating that “most of the sun-climate coupling mechanisms are probably still unknown,” and that “they might strongly amplify the effects of small solar activity increase.” That being said, however, the researchers note that in the twentieth century there was “a clear surplus warming” above and beyond what is suggested by their solar-based temperature reconstruction, such that something in addition to the sun may have been responsible for approximately 50 percent of the total global warming since 1900. This anomalous increase in temperature, it could be

argued, was due to anthropogenic greenhouse gas emissions. Scafetta and West say the temperature difference since 1975, where the most noticeable part of the discrepancy occurred, may have been due to “spurious non-climatic contamination of the surface observations such as heat-island and land-use effects (Pielke *et al.*, 2002; Kalnay and Cai, 2003),” which they say is also suggested by “an anomalous warming behavior of the global average land temperature vs. the marine temperature since 1975 (Brohan *et al.*, 2006).”

In their next paper, Scafetta and West (2007) reconstructed a phenomenological solar signature (PSS) of climate for the Northern Hemisphere for the last four centuries that matches relatively well the instrumental temperature record since 1850 and the paleoclimate temperature proxy reconstruction of Moberg (2005). The period from 1950 to 2010 showed excellent agreement between 11- and 22-year PSS cycles when compared to smoothed average global temperature data and the global *cooling* that occurred since 2002. Describing their research in an opinion essay in *Physics Today* (published by the American Institute of Physics), they say “this cooling seems to have been induced by decreased solar activity from the 2001 maximum to the 2007 minimum as depicted in two distinct TSI reconstructions” and “the same patterns are poorly reproduced by present-day GCMs and are dismissively interpreted as internal variability (noise) of climate. The nonequilibrium thermodynamic models we used suggest that the Sun is influencing climate significantly more than the IPCC report claims” (Scafetta and West, 2008).

In 2009, Scafetta and a new coauthor, Richard C. Willson, senior research scientist at Columbia’s Center for Climate Systems Research, addressed the issue of whether or not TSI increased from 1980 to 2002. The IPCC assumed there was no increase by adopting the TSI satellite composite produced by the Physikalisch-Meteorologisches Observatorium Davos (PMOD) (see Frohlich, 2006). PMOD assumed that the NIMBUS7 TSI satellite record artificially increased its sensitivity during the ACRIM-gap (1999.5-1991.75), and therefore it reduced the NIMBUS7 record by  $0.86 \text{ W/m}^2$  during the ACRIM-gap period, and consequently the TSI results changed little since 1980. However, this PMOD adjustment of NIMBUS7 TSI satellite data was never acknowledged by the experimental teams (Willson and Mordvinov, 2003; supporting material in Scafetta and Willson, 2009).

Scafetta and Willson (2009) proposed to solve the ACRIM-gap calibration controversy by developing a TSI model using a proxy model based on variations of the surface distribution of solar magnetic flux designed by Krivova *et al.* (2007) to bridge the two-year gap between ACRIM1 and ACRIM2. They use this to bridge “mixed” versions of ACRIM and PMOD TSI before and after the ACRIM-gap. Both “mixed” models show, in the authors’ words, “a significant TSI increase of 0.033%/decade between the solar activity minima of 1986 and 1996, comparable to the 0.037% found in the TSI satellite ACRIM composite.” They conclude that “increasing TSI between 1980 and 2000 could have contributed significantly to global warming during the last three decades. Current climate models have assumed that TSI did not vary significantly during the last 30 years and have, therefore, underestimated the solar contribution and overestimated the anthropogenic contribution to global warming.”

Backing up now to 2007, Krivova *et al.* (2007) note there is “strong interest” in the subject of long-term variations of total solar irradiance or TSI “due to its potential influence on global climate,” and that “only a reconstruction of solar irradiance for the pre-satellite period with the help of models can aid in gaining further insight into the nature of this influence,” which is what they set about to achieve in their paper. They developed a history of TSI “from the end of the Maunder minimum [about AD 1700] to the present based on variations of the surface distribution of the solar magnetic field,” which was “calculated from the historical record of the sunspot number using a simple but consistent physical model,” i.e., that of Solanki *et al.* (2000, 2002).

Krivova *et al.* report that their model “successfully reproduces three independent datasets: total solar irradiance measurements available since 1978, total photospheric magnetic flux since 1974 and the open magnetic flux since 1868,” which was “empirically reconstructed using the geomagnetic *aa*-index.” Based on this model, they calculated an increase in TSI since the Maunder minimum somewhere in the range of  $0.9\text{-}1.5 \text{ Wm}^{-2}$ , which encompasses the results of several independent reconstructions that have been derived over the past few years. In the final sentence of their paper, however, they also note that “all the values we obtain are significantly below the  $\Delta\text{TSI}$  values deduced from stellar data and used in older TSI reconstructions,” the results of which range from 2 to  $16 \text{ Wm}^{-2}$ .

Shaviv (2008) has attempted to quantify solar radiative forcing using oceans as a calorimeter. He evaluated three independent measures of net ocean heat flux over five decades, sea level change rate from twentieth century tide gauge records, and sea surface temperature. He found a “very clear correlation between solar activity and sea level” including the 11-year solar periodicity and phase, with a correlation coefficient of  $r=0.55$ . He also found “that the total radiative forcing associated with solar cycles variations is about 5 to 7 times larger than those associated with the TSI variations, thus implying the necessary existence of an amplification mechanism, though without pointing to which one.” Shaviv claims “the sheer size of the heat flux, and the lack of any phase lag between the flux and the driving force further implies that it cannot be part of an atmospheric feedback and very unlikely to be part of a coupled atmosphere-ocean oscillation mode. It must therefore be the manifestation of real variations in the global radiative forcing.” This provides “very strong support for the notion that an amplification mechanism exists. Given that the CRF [Cosmic Ray Flux]/climate links predicts the correct radiation imbalance observed in the cloud cover variations, it is a favorable candidate.” These results, Shaviv says, “imply that the climate sensitivity required to explain historic temperature variations is smaller than often concluded.”

Pallé *et al.* (2009) re-analyzed the overall reflectance of sunlight from Earth (“earthshine”) and re-calibrated the CERES satellite data to obtain consistent results for Earth’s solar reflectance. According to the authors, “Earthshine and FD [flux data] analyses show contemporaneous and climatologically significant increases in the Earth’s reflectance from the outset of our earthshine measurements beginning in late 1998 roughly until mid-2000. After that and to date, all three show a roughly constant terrestrial albedo, except for the FD data in the most recent years. Using satellite cloud data and Earth reflectance models, we also show that the decadal-scale changes in Earth’s reflectance measured by earthshine are reliable and are caused by changes in the properties of clouds rather than any spurious signal, such as changes in the Sun-Earth-Moon geometry.”

Ohmura (2009) reviewed surface solar irradiance at 400 sites globally to 2005. They found a brightening phase from the 1920s to 1960s followed by a 20-year dimming phase from 1960 to 1980. Then there is another 15-year brightening phase from 1990

to 2005. Ohmura finds “aerosol direct and indirect effects played about an equal weight in changing global solar radiation. The temperature sensitivity due to radiation change is estimated at 0.05 to 0.06 K/(W m<sup>-2</sup>).”

Long *et al.* (2009) analyzed “all-sky and clear-sky surface downwelling shortwave radiation and bulk cloud properties” from 1995 through 2007. They “show that widespread brightening has occurred over the continental United States ... averaging about 8 W m<sup>-2</sup>/decade for all-sky shortwave and 5 W m<sup>-2</sup>/decade for the clear-sky shortwave. This all-sky increase is substantially greater than the (global) 2 W m<sup>-2</sup>/decade previously reported ...” Their “results show that changes in dry aerosols and/or direct aerosol effects alone cannot explain the observed changes in surface shortwave (SW) radiation, but it is likely that changes in cloudiness play a significant role.”

These observations by Shaviv, Pallé, Ohmura, and Long *et al.* point to major variations in earth’s radiative budget caused by changes both in aerosols and clouds. Both are affected by natural and anthropogenic causes, including aircraft, power plants, cars, cooking, forest fires, and volcanoes. However, solar activity and cosmic rays also modulate clouds. When GCMs ignore or underestimate causes or modulation by solar cycles, magnetic fields and/or cosmic rays, they overestimate climate sensitivity and anthropogenic impacts.

Although there thus is still significant uncertainty about the true magnitude of the TSI change experienced since the end of the Maunder Minimum, the wide range of possible values suggests that long-term TSI variability cannot be rejected as a plausible cause of the majority of the global warming that has fueled earth’s transition from the chilling depths of the Little Ice Age to the much milder weather of the Current Warm Period. Indeed, the results of many of the studies reviewed in this summary argue strongly for this scenario, while others suggest it is the only explanation that fits all the data.

The measured judgment of Bard and Frank (2006) seems to us to be right on the mark. The role of solar activity in causing climate change is so complex that most theories of solar forcing of climate change must be considered to be as yet “unproven.” It would also be appropriate for climate scientists to admit the same about the role of rising atmospheric CO<sub>2</sub> concentrations in driving recent global warming. If it is fairly certain that the sun was responsible for creating multi-centennial cold and warm periods, it is clear the sun could easily be responsible for the

majority or even the entirety of the global warming of the past century or so.

## 5.3. Temperature

### 5.3.1. Global

The IPCC's claim that anthropogenic greenhouse gas emissions have been responsible for the warming detected in the twentieth century is based on what Loehle (2004) calls "the standard assumption in climate research, including the IPCC reports," that "over a century time interval there is not likely to be any recognizable trend to global temperatures (Risbey

*et al.*, 2000), and thus the null model for climate signal detection is a flat temperature trend with some autocorrelated noise," so that "any warming trends in excess of that expected from normal climatic variability are then assumed to be due to anthropogenic effects." If, however, there are significant underlying climate trends or cycles—or both—either known or unknown, that assumption is clearly invalid.

Loehle used a pair of 3,000-year proxy climate records with minimal dating errors to characterize the pattern of climate change over the past three millennia simply as a function of time, with no attempt to make the models functions of solar activity or any other physical variable. The first of the two temperature series is the sea surface temperature (SST) record of the Sargasso Sea, derived by Keigwin (1996) from a study of the oxygen isotope ratios of foraminifera and other organisms contained in a sediment core retrieved from a deep-ocean drilling site on the Bermuda Rise. This record provides SST data for about every 67th year from 1125 BC to 1975 AD. The second temperature series is the ground surface temperature record derived by Holmgren *et al.* (1999, 2001) from studies of color variations of stalagmites found in a cave in South Africa, which variations are caused by changes in the concentrations of humic materials entering the region's ground water that have been reliably correlated with regional near-surface air temperature.

Why does Loehle use these two specific records? He says "most other long-term records have large dating errors, are based on tree rings, which are not reliable for this purpose (Broecker, 2001), or are too short for estimating long-term cyclic components of climate." Also, in a repudiation of the approach employed by Mann *et al.* (1998, 1999) and Mann and Jones (2003), he reports that "synthetic series consisting of hemispheric or global mean temperatures are not suitable for such an analysis because of the inconsistent timescales in the various data sets," noting further, as a result of his own testing, that "when dating errors are present in a series, and several series are combined, the result is a smearing of the signal." But can only two temperature series reveal the pattern of global temperature change? According to Loehle, "a comparison of the Sargasso and South Africa series shows some remarkable similarities of pattern, especially considering the distance separating the two locations," and he says that this fact "suggests that the climate signal reflects some global pattern rather than

being a regional signal only.” He also notes that a comparison of the mean record with the South Africa and Sargasso series from which it was derived “shows excellent agreement,” and that “the patterns match closely,” concluding that “this would not be the case if the two series were independent or random.”

Loehle fit seven different time-series models to the two temperature series and to the average of the two series, using no data from the twentieth century. In all seven cases, he reports that good to excellent fits were obtained. As an example, the three-cycle model he fit to the averaged temperature series had a simple correlation of 0.58 and an 83 percent correspondence of peaks when evaluated by a moving window count.

Comparing the forward projections of the seven models through the twentieth century leads directly to the most important conclusions of Loehle’s paper. He notes, first of all, that six of the models “show a warming trend over the 20th century similar in timing and magnitude to the Northern Hemisphere instrumental series,” and that “one of the models passes right through the 20th century data.” These results suggest, in his words, “that 20th century warming trends are plausibly a continuation of past climate patterns” and, therefore, that “anywhere from a major portion to all of the warming of the 20th century could plausibly result from natural causes.”

As dramatic and important as these observations are, they are not the entire story of Loehle’s insightful paper. His analyses also reveal a long-term linear cooling trend of 0.25°C per thousand years since the peak of the interglacial warm period that occurred some 7,000 years ago, which result is essentially identical to the mean value of this trend that was derived from seven prior assessments of its magnitude and five prior climate reconstructions. In addition, Loehle’s analyses reveal the existence of the Medieval Warm Period of 800-1200 AD, which is shown to have been significantly warmer than the portion of the Current Warm Period we have so far experienced, as well as the existence of the Little Ice Age of 1500-1850 AD, which is shown to have been the coldest period of the entire 3,000-year record.

As corroborating evidence for the global nature of these major warm and cold intervals, Loehle cites 16 peer-reviewed scientific journal articles that document the existence of the Medieval Warm Period in all parts of the world, as well as 18 other articles that document the worldwide occurrence of the Little Ice Age. And in one of the more intriguing aspects of his study—of which Loehle makes no mention,

however—both the Sargasso Sea and South African temperature records reveal the existence of a major temperature spike that began sometime in the early 1400s. This abrupt warming pushed temperatures considerably above the peak warmth of the twentieth century before falling back to pre-spike levels in the mid 1500s, providing support for the similar finding of higher-than-current temperatures in that time interval by McIntyre and McKittrick (2003) in their reanalysis of the data employed by Mann *et al.* to create their controversial “hockey stick” temperature history, which gives no indication of the occurrence of this high-temperature regime.

In another accomplishment of note, the models developed by Loehle reveal the existence of three climate cycles previously identified by others. In his culminating seventh model, for example, there is a 2,388-year cycle that he describes as comparing “quite favorably to a cycle variously estimated as 2200, 2300, and 2500 years (Denton and Karlén, 1973; Karlén and Kuylenstierna, 1996; Magny, 1993; Mayewski *et al.*, 1997).” There is also a 490-year cycle that likely “corresponds to a 500-year cycle found previously (e.g. Li *et al.*, 1997; Magny, 1993; Mayewski *et al.*, 1997)” and a 228-year cycle that “approximates the 210-year cycle found by Damon and Jirikowic (1992).”

The compatibility of these findings with those of several studies that have identified similar solar forcing signals caused Loehle to conclude that “solar forcing (and/or other natural cycles) is plausibly responsible for some portion of 20th century warming” or, as he indicates in his abstract, maybe even all of it.

In spite of potential smearing and dating errors, other globally represented datasets have provided additional evidence of a solar influence on temperature. The 16 authors of Mayewski *et al.* (2004) examined some 50 globally distributed paleoclimate records in search of evidence for what they call rapid climate change (RCC) over the Holocene. This terminology is not to be confused with the rapid climate changes typical of glacial periods, but is used in the place of what the authors call the “more geographically or temporally restrictive terminology such as ‘Little Ice Age’ and ‘Medieval Warm Period’.” RCC events, as they also call them, are multi-century periods of time characterized by extremes of thermal and/or hydrological properties, rather than the much shorter periods of time during which the changes that led to these situations took place.

Mayewski *et al.* identify six RCCs during the Holocene: 9,000-8,000, 6,000-5,000, 4,200-3,800, 3,500-2,500, 1,200-1,000, and 600-150 cal yr BP, the last two of which intervals are, in fact, the “globally distributed” Medieval Warm Period and Little Ice Age, respectively. In speaking further of these two periods, they say that “the short-lived 1200-1000 cal yr BP RCC event coincided with the drought-related collapse of Maya civilization and was accompanied by a loss of several million lives (Hodell *et al.*, 2001; Gill, 2000), while the collapse of Greenland’s Norse colonies at ~600 cal yr BP (Buckland *et al.*, 1995) coincides with a period of polar cooling.”

With respect to the causes of these and other Holocene RCCs, the international team of scientists says that “of all the potential climate forcing mechanisms, solar variability superimposed on long-term changes in insolation (Bond *et al.*, 2001; Denton and Karlén, 1973; Mayewski *et al.*, 1997; O’Brien *et al.*, 1995) seems to be the most likely important forcing mechanism.” In addition, they note that “negligible forcing roles are played by CH<sub>4</sub> and CO<sub>2</sub>,” and that “changes in the concentrations of CO<sub>2</sub> and CH<sub>4</sub> appear to have been more the result than the cause of the RCCs.”

In another study with global implications, eight researchers hailing from China, Finland, Russia, and Switzerland published a paper wherein they describe evidence that makes the case for a causative link, or set of links, between solar forcing and climate change. Working with tree-ring width data obtained from two types of juniper found in Central Asia—*Juniperus turkestanica* (related to variations in summer temperature in the Tien Shan Mountains) and *Sabina przewalskii* (related to variations in precipitation on the Qinghai-Tibetan Plateau)—Raspopov *et al.* (2008) employed band-pass filtering in the 180- to 230-year period range, wavelet transformation (Morlet basis) for the range of periods between 100 and 300 years, as well as spectral analysis, in order to compare the variability in the two tree-ring records with independent  $\Delta^{14}\text{C}$  variations representative of the approximate 210-year de Vries solar cycle over the past millennium. These analyses indicated that the approximate 200-year cyclical variations present in the palaeoclimatic reconstructions were well correlated ( $R^2 = 0.58\text{-}0.94$ ) with similar variations in the  $\Delta^{14}\text{C}$  data, which obviously suggests the existence of a solar-climate connection. In addition, they say “the de Vries cycle has been found to occur not only during the last

millennia but also in earlier epochs, up to hundreds of millions [of] years ago.”

After reviewing additional sets of published palaeoclimatic data from various parts of the world, the eight researchers satisfied themselves that the same periodicity is evident in Europe, North and South America, Asia, Tasmania, Antarctica, and the Arctic, as well as “sediments in the seas and oceans,” citing 20 independent research papers in support of this statement. This fact led them to conclude there is “a pronounced influence of solar activity on global climatic processes” related to “temperature, precipitation and atmospheric and oceanic circulation.”

Complicating the matter, however, Raspopov *et al.* report there can sometimes be “an appreciable delay in the climate response to the solar signal,” which can be as long as 150 years, and they note that regional climate responses to the de Vries cycle “can markedly differ in phase,” even at distances of only hundreds of kilometers, due to “the nonlinear character of the atmosphere-ocean system response to solar forcing.” Nevertheless, the many results they culled from the scientific literature, as well as their own findings, all testify to the validity of their primary conclusion, that throughout the past millennium, and stretching back in time as much as 250 million years, the de Vries cycle has been “one of the most intense solar activity periodicities that affected climatic processes.”

As for the more recent historical significance of the de Vries cycle, Raspopov *et al.* write that “the temporal synchrony between the Maunder, Sporer, and Wolf minima and the expansion of Alpine glaciers (Haeblerle and Holzhauser, 2003) further points to a climate response to the deep solar minima.” In this regard, we again add that Earth’s recent recovery from those deep solar minima could well have played a major role in the planet’s emergence from the Little Ice Age, and, therefore, could well have accounted for much of twentieth century global warming, as suggested fully 20 years ago by Idso (1988).

Clearly, there is much to recommend the overriding concept that is suggested by the data of these several papers, i.e., that the sun rules the earth when it comes to orchestrating major changes in the planet’s climate. It is becoming ever more clear that the millennial-scale oscillation of climate that has reverberated throughout the Holocene is indeed the result of similar-scale oscillations in some aspect of solar activity. Consequently, Mayewski *et al.* suggest

that “significantly more research into the potential role of solar variability is warranted, involving new assessments of potential transmission mechanisms to induce climate change and potential enhancement of natural feedbacks that may amplify the relatively weak forcing related to fluctuations in solar output.”

Additional information on this topic, including reviews of newer publications as they become available, can be found at <http://www.co2science.org/subject/s/solartempglobal.php>.

### 5.3.2. Northern Hemisphere

Evidence of the influence of the sun on Northern Hemisphere temperatures can be found in the seminar research of Bond *et al.* (2001), who examined ice-rafted debris found in three North Atlantic deep-sea sediment cores and cosmogenic nuclides ( $^{10}\text{Be}$  and  $^{14}\text{C}$ ) sequestered in the Greenland ice cap ( $^{10}\text{Be}$ ) and Northern Hemispheric tree rings ( $^{14}\text{C}$ ). This study is described in depth in Section 5.1.

Bond *et al.* found that “over the last 12,000 years virtually every centennial time-scale increase in drift ice documented in our North Atlantic records was tied to a solar minimum,” and “a solar influence on climate of the magnitude and consistency implied by our evidence could not have been confined to the North Atlantic,” suggesting that the cyclical climatic effects of the variable solar inferno are experienced throughout the world. Bond *et al.* also observed that the oscillations in drift-ice they studied “persist across the glacial termination and well into the last glaciation, suggesting that the cycle is a pervasive feature of the climate system.”

Björck *et al.* (2001) assembled a wide range of lacustrine, tree-ring, ice-core, and marine records that reveal a Northern Hemispheric, and possibly global, cooling event of less than 200 years' duration with a 50-year cooling-peak centered at approximately 10,300 years BP. According to the authors, the onset of the cooling event broadly coincided with rising  $^{10}\text{Be}$  fluxes, which are indicative of either decreased solar or geomagnetic forcing; and since the authors note that “no large magnetic field variation that could have caused this event has been found,” they postulate that “the  $^{10}\text{Be}$  maximum was caused by distinctly reduced solar forcing.” They also note that

the onset of the Younger Dryas is coeval with a rise in  $^{10}\text{Be}$  flux, as is the Preboreal climatic oscillation.

Pang and Yau (2002) assembled and analyzed a vast amount of data pertaining to phenomena that have been reliably linked to variations in solar activity, including frequencies of sunspot and aurora sightings, the abundance of carbon-14 in the rings of long-lived trees, and the amount of beryllium-10 in the annual ice layers of polar ice cores. In the case of sunspot sightings, the authors used a catalogue of 235 Chinese, Korean, and Japanese records compiled by Yau (1988), a catalogue of 270 Chinese records compiled by Zhuang and Wang (1988), and a time chart of 139 records developed by Clark and Stephenson (1979), as well as a number of later catalogues that made the overall record more complete.

Over the past 1,800 years, the authors identified “some nine cycles of solar brightness change,” which include the well-known Oort, Wolf, Sporer, Maunder, and Dalton Minima. With respect to the Maunder Minimum—which occurred between 1645 and 1715 and is widely acknowledged to have been responsible for some of the coldest weather of the Little Ice Age—they report that the temperatures of that period “were about one-half of a degree Celsius lower than the mean for the 1970s, consistent with the decrease in the decadal average solar irradiance.” Then, from 1795 to 1825 came the Dalton Minimum, along with another dip in Northern Hemispheric temperatures. Since that time, however, the authors say “the sun has gradually brightened” and “we are now in the Modern Maximum,” which is likely responsible for the warmth of the Current Warm Period.

The authors say that although the long-term variations in solar brightness they identified “account for less than 1% of the total irradiance, there is clear evidence that they affect the Earth's climate.” Pang and Yau's dual plot of total solar irradiance and Northern Hemispheric temperature from 1620 to the present (their Fig. 1c) indicates that the former parameter (when appropriately scaled, but without reference to any specific climate-change mechanism) can account for essentially all of the net change experienced by the latter parameter up to about 1980. After that time, however, the IPCC surface air temperature record rises dramatically, although radiosonde and satellite temperature histories largely match what would be predicted from the solar irradiance record. These facts could be interpreted as new evidence of the corruptness of the IPCC temperature history.

In a separate study, Rohling *et al.* (2003) “narrow down” temporal constraints on the millennial-scale variability of climate evident in ice-core  $\delta^{18}\text{O}$  records by “determining statistically significant anomalies in the major ion series of the GISP2 ice core,” after which they conduct “a process-oriented synthesis of proxy records from the Northern Hemisphere.” With respect to the temporal relationships among various millennial-scale oscillations in Northern Hemispheric proxy climate records, the authors conclude that a “compelling case” can be made for their being virtually in-phase, based on (1) “the high degree of similarity in event sequences and structures over a very wide spatial domain,” and (2) “the fact that our process-oriented synthesis highlights a consistent common theme of relative dominance shifts between winter-type and summer-type conditions, ranging all the way across the Northern Hemisphere from polar into monsoonal latitudes.” These findings, they additionally note, “corroborate the in-phase relationship between climate variabilities in the high northern latitudes and the tropics suggested in Blunier *et al.* (1998) and Brook *et al.* (1999).”

Rohling *et al.* further report that although individual cycles of the persistent climatic oscillation “appear to have different intensities and durations, a mean periodicity appears around ~1500 years (Mayewski *et al.*, 1997; Van Kreveld *et al.*, 2000; Alley *et al.*, 2001).” They further report that “this cycle seems independent from the global glaciation state (Mayewski *et al.*, 1997; Bond *et al.*, 1999),” and that “ $^{10}\text{Be}$  and  $\delta^{14}\text{C}$  records may imply a link with solar variability (Mayewski *et al.*, 1997; Bond *et al.*, 2001).”

Lastly, we come to the study of Usoskin *et al.* (2003), who note that “sunspots lie at the heart of solar active regions and trace the emergence of large-scale magnetic flux, which is responsible for the various phenomena of solar activity” that may influence earth’s climate. They say “the sunspot number (SN) series represents the longest running direct record of solar activity, with reliable observations starting in 1610, soon after the invention of the telescope.” To compare SN data with the millennial-scale temperature reconstruction of Mann *et al.* (1999), the directly measured SN record must be extended back in time at least another 600 years, which Usoskin *et al.* did using records of  $^{10}\text{Be}$  cosmionuclide concentration derived from polar ice cores dating back to AD 850. In accomplishing this task, they employed detailed physical models that they say were “developed for each individual link in

the chain connecting the SN with the cosmogenic isotopes,” and they combined these models in such a way that “the output of one model [became] the input for the next step.”

The reconstructed SN history of the past millennium looks very much like the infamous “hockey stick” temperature history of Mann *et al.* (1999). It slowly declines over the entire time period—with numerous modest oscillations associated with well-known solar maxima and minima—until the end of the Little Ice Age, whereupon it rises dramatically. Usoskin *et al.* report, for example, that “while the average value of the reconstructed SN between 850 and 1900 is about 30, it reaches values of 60 since 1900 and 76 since 1944.” In addition, they report that “the largest 100-year average of the reconstructed SN prior to 1900 is 44, which occurs in 1140-1240, i.e., during the medieval maximum,” but they note that “even this is significantly less than the level reached in the last century.” Hence, they readily and correctly conclude, on the basis of their work, that “the high level of solar activity since the 1940s is unique since the year 850.”

The studies reported in this section show that the temperature record of the Northern Hemisphere supports the theory that solar cycles strongly influence temperatures. Additional information on this topic, including reviews of newer publications as they become available, can be found at <http://www.co2science.org/subject/s/solartempnhemis.php>.

### 5.3.3. North America

We begin our review of the influence of the sun on North American temperatures with the study of Wiles *et al.* (2004), who derived a composite Glacier Expansion Index (GEI) for Alaska based on "dendrochronologically derived calendar dates from forests overrun by advancing ice and age estimates of moraines using tree-rings and lichens," after which they compared this history of glacial activity with "the  $^{14}\text{C}$  record preserved in tree rings corrected for marine and terrestrial reservoir effects as a proxy for solar variability" and with the history of the Pacific Decadal Oscillation (PDO) derived by Cook (2002).

Results of the study showed Alaska ice expansions "approximately every 200 years, compatible with a solar mode of variability," specifically, the de Vries 208-year solar cycle; and by merging this cycle with the cyclical behavior of the PDO, Wiles *et al.* obtained a dual-parameter forcing function that was even better correlated with the Alaskan composite GEI, with major glacial advances clearly associated with the Sporer, Maunder, and Dalton solar minima.

In introducing the rationale for their study, Wiles *et al.* say that "increased understanding of solar variability and its climatic impacts is critical for separating anthropogenic from natural forcing and for predicting anticipated temperature change for future centuries." In this regard, it is most interesting that they make no mention of possible  $\text{CO}_2$ -induced global warming in discussing their results, presumably because there is no need to do so. Alaskan glacial activity, which, in their words, "has been shown to be primarily a record of summer temperature change (Barclay *et al.*, 1999)," appears to be sufficiently well described within the context of solar and PDO variability alone. Four years later, Wiles *et al.* (2008)

reconfirmed this Alaska solar-climate link in a separate study.

Nearby in the Columbia Icefield area of the Canadian Rockies, Luckman and Wilson (2005) used new tree-ring data to present a significant update to a millennial temperature reconstruction published for this region in 1997. The new update employed different standardization techniques, such as the regional curve standardization method, in an effort to capture a greater degree of low frequency variability (centennial to millennial scale) than reported in the initial study. In addition, the new dataset added more than one hundred years to the chronology and now covers the period AD 950-1994.

The updated proxy indicator of temperature showed considerable decadal- and centennial-scale variability, where generally warmer conditions prevailed during the eleventh and twelfth centuries, between about AD 1350-1450 and from about 1875 through the end of the record, while persistent cold conditions prevailed between 1200-1350, 1450-1550, and 1650-1850, with the 1690s being exceptionally cold (more than 0.4°C colder than the other intervals).

The revised Columbia Icefield temperature reconstruction provides further evidence for natural climate fluctuations on centennial-to-millennial timescales and demonstrates, once again, that temperatures during the Current Warm Period are no different from those observed during the Medieval Warm Period (eleventh—twelfth centuries) or the Little Medieval Warm Period (1350-1450). And since we know that atmospheric CO<sub>2</sub> concentrations had nothing to do with the warm temperatures of those earlier periods, we cannot rule out the possibility that they also have nothing to do with the warm temperatures of the modern era.

But if not CO<sub>2</sub>, then what? According to Luckman and Wilson, the Columbia Icefield reconstruction “appears to indicate a reasonable response of local trees to large-scale forcing of climates, with reconstructed cool conditions comparing well with periods of known low solar activity,” which is a nice way of suggesting that the *sun* is the main driver of these low frequency temperature trends.

Heading south to the warmer regions of North America, Barron and Bukry (2007) extracted sediment cores from three sites on the eastern slope of the Gulf of California. By examining these high-resolution records of diatoms and silicoflagellate assemblages, they were able to reconstruct sea surface temperatures there over the past 2,000 years. In all

three of the sediment cores, the relative abundance of *Azpeitia nodulifera* (a tropical diatom whose presence suggests the occurrence of higher sea surface temperatures), was found to be greater during the Medieval Warm Period than at any other time over the 2,000-year period studied, while during the Current Warm Period its relative abundance was actually lower than the 2,000-year mean, also in all three of the sediment cores. In addition, the first of the cores exhibited elevated *A. nodulifera* abundances from the start of the record to about AD 350, during the latter part of the Roman Warm Period, as well as between AD 1520 and 1560, during what we have denominated the Little Medieval Warm Period. By analyzing radiocarbon production data, Barron and Bukry determined that “intervals of increased radiocarbon production (sunspot minima) correlate with intervals of enhanced biosilica productivity,” leading the two authors to conclude that “solar forcing played a major role in determining surface water conditions in the Gulf of California during the past 2000 yr.” As for how this was accomplished, Barron and Bukry say that “reduced solar irradiance (sunspot minima) causes cooling of winter atmospheric temperatures above the southwest US,” and that “this strengthens the atmospheric low and leads to intensification of northwest winds blowing down the Gulf, resulting in increased overturn of surface waters, increased productivity, and cooler SST.”

Richey *et al.* (2007) constructed “a continuous decadal-scale resolution record of climate variability over the past 1400 years in the northern Gulf of Mexico” from a box core recovered in the Pigmy Basin, northern Gulf of Mexico [27°11.61'N, 91°24.54'W],” based on “paired analyses of Mg/Ca and δ<sup>18</sup>O in the white variety of the planktic foraminifer *Globigerinoides ruber* and relative abundance variations of *G. sacculifer* in the foraminifer assemblages.”

Results revealed that “two multi-decadal intervals of sustained high Mg/Ca indicate that Gulf of Mexico sea surface temperatures (SSTs) were as warm or warmer than near-modern conditions between 1000 and 1400 yr B.P.,” while “foraminiferal Mg/Ca during the coolest interval of the Little Ice Age (ca. 250 yr B.P.) indicate that SST was 2-2.5°C below modern SST.” In addition, they found that “four minima in the Mg/Ca record between 900 and 250 yr. B.P. correspond with the Maunder, Sporer, Wolf, and Oort sunspot minima,” providing additional evidence

that the historic warmth of earth's past was likely solar-induced.

Also in the Gulf of Mexico, Poore *et al.* (2003) developed a 14,000-year record of Holocene climate based primarily on the relative abundance of the planktic foraminifer *Globigerinoides sacculifer* found in two sediment cores. In reference to North Atlantic millennial-scale cool events 1-7 identified by Bond *et al.* (2001) as belonging to a pervasive climatic oscillation with a period of approximately 1,500 years, Poore *et al.* say of their own study that distinct excursions to lower abundances of *G. sacculifer* “match within 200 years the ages of Bond events 1-6,” noting that “major cooling events detected in the subpolar North Atlantic can be recognized in the GOM record.” They additionally note that “the GOM record includes more cycles than can be explained by a quasiperiodic 1500-year cycle,” but that such centennial-scale cycles with periods ranging from 200 to 500 years are also observed in the study of Bond *et al.*, noting further that their results “are in agreement with a number of studies indicating the presence of substantial century-scale variability in Holocene climate records from different areas,” specifically citing the reports of Campbell *et al.* (1998), Peterson *et al.* (1991), and Hodell *et al.* (2001). Last, they discuss evidence that leads them to conclude that “some of the high-frequency variation (century scale) in *G. sacculifer* abundance in our GOM records is forced by solar variability.”

In still another example of a solar-temperature connection, Lund and Curry (2004) analyzed a planktonic foraminiferal  $\delta^{18}\text{O}$  time series obtained from three well-dated sediment cores retrieved from the seabed near the Florida Keys (24.4°N, 83.3°W) that covered the past 5,200 years. As they describe it, isotopic data from the three cores “indicate the surface Florida Current was denser (colder, saltier or both) during the Little Ice Age than either the Medieval Warm Period or today,” and that “when considered with other published results (Keigwin, 1996; deMenocal *et al.*, 2000), it is possible that the entire subtropical gyre of the North Atlantic cooled during the Little Ice Age ... perhaps consistent with the simulated effects of reduced solar irradiance (Rind and Overpeck, 1993; Shindell *et al.*, 2001).” In addition, they report that “the coherence and phasing of atmospheric  $^{14}\text{C}$  production and Florida Current  $\delta^{18}\text{O}$  during the Late Holocene implies that solar variability may influence Florida Current surface density at frequencies between 1/300 and 1/100 years,” demonstrating once again a situation where

both centennial- and millennial-scale climatic variability is explained by similar-scale variability in solar activity.

We conclude with the study of Li *et al.* (2006), who “recovered a 14,000-year mineral-magnetic record from White Lake (~41°N, 75°W), a hardwater lake containing organic-rich sediments in northwestern New Jersey, USA.” According to these researchers, a comparison of the White Lake data with climate records from the North Atlantic sediments “shows that low lake levels at ~1.3, 3.0, 4.4, and 6.1 ka [1000 years before present] in White Lake occurred almost concurrently with the cold events at ~1.5, 3.0, 4.5, and 6.0 ka in the North Atlantic Ocean (Bond *et al.*, 2001),” and that “these cold events are associated with the 1500-year warm/cold cycles in the North Atlantic during the Holocene” that have “been interpreted to result from solar forcing (Bond *et al.*, 2001).”

It is clear that broad-scale periods of warmth in North America have occurred over and over again throughout the Holocene—and beyond (Oppo *et al.*, 1998; Raymo *et al.*, 1998)—forced by variable solar activity. This suggests that the Current Warm Period was also instigated by this recurring phenomenon, not the CO<sub>2</sub> output of the Industrial Revolution.

Additional information on this topic, including reviews of newer publications as they become available, can be found at <http://www.co2science.org/subject/s/solartempnamer.php>.

### 5.3.4. South America

Nordemann *et al.* (2005) examined tree rings from species sensitive to fluctuations in temperature and precipitation throughout the southern region of Brazil and Chile, along with sunspot data, via harmonic spectral and wavelet analysis in an effort to obtain a greater understanding of the effects of solar activity, climate, and geophysical phenomena on the continent of South America, where the time interval covered by the tree-ring samples from Brazil was 200 years and that from Chile was 2,500 years. Results of the spectral analysis revealed periodicities in the tree rings that corresponded well with the DeVries-Suess (~200 yr), Gleissberg (~80 yr), Hale (~22 yr), and Schwabe (~11 yr) solar activity cycles, while wavelet cross-spectrum analysis of sunspot number and tree-ring growth revealed a clear relation between the tree-ring and solar series.

Next, utilizing a lichenometric method for dating glacial moraines, the Bolivian and French research team of Rabatel *et al.* (2005) developed what they call “the first detailed chronology of glacier fluctuations in a tropical area during the Little Ice Age,” focusing on fluctuations of the Charquini glaciers of the Cordillera Real in Bolivia, where they studied a set of 10 moraines that extend below the present glacier termini. Based on the chronology, the researchers determined that the maximum glacier extension in Bolivia “occurred in the second half of the 17th century, as observed in many mountain areas of the Andes and the Northern Hemisphere.” In addition, they found that “this expansion has been of a comparable magnitude to that observed in the Northern Hemisphere, with the equilibrium line altitude depressed by 100-200 m during the glacier maximum.” They say “the synchronization of glacier expansion with the Maunder and Dalton minima supports the idea that solar activity could have cooled enough the tropical atmosphere to provoke this evolution.”

As for the magnitude and source of the cooling in the Bolivian Andes during the Little Ice Age, three years later Rabatal *et al.* (2008) estimated it to have been 1.1 to 1.2°C below that of the present, while once again noting that at that time there was a “striking coincidence between the glacier expansion

in this region of the tropics and the decrease in solar irradiance: the so-called ‘Maunder minimum’ (AD 1645-1715) during which irradiance might have decreased by around 0.24% (Lean and Rind, 1998) and could have resulted in an atmospheric cooling of 1°C worldwide (Rind *et al.*, 2004).”

Further south, Glasser *et al.* (2004) analyzed a large body of evidence related to glacier fluctuations in the two major ice fields of Patagonia: the Hielo Patagonico Norte (47°00’S, 73°39’W) and the Hielo Patagonico Sur (between 48°50’S and 51°30’S). With respect to the glacial advancements that occurred during the cold interval that preceded the Roman Warm Period, they say they are “part of a body of evidence for global climatic change around this time (e.g., Grosjean *et al.*, 1998; Wasson and Claussen, 2002), which coincides with an abrupt decrease in solar activity,” adding that this observation “led van Geel *et al.* (2000) to suggest that variations in solar irradiance are more important as a driving force in variations in climate than previously believed.”

With respect to the most recent recession of Hielo Patagonico Norte outlet glaciers from their late historic moraine limits at the end of the nineteenth century, Glasser *et al.* say that “a similar pattern can be observed in other parts of southern Chile (e.g., Kuylenstierna *et al.*, 1996; Koch and Kilian, 2001).” Likewise, they note that “in areas peripheral to the North Atlantic and in central Asia the available evidence shows that glaciers underwent significant recession at this time (cf. Grove, 1988; Savoskul, 1997),” which again suggests the operation of a globally distributed forcing factor such as cyclically variable solar activity.

Working on a bog, as opposed to a glacier, Chambers *et al.* (2007) presented new proxy climate data they obtained from the Valle de Andorra northeast of Ushuaia, Tierra del Fuego, Argentina, which data, they emphasize, are “directly comparable” with similar proxy climate data obtained in numerous studies conducted in European bogs, “as they were produced using identical laboratory methods.” This latter point is very important because Chambers *et al.* say their new South American data show there was “a major climate perturbation at the same time as in northwest Europe,” which they describe as “an abrupt climate cooling” that occurred approximately 2,800 years ago, and that “its timing, nature and apparent global synchronicity lend support to the notion of solar forcing of past climate change, amplified by oceanic circulation.”

The five European researchers further state their finding that “rapid, high-magnitude climate changes might be produced within the Holocene by an inferred *decline* in solar activity (van Geel *et al.*, 1998, 2000, 2003; Bond *et al.*, 2001; Blaauw *et al.*, 2004; Renssen *et al.*, 2006) has implications for rapid, high-magnitude climate changes of the opposite direction—climatic warmings, possibly related to *increases* in solar activity.” In this regard, they further note that “for the past 100 years any solar influence would for the most part have been in the opposite direction (i.e., to help generate a global climate warming) to that inferred for c. 2800-2710 cal. BP.” And they conclude that this observation “has implications for interpreting the relative contribution of climate drivers of recent ‘global warming’,” implying that a solar-induced, rather than a CO<sub>2</sub>-induced, climate driver may have been the primary cause of twentieth century global warming.

Polissar *et al.* (2006) worked with data derived from sediment records of two Venezuelan watersheds along with ancillary data obtained from other studies that had been conducted in the same general region. They developed continuous decadal-scale histories of glacier activity and moisture balance in a part of the tropical Andes (the Cordillera de Merida) over the past millennium and a half, from which they were able to deduce contemporary histories of regional temperature and precipitation. The international (Canada, Spain, United States, Venezuela) team of scientists write that “comparison of the Little Ice Age history of glacier activity with reconstructions of solar and volcanic forcing suggest that solar variability is the primary underlying cause of the glacier fluctuations,” because (1) “the peaks and troughs in the susceptibility records match fluctuations of solar irradiance reconstructed from <sup>10</sup>Be and δ<sup>14</sup>C measurements,” (2) “spectral analysis shows significant peaks at 227 and 125 years in both the irradiance and magnetic susceptibility records, closely matching the de Vreis and Gleissberg oscillations identified from solar irradiance reconstructions,” and (3) “solar and volcanic forcing are uncorrelated between AD 1520 and 1650, and the magnetic susceptibility record follows the solar-irradiance reconstruction during this interval.” In addition, they write that “four glacial advances occurred between AD 1250 and 1810, coincident with solar-activity minima,” and that “temperature declines of  $-3.2 \pm 1.4^{\circ}\text{C}$  and precipitation increases of  $\sim 20\%$  are required to produce the observed glacial responses.”

In discussing their findings, Polissar *et al.* say their results “suggest considerable sensitivity of tropical climate to small changes in radiative forcing from solar irradiance variability.” This research from South America strongly suggests that the IPCC is failing to take into account the effect of solar cycles on temperatures.

Additional information on this topic, including reviews of newer publications as they become available, can be found at <http://www.co2science.org/subject/s/solartempsamer.php>.

### 5.3.5. Asia

We begin our study of Asia with a 2003 paper published in the Russian journal *Geomagnetizm i Aeronomiya*, where two scientists from the Institute of Solar-Terrestrial Physics of the Siberian Division of the Russian Academy of Sciences, Bashkirtsev and Mashnich (2003), say “a number of publications report that the anthropogenic impact on the Earth’s climate is an obvious and proven fact,” when in their opinion “none of the investigations dealing with the anthropogenic impact on climate convincingly argues for such an impact.”

In the way of contrary evidence, they begin by citing the work of Friis-Christensen and Lassen (1991), who first noted the close relationship ( $r = -0.95$ ) between the length of the sunspot cycle and the surface air temperature of the Northern Hemisphere over the period 1861-1989, where “warming and cooling corresponded to short (~10 yr) and prolonged (~11.5 yr) solar cycles, respectively.” They then cite the work of Zherebtsov and Kovalenko (2000), who they say established a high correlation ( $r = 0.97$ ) between “the average power of the solar activity cycle and the surface air temperature in the Baikal region averaged over the solar cycle.” These two findings, they contend, “leave little room for the anthropogenic impact on the Earth’s climate.” In addition, they note that “solar variations naturally explain global cooling observed in 1950-1970, which cannot be understood from the standpoint of the greenhouse effect, since CO<sub>2</sub> was intensely released into the atmosphere in this period,” citing in support of this statement the work of Dergachev and Raspopov (2000).

Bashkirtsev and Mashnich conducted their own wavelet-spectra and correlation analyses of Irkutsk and world air temperatures and Wolf number data for the period 1882-2000, finding periodicities of 22 (Hale cycle) and 52 (Fritz cycle) years and reporting that “the temperature response of the air lags behind the sunspot cycles by approximately 3 years in Irkutsk and by 2 years over the entire globe.”

Noting that one could thus expect the upper envelope of sunspot cycles to reproduce the global temperature trend, they created such a plot and found that such is indeed the case. As they describe their results, “the lowest temperatures in the early 1900s correspond to the lowest solar activity (weak cycle 14), the further temperature rise follows the increase in solar activity; the decrease in solar activity in cycle 20 is accompanied by the temperature fall [from 1950-1970], and the subsequent growth of solar

activity in cycles 21 and 22 entails the temperature rise [of the last quarter century].”

Bashkirtsev and Mashnich say “it has become clear that the current sunspot cycle (cycle 23) is weaker than the preceding cycles (21 and 22),” and that “solar activity during the subsequent cycles (24 and 25) will be, as expected, even lower,” noting that “according to Chistyakov (1996, 2000), the minimum of the secular cycle of solar activity will fall on cycle 25 (2021-2026), which will result in the minimum global temperature of the surface air (according to our prediction).” Only time will tell if such predictions will prove correct.

Turning our attention back toward the past, but staying in the Asian subarctic, Vaganov *et al.* (2000) utilized tree-ring width as a proxy for temperature to examine temperature variations in this region over the past 600 years. According to a graph of the authors’ data, temperatures in the Asian subarctic exhibited a small positive trend from the start of the record until about 1750. Thereafter, a severe cooling trend ensued, followed by a 130-year warming trend from about 1820 through 1950, after which temperatures fell once again. In considering the entire record, the authors state that the amplitude of twentieth century warming “does not go beyond the limits of reconstructed natural temperature fluctuations in the Holocene subarctic zone.”

In attempting to determine the cause or causes of the temperature fluctuations, the authors report finding a significant correlation with solar radiation and volcanic activity over the entire 600-year period ( $R = 0.32$  for solar radiation,  $R = -0.41$  for volcanic activity), which correlation *improved* over the shorter interval of the industrial period—1800 to 1990—( $R = 0.68$  for solar radiation,  $R = -0.59$  for volcanic activity).

It is interesting to note that in this region of the world, where climate models predict large increases in temperature as a result of the historical rise in the air’s CO<sub>2</sub> concentration, real-world data show a *cooling* trend since around 1940, when the greenhouse effect of CO<sub>2</sub> should have been most prevalent. And, where warming does exist in the record (between about 1820 and 1940), much of it correlates with changes in solar irradiance and volcanic activity—two factors free of anthropogenic influence.

In two additional paleoclimate studies from the continental interior of Russia’s Siberia, Kalugin *et al.* (2005) and Kalugin *et al.* (2007) analyzed sediment cores from Lake Teletskoye in the Altai Mountains

(51°42.90'N, 87°39.50'E) to produce multi-proxy climate records spanning the past 800 years. Analyses of the multi-proxy records revealed several distinct climatic periods over the past eight centuries. With respect to temperature, the regional climate was relatively warm with high terrestrial productivity from AD 1210 to 1380. Thereafter, temperatures cooled, reaching peak deterioration between 1660 and 1700, which time period, in the words of Kalugin *et al.* (2005), “corresponds to the age range of the well-known Maunder Minimum (1645-1715)” of solar sunspot activity.

Moving to Japan, an uninterrupted 1,100-year history of March mean temperature at Kyoto was developed by Aono and Kazui (2008), who used phenological data on the times of full-flowering of cherry trees (*Prunus jamasakura*) acquired from old diaries and chronicles written at Kyoto. Upon calibration with instrumental temperature measurements obtained over the period 1881-2005, the results were compared with the sunspot number history developed by Solanki *et al.* (2004).

The results of the study suggest “the existence of four cold periods, 1330-1350, 1520-1550, 1670-1700, and 1825-1830, during which periods the estimated March mean temperature was 4-5°C, about 3-4°C lower than the present normal temperature,” and that “these cold periods coincided with the less extreme periods [of solar activity], known as the Wolf, Spörer, Maunder, and Dalton minima, in the long-term solar variation cycle, which has a periodicity of 150-250 years.” In addition, they report that “a time lag of about 15 years was detected in the climatic temperature response to short-term solar variation.”

Also in Japan, Kitagawa and Matsumoto (1995) analyzed  $\delta^{13}\text{C}$  variations of Japanese cedars growing on Yakushima Island (30°20'N, 130°30'E), in an effort to reconstruct a high-resolution proxy temperature record over the past two thousand years. In addition, they applied spectral analysis to the  $\delta^{13}\text{C}$  time series in an effort to learn if any significant periodicities were present in the record.

Results indicated significant decadal to centennial-scale variability throughout the record, with temperatures fluctuating by about 5°C across the series. Most notable among the fluctuations were multi-century warm and cold epochs. Between AD 700-1200, for example, there was about a 1°C rise in average temperature (pre-1850 average), which the authors state “appears to be related to the ‘Medieval Warm Period’.” In contrast, temperatures were about 2°C below the long-term pre-1850 average during the

multi-century Little Ice Age that occurred between AD 1580 and 1700. Kitagawa and Matsumoto also report finding significant temperature periodicities of 187, 89, 70, 55, and 44 years. Noting that the 187-year cycle closely corresponds to the well-known Suess cycle of solar activity and that the 89-year cycle compares well with the Gleissberg solar cycle, they conclude that their findings provide further support for a sun-climate relationship.

Ten years later, Cini Castagnoli *et al.* (2005) re-examined the Kitagawa and Matsumoto dataset for evidence of recurring cycles using Singular Spectrum Analysis and Wavelet Transform, after which it was compared with a 300-year record of sunspots. Results of the newer analyses showed a common 11-year oscillation in phase with the Schwabe cycle of solar activity, plus a second multi-decadal oscillation (of about 87 years for the tree-ring series) in phase with the amplitude modulation of the sunspot number series over the past 300 years, which led this second group of authors to conclude that the overall phase agreement between the climate reconstruction and variation in the sunspot number series “favors the hypothesis that the [multi-decadal] oscillation” revealed in the record “is connected to the solar activity.”

Turning to China, there have been several studies documenting a solar influence on temperature from several proxy temperature indicators. Beginning with stalagmite-derived proxies, Paulsen *et al.* (2003) utilized high-resolution records of  $\delta^{13}\text{C}$  and  $\delta^{18}\text{O}$  from a stalagmite in Buddha Cave, central China [33°40'N, 109°05'E], to infer changes in climate there over the past 1,270 years. Among the climatic episodes evident in the authors' data were “those corresponding to the Medieval Warm Period, Little Ice Age and 20th-century warming, lending support to the global extent of these events.” The authors' data also revealed a number of other cycles superimposed on these major millennial-scale temperature cycles, which they attributed to cyclical solar and lunar phenomena.

In a separate study, Tan *et al.* (2004) established an annual layer thickness chronology for a stalagmite from Beijing Shihua Cave and reconstructed a 2,650-year (BC 665-AD 1985) warm season (MJJA: May, June, July, August) temperature record for Beijing by calibrating the thickness chronology with the observed MJJA temperature record (Tan *et al.*, 2003). Results of the analysis showed that the warm season temperature record was “consistent with oscillations in total solar irradiance inferred from cosmogenic

$^{10}\text{Be}$  and  $^{14}\text{C}$ ,” and that it also “is remarkably consistent with Northern Atlantic drift ice cycles that were identified to be controlled by the sun through the entire Holocene [Bond *et al.*, 2001].” Going backwards in time, both records clearly depict the start of the Current Warm Period, the prior Little Ice Age, the Medieval Warm Period, the Dark Ages Cold Period, the Roman Warm Period, and the cold climate at the start of both records.

The authors conclude that “the synchronism between the two independent sun-linked climate records therefore suggests that the sun may directly couple hemispherical climate changes on centennial to millennial scales.” It stands to reason that the cyclical nature of the millennial-scale oscillation of climate evident in both climate records suggests there is no need to invoke rising atmospheric  $\text{CO}_2$  concentrations as a cause of the Current Warm Period.

Working with a stalagmite found in another China cave, Wanxiang Cave ( $33^\circ 19' \text{N}$ ,  $105^\circ 00' \text{E}$ ), Zhang *et al.* (2008) developed a  $\delta^{18}\text{O}$  record with an average resolution of 2.5 years covering the period AD 190 to 2003. According to the 17 authors of this study, the  $\delta^{18}\text{O}$  record “exhibits a series of centennial to multi-centennial fluctuations broadly similar to those documented in Northern Hemisphere temperature reconstructions, including the Current Warm Period, Little Ice Age, Medieval Warm Period and Dark Age Cold Period.”

In addition, Zhang *et al.* state that it “correlates with solar variability, Northern Hemisphere and Chinese temperature, Alpine glacial retreat, and Chinese cultural changes.” And since none of the last four phenomena can influence the first one, solar variability appears to have driven the variations in the other factors mentioned. In a commentary that accompanied Zhang *et al.*'s article, Kerr (2008) quotes other researchers calling the Zhang *et al.* record “amazing,” “fabulous,” and “phenomenal,” and it “provides the strongest evidence yet for a link among sun, climate, and culture.”

Still in China, we turn next to the study of Hong *et al.* (2000), who developed a 6,000-year high-resolution  $\delta^{18}\text{O}$  record from plant cellulose deposited in a peat bog in the Jilin Province of China ( $42^\circ 20' \text{N}$ ,  $126^\circ 22' \text{E}$ ), from which they inferred the temperature history of that location over the past six millennia. They then compared this record with a previously derived  $\delta^{14}\text{C}$  tree-ring record that is representative of the intensity of solar activity over this period.

Results indicated the study area was relatively cold between 4000 and 2600 BC. Then it warmed fairly continuously until it reached the maximum warmth of the record about 1600 BC, after which it fluctuated about this warm mean for approximately 2,000 years. Starting about AD 350, however, the climate began to cool, with the most dramatic cold associated with three temperature minima centered at about AD 1550, 1650, and 1750, corresponding to the most severe cold of the Little Ice Age.

Of particular note is the authors' finding of “an obvious warm period represented by the high  $\delta^{18}\text{O}$  from around AD 1100 to 1200 which may correspond to the Medieval Warm Epoch of Europe.” They also report that “at that time, the northern boundary of the cultivation of citrus tree (*Citrus reticulata* Blanco) and *Boehmeria nivea* (a perennial herb), both subtropical and thermophilous plants, moved gradually into the northern part of China, and it has been estimated that the annual mean temperature was  $0.9\text{--}1.0^\circ\text{C}$  higher than at present.”

Hong *et al.* also note “there is a remarkable, nearly one to one, correspondence between the changes of atmospheric  $\delta^{14}\text{C}$  and the variation in  $\delta^{18}\text{O}$  of the peat cellulose,” which led them to conclude that the temperature history of the past 6,000 years at the site of their study has been “forced mainly by solar variability.”

In another study, 18 radiocarbon-dated aeolian and paleosol profiles within a 1,500-km-long belt along the arid to semi-arid transition zone of north-central China were analyzed by Porter and Weijian (2006) to determine variations in the extent and strength of the East Asian summer monsoon throughout the Holocene.

The dated paleosols and peat layers, in the words of Porter and Weijian, “represent intervals when the zone was dominated by a mild, moist summer monsoon climate that favored pedogenesis and peat accumulation,” while “brief intervals of enhanced aeolian activity that resulted in the deposition of loess and aeolian sand were times when strengthened winter monsoon conditions produced a colder, drier climate.” They also report that the climatic variations they discovered “correlate closely with variations in North Atlantic drift-ice tracers that represent episodic advection of drift ice and cold polar surface water southward and eastward into warmer subpolar water.”

The researchers state that “the correspondence of these records over the full span of Holocene time implies a close relationship between North Atlantic climate and the monsoon climate of central China.”

They also state that the most recent of the episodic cold periods, which they identify as the Little Ice Age, began about AD 1370, while the preceding cold period ended somewhere in the vicinity of AD 810. Consequently, their work implies the existence of a medieval warm period that began some time after AD 810 and ended some time before AD 1370. In addition, their relating of this millennial-scale climate cycle to the similar-scale drift-ice cycle of Bond *et al.* (2001) implies they accept solar forcing as the most likely cause of the alternating multi-century mild/moist and cold/dry periods of North-Central China. As a result, Porter and Weijian's work helps to establish the global extent of the Medieval Warm Period, as well as its likely solar origin.

Much more evidence of a solar-climate link has been obtained from the Tibetan Plateau in China. Wang *et al.* (2002), for example, studied changes in  $\delta^{18}\text{O}$  and  $\text{NO}_3^-$  in an ice core retrieved from the Guliya Ice Cap (35°17'N, 81°29'E) there, comparing the results they obtained with ancillary data from Greenland and Antarctica. Two cold events—a weak one around 9.6-9.2 thousand years ago (ka) and a strong one universally referred to as the “8.2 ka cold event”—were identified in the Guliya ice core record. The authors report that these events occurred “nearly simultaneously with two ice-rafted episodes in the North Atlantic Ocean.” They additionally report that both events occurred during periods of weakened solar activity.

Remarking that evidence for the 8.2 ka cold event “occurs in glacial and lacustrine deposits from different areas,” the authors say this evidence “suggests that the influence of this cold event may have been global.” They also say that “comprehensive analyses indicate that the weakening of solar insolation might have been the external cause of the ‘8.2 ka cold event’,” and that “the cause of the cold event around 9.6-9.2 ka was also possibly related to the weaker solar activity.” The authors thus conclude that all of these things considered together imply that “millennial-scale climatic cyclicity might exist in the Tibetan Plateau as well as in the North Atlantic.”

In a contemporaneous paper enlarging this thesis, Xu *et al.* (2002) studied plant cellulose  $\delta^{18}\text{O}$  variations in cores retrieved from peat deposits west of Hongyuan County at the northeastern edge of the Qinghai-Tibetan Plateau (32° 46'N, 102° 30'E). Based on their analysis, the authors report finding the existence of three consistently cold events that were centered at approximately 500, 700, and 900 AD, during what is sometimes referred to as the Dark

Ages Cold Period. Then, from 1100-1300 AD, they report “the  $\delta^{18}\text{O}$  of Hongyuan peat cellulose increased, consistent with that of Jinchuan peat cellulose and corresponding to the ‘Medieval Warm Period’.” Finally, they note that “the periods 1370-1400 AD, 1550-1610 AD, [and] 1780-1880 AD recorded three cold events, corresponding to the ‘Little Ice Age’.”

Regarding the origins of these climatic fluctuations, power spectrum analyses of their data revealed periodicities of 79, 88, and 123-127 years, “suggesting,” in the words of the authors, “that the main driving force of Hongyuan climate change is from solar activities.” In a subsequent paper by the same authors, Xu *et al.* (2006) compared the Hongyuan temperature variations with solar activity inferred from atmospheric  $^{14}\text{C}$  and  $^{10}\text{Be}$  concentrations measured in a South Pole ice core, after which they performed cross-spectral analyses to determine the relationship between temperature and solar variability, comparing their results with similar results obtained other researchers around the world. What did they learn this time?

Xu *et al.* (2006) report that “during the past 6000 years, temperature variations in China exhibit high synchrony among different regions, and importantly, are in-phase with those discovered in other regions in the northern hemisphere.” They also say that their “comparisons between temperature variations and solar activities indicate that both temperature trends on centennial/millennial timescales and climatic events are related to solar variability.”

The researchers' final conclusion was that “quasi-100-year fluctuations of solar activity may be the primary driving force of temperature during the past 6000 years in China.” And since their data indicate that peak Medieval Warm Period temperatures were higher than those of the recent past, it is not unreasonable to assume that the planet's recent warmth may have been solar-induced as well.

Still in the northeast edge of the Tibetan Plateau, two years later Tan *et al.* (2008) developed a precipitation history of the Longxi area of the plateau's northeast margin since AD 960 based on an analysis of Chinese historical records, after which they compared the result with the same-period Northern Hemisphere temperature record and contemporaneous atmospheric  $^{14}\text{C}$  and  $^{10}\text{Be}$  histories.

In their words, Tan *et al.* discovered that “high precipitation of Longxi corresponds to high temperature of the Northern Hemisphere, and low precipitation of Longxi corresponds to low

temperature of the Northern Hemisphere.” Consequently, their precipitation record may be used to infer a Medieval Warm Period that stretched from approximately AD 960 to 1230, with temperature peaks in the vicinity of AD 1000 and 1215 that clearly exceeded the twentieth century peak temperature of the Current Warm Period. They also found “good coherences among the precipitation variations of Longxi and variations of atmospheric  $^{14}\text{C}$  concentration, the averaged  $^{10}\text{Be}$  record and the reconstructed solar modulation record,” which findings harmonize, in their words, with “numerous studies [that] show that solar activity is the main force that drives regional climate changes in the Holocene,” in support of which statement they attach 22 other scientific references.

The researchers ultimately concluded that the “synchronous variations between Longxi precipitation and Northern Hemisphere temperature may be ascribed to solar activity,” which apparently produced a Medieval Warm Period that was both longer and stronger than what has been experienced to date during the Current Warm Period in the northeast margin of the Tibetan Plateau.

Lastly, Xu *et al.* (2008) studied decadal-scale temperature variations of the past six centuries derived from four high-resolution temperature indicators—the  $\delta^{18}\text{O}$  and  $\delta^{13}\text{C}$  of bulk carbonate, total carbonate content, and the detrended  $\delta^{15}\text{N}$  of organic matter—which they extracted from Lake Qinghai ( $36^{\circ}32' - 37^{\circ}15'\text{N}$ ,  $99^{\circ}36' - 100^{\circ}47'\text{E}$ ) on the northeast Qinghai-Tibet plateau, comparing the resultant variations with proxy temperature indices derived from nearby tree rings and reconstructed solar activity. Results of the analysis showed that “there are four obvious cold intervals during the past 600 years at Lake Qinghai, namely 1430-1470, 1650-1715, 1770-1820 and 1920-1940,” and that “these obvious cold intervals are also synchronous with the minimums of the sunspot numbers during the past 600 years,” namely, “the Sporer, the Maunder, and the Dalton minimums,” which facts strongly suggest, in their words, “that solar activities may dominate temperature variations on decadal scales at the northeastern Qinghai-Tibet plateau.”

If the development of the significant cold of the worldwide Little Ice Age was driven by a concomitant change in some type of solar activity, which seems fairly well proven by a wealth of real-world data, it logically follows that the global warming of the twentieth century was driven primarily by the reversal of that change in solar

activity, and not by the historical rise in the air’s  $\text{CO}_2$  content. However, as also noted by Xu *et al.*, how small perturbations of solar activity have led “to the observed global warming, what is the mechanism behind it, etc., are still open questions.”

### 5.3.6. Europe

We begin our review of the sun's influence on Europe's temperatures with the study of Holzhauser *et al.* (2005), who presented high-resolution records of variations in glacier size in the Swiss Alps together with lake-level fluctuations in the Jura mountains, the northern French Pre-Alps, and the Swiss Plateau in developing a 3,500-year climate history of west-central Europe, beginning with an in-depth analysis of the Great Aletsch glacier, which is the largest of all glaciers located in the European Alps.

Near the beginning of the time period studied, the three researchers report that "during the late Bronze Age Optimum from 1350 to 1250 BC, the Great Aletsch glacier was approximately 1000 m shorter than it is today," noting that "the period from 1450 to 1250 BC has been recognized as a warm-dry phase in other Alpine and Northern Hemisphere proxies (Tinner *et al.*, 2003)." Then, after an intervening unnamed cold-wet phase, when the glacier grew in both mass and length, they say that "during the Iron/Roman Age Optimum between c. 200 BC and AD 50," which is perhaps better known as the Roman Warm Period, the glacier again retreated and "reached today's extent or was even somewhat shorter than

today.” Next came the Dark Ages Cold Period, which they say was followed by “the Medieval Warm Period, from around AD 800 to the onset of the Little Ice Age around AD 1300,” which latter cold-wet phase was “characterized by three successive [glacier length] peaks: a first maximum after 1369 (in the late 1370s), a second between 1670 and 1680, and a third at 1859/60,” following which the glacier began its latest and still-ongoing recession in 1865. In addition, they state that written documents from the fifteenth century AD indicate that at some time during that hundred-year interval “the glacier was of a size similar to that of the 1930s,” which latter period in many parts of the world was as warm as, or even warmer than, it is today. Data pertaining to the Gorner glacier (the second largest of the Swiss Alps) and the Lower Grindelwald glacier of the Bernese Alps tell much the same story, as Holzhauser *et al.* report that these glaciers and the Great Aletsch glacier “experienced nearly synchronous advances” throughout the study period.

With respect to what was responsible for the millennial-scale climatic oscillation that produced the alternating periods of cold-wet and warm-dry conditions that fostered the similarly paced cycle of glacier growth and retreat, the Swiss and French scientists report that “glacier maximums coincided with radiocarbon peaks, i.e., periods of weaker solar activity,” which in their estimation “suggests a possible solar origin of the climate oscillations punctuating the last 3500 years in west-central Europe, in agreement with previous studies (Denton and Karlén, 1973; Magny, 1993; van Geel *et al.*, 1996; Bond *et al.*, 2001).” And to underscore that point, they conclude their paper by stating that “a comparison between the fluctuations of the Great Aletsch glacier and the variations in the atmospheric residual  $^{14}\text{C}$  records supports the hypothesis that variations in solar activity were a major forcing factor of climate oscillations in west-central Europe during the late Holocene.”

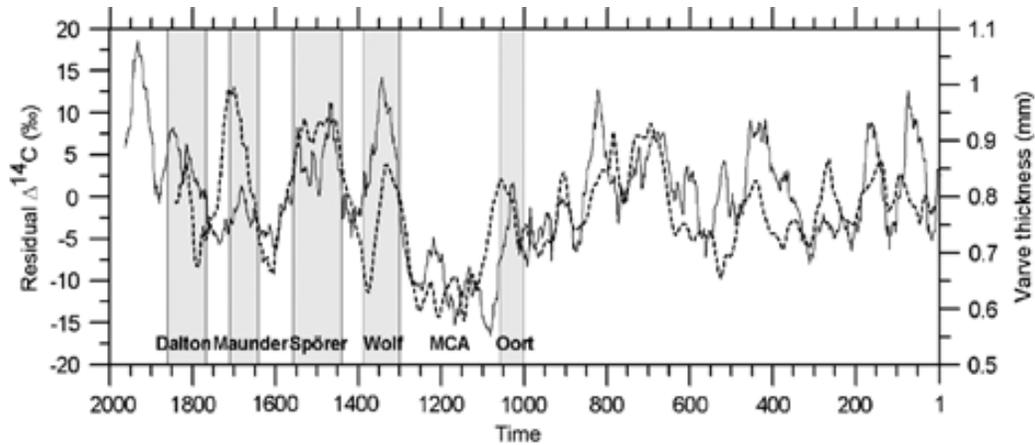

In another study of paleoclimate in western Europe, Mauquoy *et al.* (2002a) extracted peat monoliths from ombrotrophic mires at Lille Vildmose, Denmark (56°50'N, 10°15'E) and Walton Moss, UK (54°59'N, 02°46'W), which sites, being separated by about 800 km, “offer the possibility of detecting supraregional changes in climate.” From these monoliths, vegetative macrofossils were extracted at contiguous 1-cm intervals and examined using light microscopy. Where increases in the abundances of *Sphagnum tenellum* and *Sphagnum*

*cuspidatum* were found, a closely spaced series of  $^{14}\text{C}$  AMS-dated samples immediately preceding and following each increase was used to “wobble-match” date them (van Geel and Mook, 1989), thereby enabling comparison of the climate-induced shifts with the history of  $^{14}\text{C}$  production during the Holocene.

Results indicated the existence of a climatic deterioration that marked the beginning of a period of inferred cool, wet conditions that correspond fairly closely in time with the Wolf, Sporer, and Maunder Minima of solar activity, as manifest in contemporary  $\delta^{14}\text{C}$  data. The authors report “these time intervals correspond to periods of peak cooling in 1000-year Northern Hemisphere climate records,” adding to the “increasing body of evidence” that “variations in solar activity may well have been an important factor driving Holocene climate change.”

Two years later, Mauquoy *et al.* (2004) reviewed the principles of  $^{14}\text{C}$  wiggle-match dating, its limitations, and the insights it has provided about the timing and possible causes of climate change during the Holocene. Based upon their review, the authors stated that “analyses of microfossils and macrofossils from raised peat bogs by Kilian *et al.* (1995), van Geel *et al.* (1996), Speranza *et al.* (2000), Speranza (2000) and Mauquoy *et al.* (2002a, 2002b) have shown that climatic deteriorations [to cooler and wetter conditions] occurred during periods of transition from low to high delta  $^{14}\text{C}$  (the relative deviation of the measured  $^{14}\text{C}$  activity from the standard after correction for isotope fractionation and radioactive decay; Stuiver and Polach, 1977).” This close correspondence, in the words of the authors, again suggests that “changes in solar activity may well have driven these changes during the Bronze Age/Iron Age transition around c. 850 cal. BC (discussed in detail by van Geel *et al.*, 1996, 1998, 1999, 2000) and the ‘Little Ice Age’ series of palaeoclimatic changes.”

Working with a marine sediment core retrieved from the southern Norwegian continental margin, Berstad *et al.* (2003) reconstructed sea surface temperatures (SSTs) from  $\delta^{18}\text{O}$  data derived from the remains of the planktonic foraminifera species *Neogloboquadrina pachyderma* (summer temperatures) and *Globigerina bulloides* (spring temperatures). Among other things, the authors’ work depicted a clear connection between the cold temperatures of the Little Ice Age and the reduced solar activity of the concomitant Maunder and Sporer solar minima, as well as between the warm

**Figure 5.3.6.** Residual  $\Delta^{14}\text{C}$  data (dashed line) and varve thickness (smooth line) vs. time, specifically highlighting the Oort, Wolf, Sporer, Maunder and Dalton solar activity minima, as well as the “Medieval Climate Anomaly (also referred to as Medieval Warm Period),” during the contemporaneous “solar activity maxima in the Middle Ages.” Adapted from Haltia-Hovi *et al.* (2007).

temperatures of the most recent 70 years and the enhanced solar activity of the concomitant Modern solar maximum, which they clearly implied in their paper is a causative connection, as is also implied by the recent sunspot number reconstruction of Usoskin *et al.* (2003).

Nearby in Finland, Haltia-Hovi *et al.* (2007) extracted sediment cores from beneath the 0.7-m-thick ice platform on Lake Lehmilampi (63°37'N, 29°06'E) in North Karelia, eastern Finland, after which they identified and counted the approximately 2,000 annual varves contained in the cores and measured their individual thicknesses and mineral and organic matter contents. These climate-related data were then compared with residual  $\Delta^{14}\text{C}$  data derived from tree rings, which serve as a proxy for solar activity.

According to Haltia-Hovi *et al.*, their “comparison of varve parameters (varve thickness, mineral and organic matter accumulation) and the activity of the sun, as reflected in residual  $\Delta^{14}\text{C}$  [data] appears to coincide remarkably well in Lake Lehmilampi during the last 2000 years, suggesting solar forcing of the climate,” as depicted in Figure 5.3.6 for the case of varve thickness. What is more, the low deposition rate of mineral matter in Lake Lehmilampi in AD 1060-1280 “possibly implies mild winters with a short ice cover period during that time with minor snow accumulation interrupted by thawing periods.” Likewise, they say that the low accumulation of organic matter during this period “suggests a long open water season and a high decomposition rate of organic matter.” Consequently,

since the AD 1060-1280 period shows the lowest levels of both mineral and organic matter content, and since “the thinnest varves of the last 2000 years were deposited during [the] solar activity maxima in the Middle Ages,” it is difficult not to conclude that that period was likely the warmest of the past two millennia in the part of the world studied by the three scientists.

Hanna *et al.* (2004) analyzed several climatic variables over the past century in Iceland in an effort to determine if there is “possible evidence of recent climatic changes” in that cold island nation. Results indicated that for the period 1923-2002, no trend was found in either annual or monthly sunshine data. Similar results were reported for annual and monthly pressure data, which exhibited semi-decadal oscillations throughout the 1820-2002 period but no significant upward or downward trend. Precipitation, on the other hand, appears to have increased slightly, although the authors question the veracity of the trend, citing a number of biases that have potentially corrupted the database.

With respect to temperature, however, the authors indicate that of the handful of locations they examined for this variable, all stations experienced a net warming since the mid-1800s. The warming, however, was not linear over the entire time period. Rather, temperatures rose from their coldest levels in the mid-1800s to their warmest levels in the 1930s, whereupon they remained fairly constant for approximately three decades. Then came a period of rapid cooling, which ultimately gave way to the warming of the 1980s and 1990s. However, it is

important to note that the warming of the past two decades has not resulted in temperatures rising above those observed in the 1930s. In this point the authors are particularly clear, stating emphatically that “the 1990s was definitely *not* the warmest decade of the 20th century in Iceland, in contrast to the Northern Hemisphere land average.” In fact, a linear trend fit to the post-1930 data would indicate an overall temperature decrease since that time.

As for what may be responsible for the various trends evident in the data, Hanna *et al.* note the likely influence of the sun on temperature and pressure values in consequence of their finding a significant correlation between 11-year running temperature means and sunspot numbers, plus the presence of a 12-year peak in their spectral analysis of the pressure data, which they say is “suggestive of solar activity.”

In another study, Mangini *et al.* (2005) develop a highly resolved 2,000-year  $\delta^{18}\text{O}$  proxy record of temperature obtained from a stalagmite recovered from Spannagel Cave in the Central Alps of Austria. Results indicated that the lowest temperatures of the past two millennia occurred during the Little Ice Age (AD 1400-1850), while the highest temperatures were found in the Medieval Warm Period (MWP: AD 800-1300). Furthermore, Mangini *et al.* say that the highest temperatures of the MWP were “slightly higher than those of the top section of the stalagmite (1950 AD) and higher than the present-day temperature.” At three different points during the MWP, their data indicate temperature spikes in excess of 1°C above present (1995-1998) temperatures.

Mangini *et al.* additionally report that their temperature reconstruction compares well with reconstructions developed from Greenland ice cores (Muller and Gordon, 2000), Bermuda Rise ocean-bottom sediments (Keigwin, 1996), and glacier tongue advances and retreats in the Alps (Holzhauser, 1997; Wanner *et al.*, 2000), as well as with the Northern Hemispheric temperature reconstruction of Moberg *et al.* (2005). Considered together, they say these several datasets “indicate that the MWP was a climatically distinct period in the Northern Hemisphere,” emphasizing that “this conclusion is in strong contradiction to the temperature reconstruction by the IPCC, which only sees the last 100 years as a period of increased temperature during the last 2000 years.”

In a second severe blow to the theory of CO<sub>2</sub>-induced global warming, Mangini *et al.* found “a high correlation between  $\delta^{18}\text{O}$  and  $\delta^{14}\text{C}$ , that reflects the amount of radiocarbon in the upper atmosphere,” and

they note that this correlation “suggests that solar variability was a major driver of climate in Central Europe during the past 2 millennia.” In this regard, they report that “the maxima of  $\delta^{18}\text{O}$  coincide with solar minima (Dalton, Maunder, Sporer, Wolf, as well as with minima at around AD 700, 500 and 300),” and that “the coldest period between 1688 and 1698 coincided with the Maunder Minimum.” Also, in a linear-model analysis of the percent of variance of their full temperature reconstruction that is individually explained by solar and CO<sub>2</sub> forcing, they found that the impact of the sun was fully 279 times greater than that of the air’s CO<sub>2</sub> concentration, noting that “the flat evolution of CO<sub>2</sub> during the first 19 centuries yields almost vanishing correlation coefficients with the temperature reconstructions.”

Two years later, Mangini *et al.* (2007) updated the 2005 study with additional data after which they compared it with the Hematite-Stained-Grain (HSG) history of ice-rafted debris in North Atlantic Ocean sediments developed by Bond *et al.* (2001), finding an undeniably good correspondence between the peaks and valleys of their  $\delta^{18}\text{O}$  curve and the HSG curve. The significance of such correspondence is evidenced by the fact that Bond *et al.* reported that “over the last 12,000 years virtually every centennial time-scale increase in drift ice documented in our North Atlantic records was tied to a solar minimum.”

Other researchers have found similar periodicities in their climate proxies. Turner *et al.* (2008), for example, found an ~1500 year cycle in a climate history reconstructed from sediment cores extracted from two crater lake basins in central Turkey, which they indicate “may be linked with large-scale climate forcing” such as that found in the North Atlantic by Bond *et al.* (1997, 2001). McDermott *et al.* (2001) found evidence of millennial-scale climate cycles in a  $\delta^{18}\text{O}$  record from a stalagmite in southwestern Ireland, as did Sbaifi *et al.* (2004) from two deep-sea sediment cores recovered from the Tyrrhenian Sea, which latter proxy corresponded well with the North Atlantic solar-driven cycles of Bond *et al.* (1997).

Nearby in the Mediterranean Sea, Cini Castagnoli *et al.* (2002) searched for possible solar-induced variations in the  $\delta^{13}\text{C}$  record of the foraminifera *Globigerinoides ruber* obtained from a sea core located in the Gallipoli terrace of the Gulf of Taranto (39°45’53”N, 17°53’33”E, depth of 178 m) over the past 1,400 years. Starting at the beginning of the 1,400-year record, the  $\delta^{13}\text{C}$  values increased from about 0.4 per mil around 600 A.D. to a value of 0.8 per mil by 900 A.D. Thereafter, the  $\delta^{13}\text{C}$  record

remained relatively constant until about 1800, when it rose another 0.2 per mil to its present-day value of around 1.0 per mil.

Using statistical procedures, the authors were able to identify three important cyclical components in their record, with periods of approximately 11.3, 100, and 200 years. Comparison of both the raw  $\delta^{13}\text{C}$  and component data with the historical aurorae and sunspot time series, respectively, revealed that the records are “associable in phase” and “disclose a statistically significant imprint of the solar activity in a climate record.” Three years later, Cini Castagnoli *et al.* (2005) extended the  $\delta^{13}\text{C}$  temperature proxy from the Gulf of Taranto an additional 600 years, reporting an overall phase agreement between the climate reconstruction and variations in the sunspot number series that “favors the hypothesis that the [multi-decadal] oscillation revealed in  $\delta^{13}\text{C}$  is connected to the solar activity.”

Finally, we report on the study of Desprat *et al.* (2003), who studied the climatic variability of the last three millennia in northwest Iberia via a high-resolution pollen analysis of a sediment core retrieved from the central axis of the Ria de Vigo in the south of Galicia (42°14.07'N, 8°47.37'W). According to the authors, over the past 3,000 years there was “an alternation of three relatively cold periods with three relatively warm episodes.” In order of their occurrence, these periods are described by the authors as the “first cold phase of the Subatlantic period (975-250 BC),” which was “followed by the Roman Warm Period (250 BC-450 AD),” which was followed by “a successive cold period (450-950 AD), the Dark Ages,” which “was terminated by the onset of the Medieval Warm Period (950-1400 AD),” which was followed by “the Little Ice Age (1400-1850 AD), including the Maunder Minimum (at around 1700 AD),” which “was succeeded by the recent warming (1850 AD to the present).” Based upon this “millennial-scale climatic cyclicity over the last 3000 years,” which parallels “global climatic changes recorded in North Atlantic marine records (Bond *et al.*, 1997; Bianchi and McCave, 1999; Chapman and Shackleton, 2000),” Desprat *et al.* conclude that “solar radiative budget and oceanic circulation seem to be the main mechanisms forcing this cyclicity in NW Iberia.”

In conclusion, paleoclimatic studies from Europe provide more evidence is for the global reality of the solar-induced millennial-scale oscillation of temperatures pervading both glacial and interglacial periods. The Current Warm Period can consequently

be viewed as the most recent manifestation of this recurring phenomenon and unrelated to the concurrent historical increase in the air's  $\text{CO}_2$  content.

### 5.3.7. Other

Rounding out our examination of the influence of the sun on earth's temperatures, we begin with the review study of Van Geel *et al.* (1999), who examined what is known about the relationship between variations in the abundances of the cosmogenic isotopes  $^{14}\text{C}$  and  $^{10}\text{Be}$  and millennial-scale climate oscillations during the Holocene and portions of the last great ice age. As they describe it, "there is mounting evidence suggesting that the variation in solar activity is a cause for millennial-scale climate change," which is known to operate independently of the glacial-interglacial cycles that are forced by variations in the earth's orbit about the sun. Continuing, they add that "accepting the idea of solar forcing of Holocene and Glacial climatic shifts has major implications for our view of present and future climate," for it implies, as they note, that "the climate system is far more sensitive to small variations in solar activity than generally believed" and that "it could mean that the global temperature fluctuations during the last decades are partly, or completely explained by small changes in solar radiation." These observations, of course, call into question the conventional wisdom of attributing the global warming of the past century or so to the ongoing rise in the air's  $\text{CO}_2$  content.

In a study published the following year, Tyson *et al.* (2000) obtained a quasi-decadal-resolution record of oxygen and carbon-stable isotope data from a well-dated stalagmite recovered from Cold Air Cave in the Makapansgat Valley, 30 km southwest of Pietersburg, South Africa, which they augmented with temperature data reconstructed from color variations in banded

growth-layer laminations of the stalagmite that were derived from a relationship calibrated against actual air temperatures obtained from a surrounding 49-station climatological network over the period 1981-1995, which had a correlation of +0.78 that was significant at the 99 percent confidence level.

According to the authors, both the Little Ice Age (prevailing from about AD 1300 to 1800) and the Medieval Warm Period (prevailing from before AD 1000 to around 1300) were found to be distinctive features of the climate of the last millennium. Relative to the period 1961-1990, in fact, the Little Ice Age, which "was a widespread event in South Africa specifically and southern Africa generally," was characterized by a mean annual temperature depression of about  $1^\circ\text{C}$  at its coolest point. The Medieval Warm Period, on the other hand, was as much as  $3\text{-}4^\circ\text{C}$  warmer at its warmest point. The researchers also note that the coolest point of the Little Ice Age corresponded in time with the Maunder Minimum of sunspot activity and that the Medieval Warm Period corresponded with the Medieval Maximum in solar activity.

In a study demonstrating a solar-climate link on shorter decadal to centennial time scales, Domack *et al.* (2001) examined ocean sediment cores obtained from the Palmer Deep on the inner continental shelf of the western Antarctic Peninsula ( $64^\circ 51.71' \text{ S}$ ,  $64^\circ 12.47' \text{ W}$ ) to produce a high-resolution proxy temperature history of that area spanning the past 13,000 years. Results indicated the presence of five prominent palaeoenvironmental intervals over the past 14,000 years: (1) a "Neoglacial" cool period beginning 3,360 years ago and continuing to the present, (2) a mid-Holocene climatic optimum from 9,070 to 3,360 years ago, (3) a cool period beginning 11,460 years ago and ending at 9,070 years ago, (4) a warm period from 13,180 to 11,460 years ago, and (5) cold glacial conditions prior to 13,180 years ago. Spectral analyses of the data revealed that superimposed upon these broad climatic intervals were decadal and centennial-scale temperature cycles. Throughout the current Neoglacial period, they report finding "very significant" (above the 99 percent confidence level) peaks, or oscillations, that occurred at intervals of 400, 190, 122, 85, and 70 years, which they suggest are perhaps driven by solar variability.

Moving upward to the warmer ocean waters off the Cook Islands, South Pacific Ocean, Dima *et al.* (2005) performed Singular Spectrum Analysis on a Rarotonga coral-based sea surface temperature (SST) reconstruction in an effort to determine the dominant

periods of multi-decadal variability in the series over the period 1727-1996. Results of the analysis revealed two dominant multi-decadal cycles, with periods of about 25 and 80 years. These modes of variability were determined to be similar to multi-decadal modes found in the global SST field of Kaplan *et al.* (1998) for the period 1856-1996. The ~25-year cycle was found to be associated with the well-known Pacific Decadal Oscillation, whereas the ~80-year cycle was determined to be “almost identical” to a pattern of solar forcing found by Lohmann *et al.* (2004), which, according to Dima *et al.*, “points to a possible solar origin” of this mode of SST variability.

We conclude this brief review with the study of Bard and Frank (2006), who reviewed what is known, and unknown, about solar variability and its effects on earth’s climate, focusing on the past few decades, the past few centuries, the entire Holocene, and orbital timescales. Of greatest interest to the present discussion are Bard and Frank’s conclusions about sub-orbital time scales, i.e., the first three of their four major focal points. Within this context, as they say in the concluding section of their review, “it appears that solar fluctuations were involved in causing widespread but limited climatic changes, such as the Little Ice Age (AD 1500-1800) that followed the Medieval Warm Period (AD 900-1400).” Or as they say in the concluding sentence of their abstract, “the weight of evidence suggests that solar changes have contributed to small climate oscillations occurring on time scales of a few centuries, similar in type to the fluctuations classically described for the last millennium: The so-called Medieval Warm Period (AD 900-1400) followed on by the Little Ice Age (AD 1500-1800).”

In the words of Bard and Frank, “Bond *et al.* (1997, 2001) followed by Hu *et al.* (2003) proposed that variations of solar activity are responsible for quasi-periodic climatic and oceanographic fluctuations that follow cycles of about one to two millennia.” As a result, they say that “the succession from the Medieval Warm Period to the Little Ice Age would thus represent the last [such] cycle,” leading to the conclusion that “our present climate is in an ascending phase on its way to attaining a new warm optimum,” due to some form of solar variability. In addition, they note that “a recent modeling study suggests that an apparent 1500-year cycle could arise from the superimposed influence of the 90 and 210 year solar cycles on the climate system, which is characterized by both nonlinear dynamics and long time scale memory effects (Braun *et al.* 2005).”

These studies demonstrate that the warming of the earth since the termination of the Little Ice Age is not unusual or different from other climate changes of the past millennium, when atmospheric CO<sub>2</sub> concentrations were stable, lower than at present, and obviously not responsible for the observed variations in temperature. This further suggests that the warming of the past century was not due to the contemporaneous historical increase in the air’s CO<sub>2</sub> content.

Additional information on this topic, including reviews of newer publications as they become available, can be found at <http://www.co2science.org/subject/s/solartempmisc.php>.

## 5.4. Precipitation

The IPCC claims to have found a link between CO<sub>2</sub> concentrations in the air and precipitation trends. In this section of our report, we show that solar variability offers a superior explanation of past trends in precipitation.

### 5.4.1. North America

We begin our review of the influence of the sun on North American precipitation with a study that examines the relationship between the sun and low-level clouds, considering the presence of low-level clouds to be correlated with precipitation. According to Kristjansson *et al.* (2002), solar irradiance “varies by about 0.1% over the 11-year solar cycle, which would appear to be too small to have an impact on climate.” Nevertheless, they report that “persistent claims have been made of 11-year signals in various meteorological time series, e.g., sea surface temperature (White *et al.*, 1997) and cloudiness over North America (Udelhofen and Cess, 2001).” Kristjansson *et al.* purposed to “re-evaluate the statistical relationship between low cloud cover and solar activity adding 6 years of ISCCP [International Satellite Cloud Climatology Project] data that were recently released.”

For the period 1983-1999, the authors compared temporal trends of solar irradiance at the top of the atmosphere with low cloud cover derived from different sets of satellite-borne instruments that provided two measures of the latter parameter: full temporal coverage and daytime-only coverage. Results indicated that “solar irradiance correlates well

with low cloud cover,” with the significance level of the correlation being 98 percent for the case of full temporal coverage and 90 percent for the case of daytime-only coverage. As would be expected if the variations in cloud cover were driven by variations in solar irradiance, they also report that lagged correlations between the two parameters reveal a maximum correlation between solar irradiance and low cloud cover when the former leads the latter by one month for the full temporal coverage case and by four months for the daytime-only situation.

The authors’ observation that “low clouds appear to be significantly inversely correlated with solar irradiance” compelled them to suggest a possible physical mechanism that could explain this phenomenon. Very briefly, this mechanism, in their words, “acts through UV [ultraviolet radiation] in the stratosphere affecting tropospheric planetary waves and hence the subtropical highs, modulated by an interaction between sea surface temperature [SST] and lower tropospheric static stability,” which “relies on a positive feedback between changes in SST and low cloud cover changes of opposite sign, in the subtropics.” Based on experimentally determined values of factors that enter into this scenario, they obtain a value for the amplitude of the variation in low cloud cover over a solar cycle that “is very close to the observed amplitude.”

In pursuing other indirect means of ferreting out a solar influence on precipitation, several authors have examined lake level fluctuations, which are generally highly dependent on precipitation levels. Cumming *et al.* (2002), for example, studied a sediment core retrieved from Big Lake (51°40’N, 121°27’W) on the Cariboo Plateau of British Columbia, Canada, carefully dating it and deriving estimates of changes in precipitation-sensitive limnological variables (salinity and lake depth) from transfer functions based on modern distributions of diatom assemblages in 219 lakes from western Canada.

On the basis of observed changes in patterns of the floristic composition of diatoms over the past 5,500 years, the authors report that “alternating millennial-scale periods of high and low moisture availability were inferred, with *abrupt* [our italics] transitions in diatom communities occurring 4960, 3770, 2300 and 1140 cal. yrs. BP.” They also indicate that “periods of inferred lower lake depth correspond closely to the timing of worldwide Holocene glacier expansions,” and that the mean length of “the relatively stable intervals between the abrupt transitions ... is similar to the mean Holocene pacing

of IRD [ice rafted debris] events ... in the North Atlantic,” which have been described by Bond *et al.* (1997) and attributed to “solar variability amplified through oceanic and atmospheric dynamics,” as detailed by Bond *et al.* (2001).

Li *et al.* (2006, 2007) also developed a precipitation proxy from a lake-level record, based on lithologic and mineral magnetic data from the Holocene sediments of White Lake, New Jersey, northeastern USA (41°N, 74.8°W), the characteristics of which they compared with a host of other paleoclimatic reconstructions from this region and beyond.

According to the authors of these two papers, the lake-level history revealed low lake levels at ~1.3, 3.0, 4.4, and 6.1 thousand years before present; comparison of the results with drift-ice records from the North Atlantic Ocean according to Li *et al.* (2007) “indicates a striking correspondence,” as they “correlate well with cold events 1, 2, 3 and 4 of Bond *et al.* (2001).” They also report that a comparison of their results with those of other land-based studies suggests “a temporally coherent pattern of climate variations at a quasi-1500-year periodicity at least in the Mid-Atlantic region, if not the entire northeastern USA.” In addition, and with respect to the other node of the climatic cycle, they note that “the Mid-Atlantic region was dominated by wet conditions, while most parts of the conterminous USA experienced droughts, when the North Atlantic Ocean was warm.”

In discussing their findings, the three researchers say the dry-cold correlation they found “resembles the modern observed relationship between moisture conditions in eastern North America and the North Atlantic Oscillation (NAO), but operates at millennial timescales, possibly through modulation of atmospheric dynamics by solar forcing,” and in this regard they write that the sun-climate link on millennial timescales has “been demonstrated in several records (e.g., Bond *et al.*, 2001; Hu *et al.*, 2003; Niggemann *et al.*, 2003), supporting solar forcing as a plausible mechanism for modulating the AO [Arctic Oscillation]/NAO at millennial timescales.”

Along the same vein of research, Dean *et al.* (2002) analyzed the varve thickness and continuous gray-scale density of sediment cores taken from Elk Lake, MN (47°12'N, 95°15'W) for the past 1,500 years. Results indicated the presence of significant periodicities throughout the record, including multidecadal periodicities of approximately 10, 29, 32, 42, and 96 years, and a strong multicentennial

periodicity of about 400 years, leading the authors to wonder whether the observed periodicities are manifestations of solar-induced climate signals, upon which they present strong correlative evidence that they are. The 10-year oscillation was found to be strongest in the time series between the fourteenth and nineteenth centuries, during the Little Ice Age, and may well have been driven by the 11-year sunspot cycle.

Further south in Mexico, Lozano-Garcia *et al.* (2007) conducted a high-resolution multi-proxy analysis of pollen, charcoal particles, and diatoms found in the sediments of Lago Verde (18°36'46" N, 95°20'52"W)—a small closed-basin lake on the outskirts of the Sierra de Los Tuxtlas (a volcanic field on the coast of the Gulf of Mexico)—which covered the past 2,000 years. The five Mexican researchers who conducted the study say their data “provide evidence that the densest tropical forest cover and the deepest lake of the last two millennia were coeval with the Little Ice Age, with two deep lake phases that follow the Sporer and Maunder minima in solar activity.” In addition, they suggest that “the high tropical pollen accumulation rates limit the Little Ice Age’s winter cooling to a maximum of 2°C,” and they conclude that the “tropical vegetation expansion during the Little Ice Age is best explained by a reduction in the extent of the dry season as a consequence of increased meridional flow leading to higher winter precipitation.” Concluding their study, Lozano-Garcia *et al.* state “the data from Lago Verde strongly suggest that during the Little Ice Age lake levels and vegetation at Los Tuxtlas were responding to solar forcing and provide further evidence that solar activity is an important element controlling decadal to centennial scale climatic variability in the tropics (Polissar *et al.*, 2006) and in general over the North Atlantic region (Bond *et al.*, 2001; Dahl-Jensen *et al.*, 1998).”

Across the Gulf of Mexico in a study from the sea, as opposed to from a lake, Lund and Curry (2004) analyzed planktonic foraminiferal  $\delta^{18}\text{O}$  time series obtained from three well-dated sediment cores retrieved from the seabed near the Florida Keys (24.4°N, 83.3°W) in an effort to examine centennial to millennial timescale changes in the Florida Current-Gulf Stream system over the past 5,200 years. Based upon the analysis, isotopic data from the three cores indicated that “the surface Florida Current was denser (colder, saltier or both) during the Little Ice Age than either the Medieval Warm Period or today,” and that “when considered with other

published results (Keigwin, 1996; deMenocal *et al.*, 2000), it is possible that the entire subtropical gyre of the North Atlantic cooled during the Little Ice Age ... perhaps consistent with the simulated effects of reduced solar irradiance (Rind and Overpeck, 1993; Shindell *et al.*, 2001).” In addition, they report that “the coherence and phasing of atmospheric  $^{14}\text{C}$  production and Florida Current  $\delta^{18}\text{O}$  during the Late Holocene implies that solar variability may influence Florida Current surface density at frequencies between 1/300 and 1/100 years.” Hence, we once again have a situation where both centennial- and millennial-scale climatic variability is explained by similar-scale variability in solar activity.

Moving up the Atlantic coast to Newfoundland, Hughes *et al.* (2006) derived a multi-proxy palaeoclimate record from Nordan’s Pond Bog, a coastal plateau bog in Newfoundland, based upon “analyses of plant macrofossils, testate amoebae and the degree of peat humification,” which enabled them to create “a single composite reconstruction of bog surface wetness (BSW)” that they compare with “records of cosmogenic isotope flux.”

Results of the analysis indicated that “at least 14 distinctive phases of increased BSW may be inferred from the Nordan’s Pond Bog record,” commencing at 8,270 cal. years BP, and that “comparisons of the BSW reconstruction with records of cosmogenic isotope flux ... suggest a persistent link between reduced solar irradiance and increased BSW during the Holocene.” Furthermore, Hughes *et al.* conclude that the “strong correlation between increased  $^{14}\text{C}$  production [which accompanies reduced solar activity] and phases of maximum BSW supports the role of solar forcing as a persistent driver of changes to the atmospheric moisture balance throughout the Holocene,” which finding further suggests that the sun likely orchestrated the Little Ice Age to Current Warm Period transition, which altered precipitation regimes around the globe. Consequently, the authors state that “evidence suggesting a link between solar irradiance and sub-Milankovitch-scale palaeoclimatic change has mounted,” and the “solar hypothesis, as an explanation for Holocene climate change, is now gaining wider acceptance.”

Asmerom *et al.* (2007) developed a high-resolution Holocene climate proxy for the southwest United States from  $\delta^{18}\text{O}$  variations in a stalagmite obtained in Pink Panther Cave in the Guadalupe Mountains of New Mexico. Spectral analysis performed on the raw  $\delta^{18}\text{O}$  data revealed significant peaks that the researchers say “closely match

previously reported periodicities in the  $^{14}\text{C}$  content of the atmosphere, which have been attributed to periodicities in the solar cycle (Stuiver and Braziunas, 1993).” More specifically, they say that cross-spectral analysis of the  $\Delta^{14}\text{C}$  and  $\delta^{18}\text{O}$  data confirms that the two records have matching periodicities at 1,533 years (the Bond cycle), 444 years, 170 years, 146 years, and 88 years (the Gleissberg cycle). In addition, they report that periods of increased solar radiation correlate with periods of decreased rainfall in the southwestern United States (via changes in the North American monsoon), and that this behavior is just the opposite of what is observed with the Asian monsoon. These observations lead them to suggest that the proposed solar link to Holocene climate operates “through changes in the Walker circulation and the Pacific Decadal Oscillation and El Niño-Southern Oscillation systems of the tropical Pacific Ocean.”

Since the warming of the twentieth century appears to represent the most recent rising phase of the Bond cycle, which in its previous rising phase produced the Medieval Warm Period (see Bond *et al.*, 2001), and since we could still be embedded in that rising temperature phase, which could well continue for some time to come, there is a reasonable probability that the desert southwest of the United States could experience an intensification of aridity in the not-too-distant future, and that wetter conditions could be expected in the monsoon regions of Asia, without atmospheric greenhouse gases playing any role.

#### 5.4.2. South America

We begin our investigation of the influence of the sun on precipitation in South America with the study of Nordemann *et al.* (2005), who analyzed tree rings from species sensitive to fluctuations in precipitation from the southern region of Brazil and Chile along with sunspot data via harmonic spectral and wavelet analysis in an effort to obtain a greater understanding of the effects of solar activity, climate, and geophysical phenomena on the continent of South America, where the time interval covered by the tree-ring samples from Brazil was 200 years and that from Chile was 2,500 years. Results from the spectral analysis revealed periodicities in the tree rings that corresponded well with the DeVries-Suess (~200 yr), Gleissberg (~80 yr), Hale (~22 yr), and Schwabe (~11 yr) solar activity cycles; while wavelet cross-spectrum analysis of sunspot number and tree-ring growth revealed a clear relation between the tree-ring and solar series.

Working with a sediment core retrieved from the main basin of Lake Titicaca (16°S, 69°W) on the Altiplano of Bolivia and Peru, Baker *et al.* (2005) reconstructed the lake-level history of the famous South American water body over the past 13,000 years at decadal to multi-decadal resolution based on  $\delta^{13}\text{C}$  measurements of sediment bulk organic matter.

Baker *et al.* report that “the pattern and timing of lake-level change in Lake Titicaca is similar to the ice-rafted debris record of Holocene Bond events, demonstrating a possible coupling between precipitation variation on the Altiplano and North Atlantic sea-surface temperatures.” Noting that “cold periods of the Holocene Bond events correspond with periods of increased precipitation on the Altiplano,” they further conclude that “Holocene precipitation variability on the Altiplano is anti-phased with respect to precipitation in the Northern Hemisphere monsoon region.” In further support of these findings, they add that “the relationship between lake-level variation at Lake Titicaca and Holocene Bond events also is supported by the more coarsely resolved (but very well documented) record of water-level fluctuations over the past 4000 years based on the sedimentology of cores from the shallow basin of the lake (Abbott *et al.*, 1997).”

Also examining a time interval spanning the length of the Holocene, Haug *et al.* (2001) utilized the titanium and iron concentrations of an ocean sediment core taken from a depth of 893 meters in the Cariaco Basin on the Northern Shelf of Venezuela (10°42.73'N, 65°10.18'W) to infer variations in the hydrologic cycle over northern South America over the past 14,000 years. Results indicated that titanium and iron concentrations were lower during the Younger Dryas cold period between 12.6 and 11.5 thousand years ago, corresponding to a weakened hydrologic cycle with less precipitation and runoff. During the Holocene Optimum (10.5 to 5.4 thousand years ago), however, concentrations of these metals remained at or near their highest values, suggesting wet conditions and an enhanced hydrologic cycle for more than five thousand years. Closer to the present, the largest century-scale variations in precipitation are inferred in the record between approximately 3.8 and 2.8 thousand years ago, as the amounts of these metals in the sediment record varied widely over short time intervals. Higher precipitation was noted during the Medieval Warm Period from 1.05 to 0.7 thousand years ago, followed by drier conditions associated with the Little Ice Age (between 550 and 200 years ago).

With respect to what factor(s) might best explain the regional changes in precipitation inferred from the Cariaco metals' records of the past 14,000 years, the authors state that the regional changes in precipitation “are best explained by shifts in the mean latitude of the Atlantic Intertropical Convergence Zone,” which, in turn, “can be explained by the Holocene history of insolation, both directly and through its effect on tropical Pacific sea surface conditions.”

The results of these studies in South America demonstrate the important influence of solar variations on precipitation, necessarily implying a smaller possible role or no role at all for greenhouse gases.

### 5.4.3. Africa

We begin our examination of Africa with a study covering the period 9,600-6,100 years before present, where Neff *et al.* (2001) investigated the relationship between a  $^{14}\text{C}$  tree-ring record and a  $\delta^{18}\text{O}$  proxy record of monsoon rainfall intensity as recorded in

calcite  $\delta^{18}\text{O}$  data obtained from a stalagmite in northern Oman. The correlation between the two datasets was reported to be “extremely strong,” and a spectral analysis of the data revealed statistically significant periodicities centered on 779, 205, 134, and 87 years for the  $\delta^{18}\text{O}$  record and periodicities of 206, 148, 126, 89, 26, and 10.4 years for the  $^{14}\text{C}$  record. Because variations in  $^{14}\text{C}$  tree-ring records are generally attributed to variations in solar activity and intensity, and because of this particular  $^{14}\text{C}$  record’s strong correlation with the  $\delta^{18}\text{O}$  record, as well as the closely corresponding results of the spectral analyses, Neff *et al.* conclude there is “solid evidence” that both signals (the  $^{14}\text{C}$  and  $\delta^{18}\text{O}$  records) are responding to solar forcing.

In another study from eastern Africa, Stager *et al.* (2003) studied changes in diatom assemblages preserved in a sediment core extracted from Pilkington Bay, Lake Victoria, together with diatom and pollen data acquired from two nearby sites. According to the authors, the three coherent datasets revealed a “roughly 1400- to 1500-year spacing of century-scale P:E [precipitation:evaporation] fluctuations at Lake Victoria,” which they say “may be related to a ca. 1470-year periodicity in northern marine and ice core records that has been linked to solar variability (Bond *et al.*, 1997; Mayewski *et al.*, 1997).”

Further support of Stager *et al.*’s thesis comes from Verschuren *et al.* (2000), who developed a decadal-scale history of rainfall and drought in equatorial east Africa for the past thousand years based on lake-level and salinity fluctuations of a small crater-lake basin in Kenya, as reconstructed from sediment stratigraphy and the species compositions of fossil diatom and midge assemblages. They compared this history with an equally long record of atmospheric  $^{14}\text{CO}_2$  production, which is a proxy for solar radiation variations.

They found equatorial east Africa was significantly drier than today during the Medieval Warm Period from AD 1000 to 1270, while it was relatively wet during the Little Ice Age from AD 1270 to 1850. However, this latter period was interrupted by three periods of prolonged dryness: 1390-1420, 1560-1625, and 1760-1840. These “episodes of persistent aridity,” in the words of the authors, were “more severe than any recorded drought of the twentieth century.” In addition, they discovered that “all three severe drought events of the past 700 years were broadly coeval with phases of high solar radiation, and the intervening periods of increased

moisture were coeval with phases of low solar radiation.”

Verschuren *et al.* note that their results “corroborate findings from north-temperate dryland regions that instrumental climate records are inadequate to appreciate the full range of natural variation in drought intensity at timescales relevant to socio-economic activity.” This point is important, for with almost every new storm of significant size, with every new flood, or with every new hint of drought almost anywhere in the world, there are claims that the weather is becoming more extreme than ever before as a consequence of global warming. What we can learn from this study, however, is that there were more intense droughts in the centuries preceding the recent rise in the air’s  $\text{CO}_2$  content.

Verschuren *et al.* state that variations in solar radiative output “may have contributed to decade-scale rainfall variability in equatorial east Africa.” This conclusion is hailed as robust by Oldfield (2000), who states that the thinking of the authors on this point is “not inconsistent with current views.” Indeed, he too suggests that their results “provide strong evidence for a link between solar and climate variability.”

#### 5.4.4. Asia

Our review of the influence of the sun on Asian precipitation trends begins with the study of Pederson *et al.* (2001), who utilized tree-ring chronologies from northeastern Mongolia to reconstruct annual precipitation and streamflow histories for this region over the period 1651-1995.

Analyses of both standard deviations and five-year intervals of extreme wet and dry periods revealed that “variations over the recent period of instrumental data are not unusual relative to the prior record.” (See Figures 5.4.4.1 and 5.4.4.2.) The authors state, however, that the reconstructions “appear to show more frequent extended wet periods in more recent decades,” but they note that this observation “does not demonstrate unequivocal evidence of an increase in precipitation as suggested by some climate models.” More important to the present discussion, however, is the observation that spectral analysis of the data revealed significant periodicities of around 12 and 20-24 years, suggesting “possible evidence for solar influences in these reconstructions for northeastern Mongolia.”

Nearby, Tan *et al.* (2008) developed a precipitation history of the Longxi area of the Tibetan Plateau’s northeast margin since AD 960 based on an analysis of Chinese historical records, after which they compared the result with the same-period Northern Hemisphere temperature record and contemporaneous atmospheric  $^{14}\text{C}$  and  $^{10}\text{Be}$  histories. Results indicated that “high precipitation of Longxi corresponds to high temperature of the Northern Hemisphere, and low precipitation of Longxi corresponds to low temperature of the Northern Hemisphere.” They also found “good coherences among the precipitation variations of Longxi and variations of atmospheric  $^{14}\text{C}$  concentration, the averaged  $^{10}\text{Be}$  record and the reconstructed solar modulation record,” which findings harmonize, in their words, with “numerous studies [that] show that solar activity is the main force that drives regional climate changes in the Holocene,” in support of which statement they attach 22 other scientific references. As a result, the researchers ultimately concluded that the “synchronous variations between Longxi

**Figure 5.4.4.1.** Pederson *et al.* (2001) reconstruction of annual precipitation in mm in northeastern Mongolia over the period 1651-1995.

**Figure 5.4.4.2.** Pederson *et al.* (2001) reconstruction of annual variation in streamflow ( $\text{m}^3\text{yr}^{-1}$ ) in northeastern Mongolia over the period 1651-1995.

precipitation and Northern Hemisphere temperature may be ascribed to solar activity.”

Paulsen *et al.* (2003) utilized “high-resolution records of  $\delta^{13}\text{C}$  and  $\delta^{18}\text{O}$  in stalagmite SF-1 from Buddha Cave [ $33^{\circ}40'\text{N}$ ,  $109^{\circ}05'\text{E}$ ] ... to infer changes in climate in central China for the last 1270 years in terms of warmer, colder, wetter and drier conditions.” Results indicated the presence of several major climatic episodes, including the Dark Ages Cold Period, Medieval Warm Period, Little Ice Age, and 20th-century warming, “lending support to the global extent of these events.” With respect to hydrologic balance, the last part of the Dark Ages Cold Period was characterized as wet, followed by a dry, a wet, and another dry interval in the Medieval Warm Period, which was followed by a wet and a dry interval in the Little Ice Age, and finally a mostly wet

but highly moisture-variable Current Warm Period. Some of this latter enhanced variability is undoubtedly due to the much finer one-year time resolution of the last 150 years of the record as compared to the three- to four-year resolution of the prior 1,120 years. This most recent improved resolution thus led to the major droughts centered on AD 1835, 1878, and 1955 being very well delineated.

The authors' data also revealed a number of other cycles superimposed on the major millennial-scale cycle of temperature and the centennial-scale cycle of moisture. They attributed most of these higher-frequency cycles to cyclical solar and lunar phenomena, concluding that the summer monsoon over eastern China, which brings the region much of its precipitation, may thus "be related to solar irradiance."

In conclusion, as we have consistently seen throughout this section, precipitation in Asia is determined by a conglomerate of cycles, many of which are solar-driven, but nearly all of which are independent of the air's CO<sub>2</sub> concentration.

### 5.4.5. Europe

In this section, we investigate the natural influence of the sun on precipitation in Europe.

"Raised bogs," in the words of Blaauw *et al.* (2004), "are dependent on precipitation alone for water and nutrients." In addition, the various species of plants that are found in them each have their own requirements with respect to depth of water table. As

a result, the vertical distribution of macro- and microfossils in raised bogs reveals much about past changes in local moisture conditions, especially, as the authors note, "about changes in effective precipitation (precipitation minus evapotranspiration)."

At the same time, changes in the carbon-14 content of bog deposits reveal something about solar activity, because, as Blaauw *et al.* describe the connection, "a decreased solar activity leads to less solar wind, reduced shielding against cosmic rays, and thus to increased production of cosmogenic isotopes [such as <sup>14</sup>C]." Consequently, it is possible to compare the histories of the two records (effective precipitation and δ<sup>14</sup>C) and see if inferred changes in climate bear any relationship to inferred changes in solar activity, which is exactly what Blaauw *et al.* did.

Two cores of mid-Holocene raised-bog deposits in the Netherlands were <sup>14</sup>C "wiggle-match" dated by the authors at high precision, as per the technique described by Kilian *et al.* (1995, 2000) and Blaauw *et al.* (2003), while changes in local moisture conditions were inferred from the changing species composition of consecutive series of macrofossil samples. Results indicated that nine of 11 major mid-Holocene δ<sup>14</sup>C increases (for which they provide evidence that the rises were "probably caused by declines in solar activity") were coeval with major wet-shifts (for which they provide evidence that the shifts were "probably caused by climate getting cooler and/or wetter"). In the case of the significant wet-shift at the major δ<sup>14</sup>C rise in the vicinity of 850 BC, they additionally note that this prominent climatic cooling has been independently documented in many parts of the world, including "the North Atlantic Ocean (Bond *et al.*, 2001), the Norwegian Sea (Calvo *et al.*, 2002) [see also Andersson *et al.* (2003)], Northern Norway (Vorren, 2001), England (Waller *et al.*, 1999), the Czech Republic (Speranza *et al.*, 2000, 2002), central southern Europe (Magny, 2004), Chile (van Geel *et al.*, 2000), New Mexico (Armour *et al.*, 2002) and across the continent of North America (Viau *et al.*, 2002)." This close correspondence between major shifts in δ<sup>14</sup>C and precipitation has additionally led Mauquoy *et al.* (2004) to conclude that "changes in solar activity may well have driven these changes during the Bronze Age/Iron Age transition around c. 850 cal. BC (discussed in detail by van Geel *et al.*, 1996, 1998, 1999, 2000) and the 'Little Ice Age' series of palaeoclimatic changes."

Based upon these considerations, Blaauw *et al.* (2003) state that their findings "add to the accumulating evidence that solar variability has

played an important role in forcing climatic change during the Holocene.” The broad geographic extent of the observations of the 850 BC phenomenon also adds to the accumulating evidence that many of the climate changes that have occurred in the vicinity of the North Atlantic Ocean have been truly global in scope, providing even more evidence for their having been forced by variations in solar activity, which would be expected to have considerably more than a regional climatic impact.

In another bog study, cores of peat taken from two raised bogs in the near-coastal part of Halland, Southwest Sweden (Boarps Mosse and Hyltemossen) by Björck and Clemmensen (2004) were examined for their content of wind-transported clastic material via a systematic count of quartz grains of diameter 0.2-0.35 mm and larger than 0.35 mm to determine temporal variations in Aeolian Sand Influx (ASI), which is correlated with winter storminess in that part of the world.

According to the authors, “the ASI records of the last 2500 years (both sites) indicate two timescales of winter storminess variation in southern Scandinavia.” Specifically, they note that “decadal-scale variation (individual peaks) seems to coincide with short-term variation in sea-ice cover in the North Atlantic and is thus related to variations in the position of the North Atlantic winter season storm tracks,” while “centennial-scale changes—peak families, like high peaks 1, 2 and 3 during the Little Ice Age, and low peaks 4 and 5 during the Medieval Warm Period—seem to record longer-scale climatic variation in the frequency and severity of cold and stormy winters.”

Björck and Clemmensen also found a striking association between the strongest of these winter storminess peaks and periods of reduced solar activity. They specifically note, for example, that the solar minimum between AD 1880 and 1900 “is almost exactly coeval with the period of increased storminess at the end of the nineteenth century, and the Dalton Minimum between AD 1800 and 1820 is almost coeval with the period of peak storminess reported here.” In addition, they say that an event of increased storminess they dated to AD 1650 “falls at the beginning of the Maunder solar minimum (AD 1645-1715),” while further back in time they report high ASI values between AD 1450 and 1550 with “a very distinct peak at AD 1475,” noting that this period coincides with the Sporer Minimum of AD 1420-1530. In addition, they call our attention to the fact that the latter three peaks in winter storminess all

occurred during the Little Ice Age and “are among the most prominent in the complete record.”

Shifting gears, several researchers have studied the precipitation histories of regions along the Danube River in western Europe and the effects they have on river discharge, with some of them suggesting that an anthropogenic signal is present in the latter decades of the twentieth century and is responsible for that period’s drier conditions. Ducic (2005) examined such claims by analyzing observed and reconstructed river discharge rates near Orsova, Serbia over the period 1731-1990. He notes that the lowest five-year discharge value in the pre-instrumental era (period of occurrence: 1831-1835) was practically equal to the lowest five-year discharge value in the instrumental era (period of occurrence: 1946-1950), and that the driest decade of the entire 260-year period was 1831-1840. Similarly, the highest five-year discharge value for the pre-instrumental era (period of occurrence: 1736-1740) was nearly equal to the five-year maximum discharge value for the instrumental era (period of occurrence: 1876-1880), differing by only 0.7 percent. What is more, the discharge rate for the last decade of the record (1981-1990), which prior researchers had claimed was anthropogenically influenced, was found to be “completely inside the limits of the whole series,” in Ducic’s words, and only slightly ( $38 \text{ m}^3\text{s}^{-1}$  or 0.7 percent) less than the 260-year mean of  $5356 \text{ m}^3\text{s}^{-1}$ . Thus, Ducic concludes that “modern discharge fluctuations do not point to [a] dominant anthropogenic influence.” Ducic’s correlative analysis suggests that the detected cyclicity in the record could “point to the domination of the influence of solar activity.”

Next, we turn to the study of Holzhauser *et al.* (2005), who presented high-resolution records of variations in glacier size in the Swiss Alps together with lake-level fluctuations in the Jura mountains, the northern French Pre-Alps, and the Swiss Plateau in developing a 3,500-year temperature and precipitation climate history of west-central Europe, beginning with an in-depth analysis of the Great Aletsch glacier, which is the largest of all glaciers located in the European Alps.

Near the beginning of the time period studied, the three researchers report that “during the late Bronze Age Optimum from 1350 to 1250 BC, the Great Aletsch glacier was approximately 1000 m shorter than it is today,” noting that “the period from 1450 to 1250 BC has been recognized as a warm-dry phase in other Alpine and Northern Hemisphere proxies (Tinner *et al.*, 2003).” Then, after an intervening

unnamed cold-wet phase, when the glacier grew in both mass and length, they say that “during the Iron/Roman Age Optimum between c. 200 BC and AD 50,” which is perhaps better known as the Roman Warm Period, the glacier again retreated and “reached today’s extent or was even somewhat shorter than today.” Next came the Dark Ages Cold Period, which they say was followed by “the Medieval Warm Period, from around AD 800 to the onset of the Little Ice Age around AD 1300,” which latter cold-wet phase was “characterized by three successive [glacier length] peaks: a first maximum after 1369 (in the late 1370s), a second between 1670 and 1680, and a third at 1859/60,” following which the glacier began its latest and still-ongoing recession in 1865.

Data pertaining to the Gorner glacier (the second largest of the Swiss Alps) and the Lower Grindelwald glacier of the Bernese Alps tell much the same story, as Holzhauser *et al.* report that these glaciers and the Great Aletsch glacier “experienced nearly synchronous advances” throughout the study period. With respect to what was responsible for the millennial-scale climatic oscillation that produced the alternating periods of cold-wet and warm-dry conditions that fostered the similarly paced cycle of glacier growth and retreat, the Swiss and French scientists report that “glacier maximums coincided with radiocarbon peaks, i.e., periods of weaker solar activity,” which in their estimation “suggests a possible solar origin of the climate oscillations punctuating the last 3500 years in west-central Europe, in agreement with previous studies (Denton and Karlén, 1973; Magny, 1993; van Geel *et al.*, 1996; Bond *et al.*, 2001).” And to underscore that point, they conclude their paper by stating that “a comparison between the fluctuations of the Great Aletsch glacier and the variations in the atmospheric residual  $^{14}\text{C}$  records supports the hypothesis that variations in solar activity were a major forcing factor of climate oscillations in west-central Europe during the late Holocene.”

In one final study, Lamy *et al.* (2006), utilized paleoenvironmental proxy data for ocean properties, eolian sediment input, and continental rainfall based on high-resolution analyses of sediment cores from the southwestern Black Sea and the northernmost Gulf of Aqaba to infer hydroclimatic changes in northern Anatolia and the northern Red Sea region during the last ~7500 years, after which the reconstructed hydroclimatic history was compared with  $\Delta^{14}\text{C}$  periodicities evident in the tree-ring data of Stuiver *et al.* (1998).

Analysis of the data showed “pronounced and coherent” multi-centennial variations that the authors say “strongly resemble modern temperature and rainfall anomalies related to the Arctic Oscillation/North Atlantic Oscillation (AO/NAO).” In addition, they say that “the multicentennial variability appears to be similar to changes observed in proxy records for solar output changes,” although “the exact physical mechanism that transfers small solar irradiance changes either to symmetric responses in the North Atlantic circulation or to atmospheric circulation changes involving an AO/NAO-like pattern, remains unclear.”

In conclusion, each of the studies above indicates cyclical solar activity induces similar cyclical precipitation activity in Europe. They indicate, in Lamy *et al.*’s words, that “the impact of (natural) centennial-scale climate variability on future climate projections could be more substantial than previously thought.”

## 5.5. Droughts

The IPCC claims earth's climate is becoming more variable and extreme as a result of CO<sub>2</sub>-induced global warming, and it forecasts increasing length and severity of drought as one of the consequences. In the next chapter of this report, we report evidence that modern drought frequency and severity fall well

within the range of natural variability. In the present section, however, we examine the issue of attribution, specifically investigating the natural influence of the sun on drought. We begin with a review of the literature on droughts in the United States.

According to Cook *et al.* (2007), recent advances in the reconstruction of past drought over North America “have revealed the occurrence of a number of unprecedented megadroughts over the past millennium that clearly exceed any found in the instrumental records.” Indeed, they state that “these past megadroughts dwarf the famous droughts of the twentieth century, such as the Dust Bowl drought of the 1930s, the southern Great Plains drought of the 1950s, and the current one in the West that began in 1999,” all of which dramatic droughts pale when compared to “an epoch of significantly elevated aridity that persisted for almost 400 years over the AD 900-1300 period.”

Of central importance to North American drought formation, in the words of the four researchers, “is the development of cool ‘La Niña-like’ SSTs in the eastern tropical Pacific.” Paradoxically, as they describe the situation, “warmer conditions over the tropical Pacific region lead to the development of cool La Niña-like SSTs there, which is drought inducing over North America.” In further explaining the mechanics of this phenomenon, on which both “model and data agree,” Cook *et al.* state that “if there is a heating over the entire tropics then the Pacific will warm more in the west than in the east because the strong upwelling and surface divergence in the east moves some of the heat poleward,” with the result that “the east-west temperature gradient will strengthen, so the winds will also strengthen, so the temperature gradient will increase further ... leading to a more La Niña-like state.” They add that “La Niña-like conditions were apparently the norm during much of the Medieval period when the West was in a protracted period of elevated aridity and solar irradiance was unusually high.”

Shedding some more light on the subject, Yu and Ito (1999) studied a sediment core from a closed-basin lake in the northern Great Plains of North America, producing a 2,100-year record that revealed four dominant periodicities of drought that matched “in surprising detail” similar periodicities of various solar indices. The correspondence was so close, in fact, that they say “this spectral similarity forces us to consider solar variability as the major cause of century-scale drought frequency in the northern Great Plains.”

One year later, Dean and Schwalb (2000) derived a similar-length record of drought from sediment cores extracted from Pickerel Lake, South Dakota, which also exhibited recurring incidences of major drought on the northern Great Plains. They too reported that the cyclical behavior appeared to be in synchrony with similar variations in solar irradiance. After making a case for “a direct connection between solar irradiance and weather and climate,” they thus concluded that “it seems reasonable that the cycles in aridity and eolian activity over the past several thousand years recorded in the sediments of lakes in the northern Great Plains might also have a solar connection.”

Moving to east-central North America, Springer *et al.* (2008) derived a multi-decadal-scale record of Holocene drought based on Sr/Ca ratios and  $\delta^{13}\text{C}$  data obtained from stalagmite BCC-002 from Buckeye Creek Cave (BCC), West Virginia (USA) that “grew continuously from ~7000 years B.P. to ~800 years B.P.” and then again “from ~800 years B.P. until its collection in 2002.”

Results of their study indicated the presence of seven significant Mid- to Late-Holocene droughts, six of which “correlate with cooling of the Atlantic and Pacific Oceans as part of the North Atlantic Ocean ice-rafted debris [IRD] cycle, which has been linked to the solar irradiance cycle,” as per Bond *et al.* (2001). In addition, they determined that the Sr/Ca and  $\delta^{13}\text{C}$  time series “display periodicities of ~200 and ~500 years and are coherent in those frequency bands.” They also say “the ~200-year periodicity is consistent with the de Vries (Suess) solar irradiance cycle,” and they “interpret the ~500-year periodicity to be a harmonic of the IRD oscillations.” Noting further that “cross-spectral analysis of the Sr/Ca and IRD time series yields statistically significant coherencies at periodicities of 455 and 715 years,” they go on to note that “these latter values are very similar to the second (725-years) and third (480-years) harmonics of the  $1450 \pm 500$ -years IRD periodicity.” As a result of these observations, the five researchers conclude their report by saying their findings “corroborate works indicating that millennial-scale solar-forcing is responsible for droughts and ecosystem changes in central and eastern North America (Viau *et al.*, 2002; Willard *et al.*, 2005; Denniston *et al.*, 2007),” adding that their high-resolution time series now provide even stronger evidence “in favor of solar-forcing of North American drought by yielding unambiguous spectral analysis results.”

In Nevada, Mensing *et al.* (2004) analyzed a set of sediment cores extracted from Pyramid Lake for pollen and algal microfossils deposited there over the past 7,630 years that allowed them to infer the hydrological history of the area over that time period. According to the authors, “sometime after 3430 but before 2750 cal yr B.P., climate became cool and wet,” but “the past 2500 yr have been marked by recurring persistent droughts.” The longest of these droughts, according to them, “occurred between 2500 and 2000 cal yr B.P.,” while others occurred “between 1500 and 1250, 800 and 725, and 600 and 450 cal yr B.P.” They also note that “the timing and magnitude of droughts identified in the pollen record compares favorably with previously published  $\delta^{18}\text{O}$  data from Pyramid Lake” and with “the ages of submerged rooted stumps in the Eastern Sierra Nevada and woodrat midden data from central Nevada.” When they compared the pollen record of droughts from Pyramid Lake with the stacked petrologic record of North Atlantic drift ice of Bond *et al.* (2001), like other researchers they too found “nearly every occurrence of a shift from ice maxima (reduced solar output) to ice minima (increased solar output) corresponded with a period of prolonged drought in the Pyramid Lake record.” Mensing *et al.* conclude that “changes in solar irradiance may be a possible mechanism influencing century-scale drought in the western Great Basin [of the United States].” Indeed, it would appear that variable solar activity is the major factor in determining the hydrological state of the region and all of North America.

Moving slightly south geographically, Asmerom *et al.* (2007) developed a high-resolution climate proxy for the southwest United States from  $\delta^{18}\text{O}$  variations in a stalagmite found in Pink Panther Cave in the Guadalupe Mountains of New Mexico. Spectral analysis performed on the raw  $\delta^{18}\text{O}$  data revealed significant peaks that the researchers say “closely match previously reported periodicities in the  $^{14}\text{C}$  content of the atmosphere, which have been attributed to periodicities in the solar cycle (Stuiver and Braziunas, 1993).” More specifically, they say that cross-spectral analysis of the  $\Delta^{14}\text{C}$  and  $\delta^{18}\text{O}$  data confirms that the two records have matching periodicities at 1,533 years (the Bond cycle), 444 years, 170 years, 146 years, and 88 years (the Gleissberg cycle). In addition, they report that periods of increased solar radiation correlate with periods of decreased rainfall in the southwestern United States (via changes in the North American monsoon), and

that this behavior is just the opposite of what is observed with the Asian monsoon. These observations thus lead them to suggest that the proposed solar link to Holocene climate operates “through changes in the Walker circulation and the Pacific Decadal Oscillation and El Niño-Southern Oscillation systems of the tropical Pacific Ocean.”

Making our way to Mexico, Hodell *et al.* (2001) analyzed sediment cores obtained from Lake Chichancanab on the Yucatan Peninsula, reconstructing the climatic history of this region over the past 2,600 years. Long episodes of drought were noted throughout the entire record, and spectral analysis revealed a significant periodicity that matched well with a cosmic ray-produced  $^{14}\text{C}$  record preserved in tree rings that is believed to reflect variations in solar activity. Hence, they too concluded that “a significant component of century-scale variability in Yucatan droughts is explained by solar forcing.”

Expanding the geographical scope of such studies, Black *et al.* (1999) found evidence of substantial decadal and centennial climate variability in a study of ocean sediments in the southern Caribbean that were deposited over the past 825 years. Their data suggested that climate regime shifts are a natural aspect of Atlantic variability; in relating these features to records of terrestrial climate, they concluded that “these shifts may play a role in triggering changes in the frequency and persistence of drought over North America.” In addition, because there was a strong correspondence between these phenomena and similar changes in  $^{14}\text{C}$  production rate, they further concluded that “small changes in solar output may influence Atlantic variability on centennial time scales.”

Moving to Africa, Verschuren *et al.* (2000) conducted a similar study in a small lake in Kenya, documenting the existence of three periods of prolonged dryness during the Little Ice Age that were, in their words, “more severe than any recorded drought of the twentieth century.” In addition, they discovered that all three of these severe drought events “were broadly coeval with phases of high solar radiation”—as inferred from  $^{14}\text{C}$  production data—“and the intervening periods of increased moisture were coeval with phases of low solar radiation.” They thus concluded that variations in solar activity “may have contributed to decade-scale rainfall variability in equatorial east Africa.”

Also in Africa, working with three sediment cores extracted from Lake Edward (0°N, 30°E), Russell and

Johnson (2005) developed a continuous 5,400-year record of Mg concentration and isotopic composition of authigenic inorganic calcite as proxies for the lake's water balance, which is itself a proxy for regional drought conditions in equatorial Africa. They found "the geochemical record from Lake Edward demonstrates a consistent pattern of equatorial drought during both cold and warm phases of the North Atlantic's '1500-year cycle' during the late Holocene," noting that similar "725-year climate cycles" are found in several records from the Indian and western Pacific Oceans and the South China Sea, citing as authority for the latter statement the studies of von Rad *et al.* (1999), Wang *et al.* (1999), Russell *et al.* (2003) and Staubwasser *et al.* (2003). In light of these findings, the two scientists say their results "show that millennial-scale high-latitude climate events are linked to changes in equatorial terrestrial climate ... during the late Holocene," or as they phrase it in another place, that their results "suggest a spatial footprint in the tropics for the '1500-year cycle' that may help to provide clues to discern the cycle's origin," noting there is already reason to believe that it may be solar-induced.

Lastly, Garcin *et al.* (2007) explored hydrologic change using late-Holocene paleoenvironmental data derived from several undisturbed sediment cores retrieved from the deepest central part of Lake Masoko (9°20.0'S, 33°45.3'E), which occupies a maar crater in the Rungwe volcanic highlands of the western branch of Africa's Rift Valley, where it is situated approximately 35 km north of Lake Malawi.

According to the 10 researchers who conducted the work, "magnetic, organic carbon, geochemical proxies and pollen assemblages indicate a dry climate during the 'Little Ice Age' (AD 1550-1850), confirming that the LIA in eastern Africa resulted in marked and synchronous hydrological changes," although "the direction of response varies between different African lakes." In this regard, for example, they report that "to the south (9.5-14.5°S), sediment cores from Lake Malawi have revealed similar climatic conditions (Owen *et al.*, 1990; Johnson *et al.*, 2001; Brown and Johnson, 2005)" that are "correlated with the dry period of Lakes Chilwa and Chiuta (Owen and Crossley, 1990)," and they say that "lowstands have been also observed during the LIA at Lake Tanganyika ... from AD 1500 until AD 1580, and from ca. AD 1650 until the end of the 17th century, where the lowest lake-levels are inferred (Cohen *et al.*, 1997; Alin and Cohen, 2003)." By contrast, however, they report that "further north,

evidence from Lakes Naivasha (0.7°S) and Victoria (2.5°S-0.5°N) indicates relatively wet conditions with high lake-levels during the LIA, interrupted by short drought periods (Verschuren *et al.*, 2000; Verschuren, 2004; Stager *et al.*, 2005)." Lastly, Garcin *et al.* state that "inferred changes of the Masoko hydrology are positively correlated with the solar activity proxies."

In discussing their findings, the African and French scientists note the Little Ice Age in Africa appears to have had a greater thermal amplitude than it did in the Northern Hemisphere, citing in support of this statement the paleoclimate studies of Bonnefille and Mohammed (1994), Karlén *et al.* (1999), Holmgren *et al.* (2001), and Thompson *et al.* (2002). Nevertheless, the more common defining parameter of the Little Ice Age in Africa was the moisture status of the continent, which appears to have manifested opposite directional trends in different latitudinal bands. In addition, the group of scientists emphasizes that the positive correlation of Lake Masoko hydrology with various solar activity proxies "implies a forcing of solar activity on the atmospheric circulation and thus on the regional climate of this part of East Africa."

There seems to be little question but what variations in solar activity have been responsible for much of the drought variability of the Holocene in many parts of the world.

## 5.6. Floods

The IPCC claims that floods will become more variable and extreme as a result of CO<sub>2</sub>-induced global warming. In the next chapter of this report, we show modern flood frequency and severity fall well within the range of natural variability. In the present section, we limit our examination once again to the issue of attribution, specifically investigating the influence of the sun on floods.

We begin by reviewing what is known about the relationship of extreme weather events to climate in Europe during the Holocene. According to Starkel (2002), in general, more extreme fluvial activity, of both the erosional and depositional type, is associated with cooler climates. "Continuous rains and high-intensity downpours," writes Starkel, were most common during the Little Ice Age. Such "flood phases," the researcher reports, "were periods of very unstable weather and frequent extremes of various kinds." More related to the present discussion, Starkel also notes that "most of the phases of high frequency of extreme events during the Holocene coincide with the periods of declined solar activity."

Noren *et al.* (2002) extracted sediment cores from 13 small lakes distributed across a 20,000-km<sup>2</sup> region in Vermont and eastern New York, after which

several techniques were used to identify and date terrigenous in-wash layers that depict the frequency of storm-related floods. Results of the analysis showed that "the frequency of storm-related floods in the northeastern United States has varied in regular cycles during the past 13,000 years (13 kyr), with a characteristic period of about 3 kyr." There were four major storminess peaks during this period; they occurred approximately 2.6, 5.8, 9.1, and 11.9 kyr ago, with the most recent upswing in storminess beginning "at about 600 yr BP [before present], coincident with the beginning of the Little Ice Age." With respect to the causative factor(s) behind the cyclic behavior, Noren *et al.* state that the pattern they observed "is consistent with long-term changes in the average sign of the Arctic Oscillation [AO]," further suggesting that "changes in the AO, perhaps modulated by solar forcing, may explain a significant portion of Holocene climate variability in the North Atlantic region."

Also working in the United States, Schimmelman *et al.* (2003) identified conspicuous gray clay-rich flood deposits in the predominantly olive varved sediments of the Santa Barbara Basin off the coast of California, which they accurately dated by varve-counting. Analysis of the record revealed six prominent flood events that occurred at approximately AD 212, 440, 603, 1029, 1418, and 1605, "suggesting," in their words, "a quasi-periodicity of ~200 years," with "skipped" flooding just after AD 800, 1200, and 1800. They further note that "the floods of ~AD 1029 and 1605 seem to have been associated with brief cold spells," that "the flood of ~AD 440 dates to the onset of the most unstable marine climatic interval of the Holocene (Kennett and Kennett, 2000)," and that "the flood of ~AD 1418 occurred at a time when the global atmospheric circulation pattern underwent fundamental reorganization at the beginning of the 'Little Ice Age' (Kreutz *et al.*, 1997; Meeker and Mayewski, 2002)." Lastly, they report that "the quasi-periodicity of ~200 years for southern California floods matches the ~200-year periodicities found in a variety of high-resolution palaeoclimate archives and, more importantly, a c.208-year cycle of solar activity and inferred changes in atmospheric circulation."

As a result of these findings, Schimmelman *et al.* "hypothesize that solar-modulated climatic background conditions are opening a ~40-year window of opportunity for flooding every ~200 years," and that "during each window, the danger of flooding is exacerbated by additional climatic and

environmental cofactors.” They also note that “extrapolation of the ~200-year spacing of floods into the future raises the uncomfortable possibility for historically unprecedented flooding in southern California during the first half of this century.” When such flooding occurs, there will be no need to suppose it came as a consequence of what the IPCC calls the unprecedented warming of the past century.

## 5.7. Monsoons

The IPCC’s computer models fail to predict variability in monsoon weather. One reason is because they underestimate the sun’s role.

For the period 9,600-6,100 years before present, Neff *et al.* (2001) investigated the relationship between a  $^{14}\text{C}$  tree-ring record and a  $\delta^{18}\text{O}$  proxy record of monsoon rainfall intensity as recorded in calcite  $\delta^{18}\text{O}$  data obtained from a stalagmite in northern Oman. According to the authors, the

correlation between the two datasets was reported to be “extremely strong,” and a spectral analysis of the data revealed statistically significant periodicities centered on 779, 205, 134, and 87 years for the  $\delta^{18}\text{O}$  record and periodicities of 206, 148, 126, 89, 26, and 10.4 years for the  $^{14}\text{C}$  record.

Because variations in  $^{14}\text{C}$  tree-ring records are generally attributed to variations in solar activity and intensity, and because of this particular  $^{14}\text{C}$  record’s strong correlation with the  $\delta^{18}\text{O}$  record, as well as the closely corresponding results of the spectral analyses, the authors conclude there is “solid evidence” that both signals (the  $^{14}\text{C}$  and  $\delta^{18}\text{O}$  records) are responding to solar forcing.

Similar findings were reported by Lim *et al.* (2005), who examined the eolian quartz content (EQC) of a high-resolution sedimentary core taken from Cheju Island, Korea, creating a 6,500-year proxy record of major Asian dust events produced by northwesterly winter monsoonal winds that carry dust from the inner part of China all the way to Korea and the East China Sea. The Asian dust time series was found to contain both millennial- and centennial-scale periodicities; cross-spectral analysis between the EQC and a solar activity record showed significant coherent cycles at 700, 280, 210, and 137 years with nearly the same phase changes, leading the researchers to conclude that centennial-scale periodicities in the EQC could be ascribed primarily to fluctuations in solar activity.

In another study, Ji *et al.* (2005) used reflectance spectroscopy on a sediment core taken from Qinghai Lake in the northeastern part of the Qinghai-Tibet Plateau to construct a continuous high-resolution proxy record of the Asian monsoon over the past 18,000 years. As a result of this effort, monsoonal moisture since the late glacial period was shown to be subject to “continual and cyclic variations,” including the well-known centennial-scale cold and dry spells of the Dark Ages Cold Period (DACP) and Little Ice Age, which lasted from 2,100 to 1,800 yr BP and 780 to 400 yr BP, respectively. Sandwiched between them was the warmer and wetter Medieval Warm Period, while preceding the DACP was the Roman Warm Period. Also, time series analysis of the sediment record revealed statistically significant periodicities (above the 95 percent level) of 123, 163, 200, and 293 years. The third of these periodicities corresponds well with the de Vries or Suess solar cycle, which suggests cyclical changes in solar activity are important triggers for some of the cyclical changes in monsoon moisture at Qinghai Lake.

Citing studies that suggest the Indian summer monsoon may be sensitive to changes in solar forcing of as little as 0.25 percent (Overpeck *et al.*, 1996; Neff *et al.*, 2001; Fleitmann *et al.*, 2003), Gupta *et al.* (2005) set out to test this hypothesis by comparing trends in the Indian summer monsoon with trends in solar activity across the Holocene. In this endeavor, temporal trends in the Indian summer monsoon were inferred from relative abundances of fossil shells of the planktic foraminifer *Globigerina bulloides* in sediments of the Oman margin, while temporal trends in solar variability were inferred from relative abundances of  $^{14}\text{C}$ ,  $^{10}\text{Be}$  and haematite-stained grains.

Spectral analyses of the various datasets revealed statistically significant periodicities in the *G. bulloides* time series centered at 1550, 152, 137, 114, 101, 89, 83, and 79 years, all but the first of which periodicities closely matched periodicities of sunspot numbers centered at 150, 132, 117, 104, 87, 82, and 75 years. This close correspondence, in the words of Gupta *et al.*, provides strong evidence for a “century-scale relation between solar and summer monsoon variability.” In addition, they report that intervals of monsoon minima correspond to intervals of low sunspot numbers, increased production rates of the cosmogenic nuclides  $^{14}\text{C}$  and  $^{10}\text{Be}$ , and increased advection of drift ice in the North Atlantic, such that over the past 11,100 years “almost every multi-decadal to centennial scale decrease in summer monsoon strength is tied to a distinct interval of reduced solar output,” and nearly every increase “coincides with elevated solar output,” including a stronger monsoon (high solar activity) during the Medieval Warm Period and a weaker monsoon (low solar activity) during the Little Ice Age.

As for the presence of the 1,550-year cycle in the Indian monsoon data, Gupta *et al.* consider it to be “remarkable,” since this cycle has been identified in numerous climate records of both the Holocene and the last glacial epoch (including Dansgaard/Oeschger cycles in the North Atlantic), strengthening the case for a sun-monsoon-North Atlantic link. Given the remarkable findings of this study, it is no wonder the researchers who conducted it say they are “convinced” there is a direct solar influence on the Indian summer monsoon in which small changes in solar output bring about pronounced changes in tropical climate.

In still another study, Khare and Nigam (2006) examined variations in angular-asymmetrical forms of benthic foraminifera and planktonic foraminiferal populations in a shallow-water sediment core

obtained just off Kavar (14°49'43"N, 73°59'37"E) on the central west coast of India, which receives heavy river discharge during the southwest monsoon season (June to September) from the Kali and Gangavali rivers.

Down-core plots of the data showed three major troughs separated by intervening peaks; “since angular-asymmetrical forms and planktonic foraminiferal population are directly proportional to salinity fluctuations,” according to Khare and Nigam, “the troughs ... suggest low salinity (increased river discharge and thus more rainfall),” and that “these wet phases are alternated by dry conditions.” They further report that the dry episodes of higher salinity occurred from AD 1320-1355, 1445-1535, and 1625-1660, and that the wet phases were centered at approximately AD 1410, 1590, and 1750, close to the ending of the sunspot minima of the Wolf Minima (AD 1280-1340), the Sporer Minima (AD 1420-1540), and the Maunder Minima (AD 1650-1710), respectively.

Although Khare and Nigam say that “providing a causal mechanism is beyond the scope of the present study,” they note that “the occurrence of periods of enhanced monsoonal precipitation slightly after the termination of the Wolf, Sporer and Maunder minima periods (less sun activity) and concomitant temperature changes could be a matter of further intense research.” The correspondences seem to be more than merely coincidental, especially when the inferences of the two researchers are said by them to be “in agreement with the findings of earlier workers, who reported high lake levels from Mono Lake and Chad Lake in the vicinity of solar minima,” as well as the Nile river in Africa, which “witnessed high level at around AD 1750 and AD 1575.”

Nearby in the Arabian Sea, Tiwari *et al.* (2005) conducted a high-resolution (~50 years) oxygen isotope analysis of three species of planktonic foraminifera (*Globigerinoides ruber*, *Gs. sacculifer* and *Globalotalia menardii*) contained in a sediment core extracted from the eastern continental margin (12.6°N, 74.3°E) that covered the past 13,000 years. Data for the final 1,200 years of this period were compared with the reconstructed total solar irradiance (TSI) record developed by Bard *et al.* (2000), which is based on fluctuations of  $^{14}\text{C}$  and  $^{10}\text{Be}$  production rates obtained from tree rings and polar ice sheets.

Results of the analysis showed that the Asian SouthWest Monsoon (SWM) “follows a dominant quasi periodicity of ~200 years, which is similar to that of the 200-year Suess solar cycle (Usokin *et al.*,

2003).” This finding indicates, in their words, “that SWM intensity on a centennial scale is governed by variation in TSI,” which “reinforces the earlier findings of Agnihotri *et al.* (2002) from elsewhere in the Arabian Sea.” However, in considering the SWM/TSI relationship, the five researchers note that “variations in TSI (~0.2%) seem to be too small to perturb the SWM, unless assisted by some internal amplification mechanism with positive feedback.” In this regard, they discuss two possible mechanisms. The first, in their words, “involves heating of the earth’s stratosphere by increased absorption of solar ultraviolet (UV) radiation by ozone during periods of enhanced solar activity (Schneider, 2005).” According to this scenario, more UV reception leads to more ozone production in the stratosphere, which leads to more heat being transferred to the troposphere, which leads to enhanced evaporation from the oceans, which finally enhances monsoon winds and precipitation. The second mechanism, as they describe it, is that “during periods of higher solar activity, the flux of galactic cosmic rays to the earth is reduced, providing less cloud condensation nuclei, resulting in less cloudiness (Schneider, 2005; Friis-Christensen and Svensmark, 1997),” which then allows for “extra heating of the troposphere” that “increases the evaporation from the oceans.”

In another study, Dykoski *et al.* (2005) obtained high-resolution records of stable oxygen and carbon isotope ratios from a stalagmite recovered from Dongge Cave in southern China and utilized them to develop a proxy history of Asian monsoon variability over the last 16,000 years. In doing so, they discovered numerous centennial- and multi-decadal-scale oscillations in the record that were up to half the amplitude of interstadial events of the last glacial age, indicating that “significant climate variability characterizes the Holocene.” As to what causes this variability, spectral analysis of  $\delta^{14}\text{C}$  data revealed significant peaks at solar periodicities of 208, 86, and 11 years, which they say is “clear evidence that some of the variability in the monsoon can be explained by solar variability.”

Building upon this work, as well as that of Yuan *et al.* (2004), Wang *et al.* (2005) developed a shorter (9,000-year) but higher-resolution (4.5-year) absolute-dated  $\delta^{18}\text{O}$  monsoon record for the same location, which they compared with atmospheric  $^{14}\text{C}$  data and climate records from lands surrounding the North Atlantic Ocean. This work indicated their monsoon record broadly followed summer insolation but was punctuated by eight significantly weaker

monsoon periods lasting from one to five centuries, most of which coincided with North Atlantic ice-raftering events. In addition, they found that “cross-correlation of the decadal- to centennial-scale monsoon record with the atmospheric  $^{14}\text{C}$  record shows that some, but not all, of the monsoon variability at these frequencies results from changes in solar output,” similar to “the relation observed in the record from a southern Oman stalagmite (Fleitmann *et al.*, 2003).”

In a news item by Kerr (2005) accompanying the report of Wang *et al.*, one of the report’s authors (Hai Cheng of the University of Minnesota) was quoted as saying their study suggests that “the intensity of the summer [East Asian] monsoon is affected by solar activity.” Dominik Fleitman, who worked with the Oman stalagmite, also said that “the correlation is very strong,” stating that it is probably the best monsoon record he had seen, calling it “even better than ours.” Lastly, Gerald North of Texas A & M University, who Kerr described as a “longtime doubter,” admitted that he found the monsoon’s solar connection “very hard to refute,” although he stated that “the big mystery is that the solar signal should be too small to trigger anything.”

Next, Porter and Weijian (2006) used 18 radiocarbon-dated aeolian and paleosol profiles (some obtained by the authors and some by others) within a 1,500-km-long belt along the arid to semi-arid transition zone of north-central China to determine variations in the extent and strength of the East Asian summer monsoon throughout the Holocene.

In the words of the authors, the dated paleosols and peat layers “represent intervals when the zone was dominated by a mild, moist summer monsoon climate that favored pedogenesis and peat accumulation,” while “brief intervals of enhanced aeolian activity that resulted in the deposition of loess and aeolian sand were times when strengthened winter monsoon conditions produced a colder, drier climate.” The most recent of the episodic cold periods, which they identify as the Little Ice Age, began about AD 1370, while the preceding cold period ended somewhere in the vicinity of AD 810. Consequently, their work implies the existence of a Medieval Warm Period that began some time after AD 810 and ended some time before AD 1370. They also report that the climatic variations they discovered “correlate closely with variations in North Atlantic drift-ice tracers that represent episodic advection of drift ice and cold polar surface water southward and eastward into warmer subpolar water,” which

correlation implies solar forcing (see Bond *et al.*, 2001) as the most likely cause of the alternating multi-century mild/moist and cold/dry periods of North-Central China. As a result, Porter and Weijian's work helps to establish the global extent of the Medieval Warm Period, as well as its likely solar origin.

We end with a study of the North American monsoon by Asmerom *et al.* (2007), who developed a high-resolution climate proxy for the southwest United States in the form of  $\delta^{18}\text{O}$  variations in a stalagmite found in Pink Panther Cave in the Guadalupe Mountains of New Mexico.

Spectral analysis performed on the raw  $\delta^{18}\text{O}$  data revealed significant peaks that the researchers say "closely match previously reported periodicities in the  $^{14}\text{C}$  content of the atmosphere, which have been attributed to periodicities in the solar cycle (Stuiver and Braziunas, 1993)." More specifically, they say that cross-spectral analysis of the  $\Delta^{14}\text{C}$  and  $\delta^{18}\text{O}$  data confirms that the two records have matching periodicities at 1,533 years (the Bond cycle), 444 years, 170 years, 146 years, and 88 years (the Gleissberg cycle). In addition, they report that periods of increased solar radiation correlate with periods of decreased rainfall in the southwestern United States (via changes in the North American monsoon), and that this behavior is just the opposite of what is observed with the Asian monsoon. These observations thus lead them to suggest that the proposed solar link to Holocene climate operates "through changes in the Walker circulation and the Pacific Decadal Oscillation and El Niño-Southern Oscillation systems of the tropical Pacific Ocean."

In conclusion, research conducted in countries around the world has found a significant effect of solar variability on monsoons. This necessarily implies a small role, or no role, for anthropogenic causes.

Additional information on this topic, including reviews of newer publications as they become available, can be found at <http://www.co2science.org/subject/m/monsoonsolar.php>.

## 5.8. Streamflow

In this section we highlight some of the scientific literature that demonstrates the influence of solar variability on streamflow, a climate variable related to precipitation, droughts, and floods. If a significant influence exists, it follows that greenhouse gases or global warming (regardless of its cause) played a smaller or even non-existent role in streamflow trends during the twentieth century.

Starting in northeastern Mongolia, Pederson *et al.* (2001) used tree-ring chronologies to reconstruct annual precipitation and streamflow histories in this region over the period 1651-1995. Analyses of both standard deviations and five-year intervals of extreme wet and dry periods revealed that “variations over the recent period of instrumental data are not unusual relative to the prior record.” The authors state, however, that the reconstructions “appear to show more frequent extended wet periods in more recent decades,” but they note this observation “does not

demonstrate unequivocal evidence of an increase in precipitation as suggested by some climate models.” More relevant to the present discussion is the researchers’ observation that spectral analysis of the data revealed significant periodicities around 12 and 20-24 years, suggesting “possible evidence for solar influences in these reconstructions for northeastern Mongolia.”

In Western Europe, several researchers have studied precipitation histories of regions along the Danube River and the effects they have on river discharge, with some of them suggesting that an anthropogenic signal is present in the latter decades of the twentieth century and is responsible for that period’s drier conditions. In an effort to validate such claims, Ducic (2005) analyzed observed and reconstructed river discharge rates near Orsova, Serbia over the period 1731-1990.

Results of the study indicated that the lowest five-year discharge value in the pre-instrumental era (period of occurrence: 1831-1835) was practically equal to the lowest five-year discharge value in the instrumental era (period of occurrence: 1946-1950), and that the driest decade of the entire 260-year period was 1831-1840. Similarly, the highest five-year discharge value for the pre-instrumental era (period of occurrence: 1736-1740) was nearly equal to the five-year maximum discharge value for the instrumental era (period of occurrence: 1876-1880), differing by only 0.7 percent. What is more, the discharge rate for the last decade of the record (1981-1990), which prior researchers had claimed was anthropogenically influenced, was found to be “completely inside the limits of the whole series,” in Ducic’s words, and only slightly ( $38 \text{ m}^3\text{s}^{-1}$  or 0.7 percent) less than the 260-year mean of  $5356 \text{ m}^3\text{s}^{-1}$ . In conclusion, Ducic states that “modern discharge fluctuations do not point to [a] dominant anthropogenic influence.” Ducic’s correlative analysis suggests that the detected cyclicity in the record may “point to the domination of the influence of solar activity.”

Solar-related streamflow oscillations have also been reported for the Nile. Kondrashov *et al.* (2005), for example, applied advanced spectral methods to fill in data gaps and locate interannual and interdecadal periodicities in historical records of annual low- and high-water levels on the Nile over the 1,300-year period AD 622 to 1922. In doing so, they found several statistically significant periodicities, including cycles of 256, 64, 19, 12, 7, 4.2, and 2.2 years. With respect to the causes of these cycles, Kondrashov *et*

*al.* say the 4.2- and 2.2-year oscillations are likely the product of El Niño-Southern Oscillation variations. They find the 7-year cycle may be related to North Atlantic influences, according to them, while the longer-period oscillations may be due to solar-related forcings.

Mauas *et al.* (2008) write that river streamflows “are excellent climatic indicators,” especially in the case of rivers “with continental scale basins” that “smooth out local variations” and can thus “be particularly useful to study global forcing mechanisms.” Focusing on South America’s Parana River—the world’s fifth largest in terms of drainage area and its fourth largest with respect to streamflow—Mauas *et al.* analyzed streamflow data collected continuously on a daily basis since 1904. With respect to periodicities, they report that the detrended time series of the streamflow data were correlated with the detrended times series of both sunspot number and total solar irradiance, yielding Pearson’s correlation coefficients between streamflow and the two solar parameters of 0.78 and 0.69, respectively, at “a significance level higher than 99.99% in both cases.” This is strong evidence indeed that solar variability, and not man-made greenhouse gas emissions, were responsible for variation in streamflow during the modern industrial era.

### Introduction

The Intergovernmental Panel on Climate Change (IPCC) claims, in Section 3.8 of the report of Working Group I to the Fourth Assessment Report, that global warming will cause (or already is causing) more extreme weather: droughts, floods, tropical cyclones, storms, and more (IPCC, 2007-I). Chapter 5 of the present report presented extensive evidence that solar variability, not CO<sub>2</sub> concentrations in the air or rising global temperatures (regardless of their cause) is responsible for trends in many of these weather variables. In this chapter we ask if there is evidence that the twentieth century, which the IPCC claims was the warmest century in a millennium, experienced more severe weather than was experienced in previous, cooler periods. We find no support for the IPCC's predictions. In fact, we find more evidence to support the opposite prediction: that weather would be *less* extreme in a warmer world.

### 6.1. Droughts

One of the many dangers of global warming, according to the IPCC, is more frequent, more severe, and longer-lasting droughts. In this section, we discuss the findings of scientific papers that compared droughts in the twentieth century with those longer ago, beginning with Africa and then Asia, Europe, and finally North America.

Additional information on this topic, including reviews on drought not discussed here, can be found at [http://www.co2science.org/subject/d/subject\\_d.php](http://www.co2science.org/subject/d/subject_d.php) under the heading Drought.

#### 6.1.1. Africa

Lau *et al.*, 2006 explored “the roles of sea surface temperature coupling and land surface processes in producing the Sahel drought” in the computer models used by the IPCC for its Fourth Assessment Report. These 19 computer models were “driven by combinations of realistic prescribed external forcing,

including anthropogenic increase in greenhouse gases and sulfate aerosols, long-term variation in solar radiation, and volcanic eruptions.” This work revealed that “only eight models produce a reasonable Sahel drought signal, seven models produce excessive rainfall over [the] Sahel during the observed drought period, and four models show no significant deviation from normal.” In addition, they report that “even the model with the highest skill for the Sahel drought could only simulate the increasing trend of severe drought events but not the magnitude, nor the beginning time and duration of the events.”

All 19 of the models used in preparing the IPCC’s Fourth Assessment Report were unable to adequately simulate the basic characteristics of what Lau *et al.* call one of the past century’s “most pronounced signals of climate change.” This failure of what the authors call an “ideal test” for evaluating the models’ abilities to accurately simulate “long-term drought” and “coupled atmosphere-ocean-land processes and their interactions” vividly illustrates the fallibility of computer climate models.

In a review of information pertaining to the past two centuries, Nicholson (2001) reports there has been “a long-term reduction in rainfall in the semi-arid regions of West Africa” that has been “on the order of 20 to 40% in parts of the Sahel.” Describing the phenomenon as “three decades of protracted aridity,” she reports that “nearly all of Africa has been affected ... particularly since the 1980s.” Nevertheless, Nicholson says that “rainfall conditions over Africa during the last 2 to 3 decades are not unprecedented,” and that “a similar dry episode prevailed during most of the first half of the 19th century,” when much of the planet was still experiencing Little Ice Age conditions.

Therrell *et al.* (2006) developed what they describe as “the first tree-ring reconstruction of rainfall in tropical Africa using a 200-year regional chronology based on samples of *Pterocarpus angolensis* [a deciduous tropical hardwood known locally as Mukwa] from Zimbabwe.” This project revealed that “a decadal-scale drought reconstructed from 1882 to 1896 matches the most severe sustained drought during the instrumental period (1989-1995),” and that “an even more severe drought is indicated from 1859 to 1868 in both the tree-ring and documentary data.” They report, for example, that the year 1860 (which was the most droughty year of the entire period), was described in a contemporary account from Botswana (where part of their tree-ring chronology originated) as “a season of ‘severe and

universal drought’ with ‘food of every description’ being ‘exceedingly scarce’ and the losses of cattle being ‘very severe’ (Nash and Endfield, 2002).” At the other end of the moisture spectrum, Therrell *et al.* report that “a 6-year wet period at the turn of the nineteenth century (1897-1902) exceeds any wet episode during the instrumental era.” Consequently, for a large part of central southern Africa, it is clear that the supposedly unprecedented global warming of the twentieth century did not result in an intensification of either extreme dry or wet periods.

Looking further back in time, Verschuren *et al.* (2000) developed a decadal-scale history of rainfall and drought in equatorial east Africa for the past thousand years, based on level and salinity fluctuations of a small crater-lake in Kenya that were derived from diatom and midge assemblages retrieved from the lake’s sediments. Once again, they found that the Little Ice Age was generally wetter than the Current Warm Period; but they identified three intervals of prolonged dryness within the Little Ice Age (1390-1420, 1560-1625, and 1760-1840), and of these “episodes of persistent aridity,” as they refer to them, *all* were determined to have been “more severe than any recorded drought of the twentieth century.”

Probing some 1,500 years into the past was the study of Holmes *et al.* (1997), who wrote that since the late 1960s, the African Sahel had experienced “one of the most persistent droughts recorded by the entire global meteorological record.” However, in a high-resolution study of a sediment sequence extracted from an oasis in the Manga Grasslands of northeast Nigeria, they too determined that “the present drought is not unique and that drought has recurred on a centennial to interdecadal timescale during the last 1500 years.”

Last, and going back in time almost 5,500 years, Russell and Johnson (2005) analyzed sediment cores that had been retrieved from Lake Edward—the smallest of the great rift lakes of East Africa, located on the border that separates Uganda and the Democratic Republic of the Congo—to derive a detailed precipitation history for that region. In doing so, they discovered that from the start of the record until about 1,800 years ago, there was a long-term trend toward progressively more arid conditions, after which there followed what they term a “slight trend” toward wetter conditions that has persisted to the present. In addition, superimposed on these long-term trends were major droughts of “at least century-scale duration,” centered at approximately 850, 1,500, 2,000, and 4,100 years ago. Consequently, it would

not be unnatural for another such drought to grip the region in the not-too-distant future.

In summation, real-world evidence from Africa suggests that the global warming of the past century or so has not led to a greater frequency or greater severity of drought in that part of the world. Indeed, even the continent's worst drought in recorded meteorological history was much milder than droughts that occurred periodically during much colder times.

Additional information on this topic, including reviews of newer publications as they become available, can be found at <http://www.co2science.org/subject/d/droughtafrica.php>.

## 6.1.2. Asia

Paulsen *et al.* (2003) employed high-resolution stalagmite records of  $\delta^{13}\text{C}$  and  $\delta^{18}\text{O}$  from Buddha Cave “to infer changes in climate in central China for the last 1270 years in terms of warmer, colder, wetter and drier conditions.” Among the climatic episodes evident in their data were “those corresponding to the Medieval Warm Period, Little Ice Age and twentieth century warming, lending support to the global extent of these events.” More specifically, their record begins in the depths of the Dark Ages Cold Period, which ends about AD 965 with the commencement of the Medieval Warm Period. The warming trend continues until approximately AD 1475, whereupon the Little Ice Age sets in. That cold period holds sway until about AD 1825, after which the warming responsible for the Current Warm Period begins.

With respect to hydrologic balance, the last part of the Dark Ages Cold Period was characterized as wet. It, in turn, was followed by a dry, a wet, and another dry interval in the Medieval Warm Period, which was followed by a wet and a dry interval in the Little Ice Age, and finally a mostly wet but highly moisture-variable Current Warm Period. Paulsen *et al.*'s data also reveal a number of other cycles superimposed on the major millennial-scale cycle of temperature and the centennial-scale cycle of moisture. They attribute most of these higher-frequency cycles to solar phenomena and not  $\text{CO}_2$  concentrations in the air. Paulsen *et al.* conclude that the summer monsoon over eastern China, which brings the region much of its precipitation, may “be related to solar irradiance.”

Kalugin *et al.* (2005) worked with sediment cores from Lake Teletskoye in the Altai Mountains of Southern Siberia to produce a multi-proxy climate record spanning the past 800 years. This record revealed that the regional climate was relatively warm with high terrestrial productivity from AD 1210 to 1380. Thereafter, however, temperatures cooled and productivity dropped, reaching a broad minimum between 1660 and 1700, which interval, in their words, “corresponds to the age range of the well-known Maunder Minimum (1645-1715)” and is “in agreement with the timing of the Little Ice Age in Europe (1560-1850).”

With respect to moisture and precipitation, Kalugin *et al.* state that the period between 1210 and 1480 was more humid than that of today, while the period between 1480 and 1840 was more arid. In addition, they report three episodes of multi-year

drought (1580-1600, 1665-1690, and 1785-1810), which findings are in agreement with other historical data and tree-ring records from the Mongolia-Altai region (Butvilovskii, 1993; Jacoby *et al.*, 1996; Panyushkina *et al.*, 2000). It is problematic for the IPCC to claim that global warming will lead to more frequent and more severe droughts, as *all* of the major multi-year droughts detected in this study occurred during the cool phase of the 800-year record.

Touchan *et al.* (2003) developed two reconstructions of spring precipitation for southwestern Turkey from tree-ring width measurements, one of them (1776-1998) based on nine chronologies of *Cedrus libani*, *Juniperus excelsa*, *Pinus brutia*, and *Pinus nigra*, and the other one (1339-1998) based on three chronologies of *Juniperus excelsa*. These records, according to them, “show clear evidence of multi-year to decadal variations in spring precipitation.” Nevertheless, they report that “dry periods of 1-2 years were well distributed throughout the record” and that the same was largely true of similar wet periods. With respect to more extreme events, the period preceding the Industrial Revolution stood out. They note, for example, that “all of the wettest 5-year periods occurred prior to 1756.” Likewise, the longest period of reconstructed spring drought was the four-year period 1476-79, while the single driest spring was 1746. We see no evidence that the past century produced distinctive changes in the nature of drought in this part of Asia.

Cluis and Laberge (2001) analyzed streamflow records stored in the databank of the Global Runoff Data Center at the Federal Institute of Hydrology in Koblenz (Germany) to see if there were any changes in Asian river runoff of the type predicted by the IPCC to lead to more frequent and more severe drought. This study was based on the streamflow histories of 78 rivers said to be “geographically distributed throughout the whole Asia-Pacific region.” The mean start and end dates of these series were  $1936 \pm 5$  years and  $1988 \pm 1$  year, respectively, representing an approximate half-century time span. In the case of the annual minimum discharges of these rivers, which are the ones associated with drought, 53 percent of them were unchanged over the period of the study; where there were trends, 62 percent of them were upward, indicative of a growing likelihood of both less frequent and less severe drought.

Ducic (2005) analyzed observed and reconstructed discharge rates of the Danube River near Orsova, Serbia, over the period 1731-1990,

finding that the lowest five-year discharge value in the pre-instrumental era (period of occurrence: 1831-1835) was practically equal to the lowest five-year discharge value in the instrumental era (period of occurrence: 1946-1950), and that the driest decade of the entire 260-year period was 1831-1840. The discharge rate for the last decade of the record (1981-1990), was “completely inside the limits of the whole series,” in Ducic’s words, and only slightly (0.7 percent) less than the 260-year mean. As a result, Ducic concluded that “modern discharge fluctuations do not point to [a] dominant anthropogenic influence.” Ducic’s correlative analysis suggests that the detected cyclicity in the record could “point to the domination of the influence of solar activity.”

Jiang *et al.* (2005) analyzed historical documents to produce a time series of flood and drought occurrences in eastern China’s Yangtze Delta since AD 1000. Their work revealed that alternating wet and dry episodes occurred throughout this period; the data demonstrate that droughts and floods usually occurred in the spring and autumn seasons of the same year, with the most rapid and strongest of these fluctuations occurring during the Little Ice Age (1500-1850), as opposed to the preceding Medieval Warm Period and the following Current Warm Period.

Davi *et al.* (2006) employed absolutely dated tree-ring-width chronologies from five sampling sites in west-central Mongolia—all of them “in or near the Selenge River basin, the largest river in Mongolia”—to develop a reconstruction of streamflow that extends from 1637 to 1997. Of the 10 driest five-year periods of the 360-year record, only one occurred during the twentieth century (and that just barely: 1901-1905, sixth driest of the 10 extreme periods), while of the 10 wettest five-year periods, only two occurred during the twentieth century (1990-1994 and 1917-1921, the second and eighth wettest of the 10 extreme periods, respectively). Consequently, as Davi *et al.* describe the situation, “there is much wider variation in the long-term tree-ring record than in the limited record of measured precipitation,” such that over the course of the twentieth century, extremes of both dryness and wetness were less frequent and less severe.

Sinha *et al.* (2007) derived a nearly annually resolved record of Indian summer monsoon (ISM) rainfall variations for the core monsoon region of India that stretches from AD 600 to 1500 based on a <sup>230</sup>Th-dated stalagmite oxygen isotope record from Dandak Cave, which is located at 19°00’N, 82°00’E. This work revealed that “the short instrumental record

of ISM underestimates the magnitude of monsoon rainfall variability,” and they state that “nearly every major famine in India [over the period of their study] coincided with a period of reduced monsoon rainfall as reflected in the Dandak  $\delta^{18}\text{O}$  record,” noting two particularly devastating famines that “occurred at the beginning of the Little Ice Age during the longest duration and most severe ISM weakening of [their] reconstruction.”

Sinha *et al.* state that “ISM reconstructions from Arabian Sea marine sediments (Agnihotri *et al.*, 2002; Gupta *et al.*, 2003; von Rad *et al.*, 1999), stalagmite  $\delta^{18}\text{O}$  records from Oman and Yemen (Burns *et al.*, 2002; Fleitmann *et al.*, 2007), and a pollen record from the western Himalaya (Phadtare and Pant, 2006) also indicate a weaker monsoon during the Little Ice Age and a relatively stronger monsoon during the Medieval Warm Period.” As a result, the eight researchers note that “since the end of the Little Ice Age, ca 1850 AD, the human population in the Indian monsoon region has increased from about 200 million to over 1 billion,” and that “a recurrence of weaker intervals of ISM comparable to those inferred in our record would have serious implications to human health and economic sustainability in the region.” Thus the Current Warm Period is beneficial to the population of India.

Zhang *et al.* (2007) developed flood and drought histories of the past thousand years in China’s Yangtze Delta, based on “local chronicles, old and very comprehensive encyclopaedia, historic agricultural registers, and official weather reports,” after which “continuous wavelet transform was applied to detect the periodicity and variability of the flood/drought series”—which they describe as “a powerful way to characterize the frequency, the intensity, the time position, and the duration of variations in a climate data series”—and, finally, the results of the entire set of operations were compared with two one-thousand-year temperature histories of the Tibetan Plateau: northeastern Tibet and southern Tibet.

As a result of this effort, Zhang *et al.* report that “during AD 1400-1700 [the coldest portion of their record, corresponding to much of the Little Ice Age], the proxy indicators showing the annual temperature experienced larger variability (larger standard deviation), and this time interval exactly corresponds to the time when the higher and significant wavelet variance occurred.” By contrast, they report that “during AD 1000-1400 [the warmest portion of their record, corresponding to much of the Medieval Warm

Period], relatively stable changes of climatic changes reconstructed from proxy indicators in Tibet correspond to lower wavelet variance of flood/drought series in the Yangtze Delta region.”

The research summarized in this section shows the frequency of drought in Asia varies according to millennial, centennial, and decadal cycles. Since those cycles predate any possible human influence on climate, they serve to refute the claim that today’s relatively dry climate is the result of human activity.

### 6.1.3. Europe

Linderholm and Chen (2005) derived a 500-year history of winter (September-April) precipitation from tree-ring data obtained within the Northern Boreal zone of Central Scandinavia. This chronology indicated that below-average precipitation was observed during the periods 1504-1520, 1562-1625, 1648-1669, 1696-1731, 1852-1871, and 1893-1958, with the lowest values occurring at the beginning of the record and at the beginning of the seventeenth century. These results demonstrate that for this portion of the European continent, twentieth century global warming did not result in more frequent or more severe droughts.

Another five-century perspective on the issue was provided by Wilson *et al.* (2005), who used a regional curve standardization technique to develop a summer (March-August) precipitation chronology from living and historical ring-widths of trees in the Bavarian Forest region of southeast Germany for the period 1456-2001. This technique captured low frequency variations that indicated the region was substantially drier than the long-term average during the periods 1500-1560, 1610-1730, and 1810-1870, all of which intervals were much colder than the bulk of the twentieth century.

A third study of interest concerns the Danube River in western Europe, where some researchers had previously suggested that an anthropogenic signal was present in the latter decades of the twentieth century, and that it was responsible for that period's supposedly drier conditions. Ducic (2005) tested these claims by analyzing observed and reconstructed discharge rates of the river near Orsova, Serbia over the period 1731-1990. This work revealed that the lowest five-year discharge value in the pre-instrumental era (1831-1835) was practically equal to the lowest five-year discharge value in the instrumental era (1946-1950), and that the driest decade of the entire 260-year period was 1831-1840. What is more, the discharge rate for the last decade of the record (1981-1990), which prior researchers had claimed was anthropogenically influenced, was found to be "completely inside the limits of the whole series," in Ducic's words, and only 0.7 percent less than the 260-year mean, leading to the conclusion that "modern discharge fluctuations do not point to dominant anthropogenic influence." In fact, Ducic's correlative analysis suggests that the detected cyclicity in the record could "point to the domination of the influence of solar activity."

In much the same vein and noting that “the media often reflect the view that recent severe drought events are signs that the climate has in fact already changed owing to human impacts,” Hisdal *et al.* (2001) examined pertinent data from many places in Europe. They performed a series of statistical analyses on more than 600 daily streamflow records from the European Water Archive to examine trends in the severity, duration, and frequency of drought over the following four time periods: 1962-1990, 1962-1995, 1930-1995, and 1911-1995. This work revealed, in their words, that “despite several reports on recent droughts in Europe, there is no clear indication that streamflow drought conditions in Europe have generally become more severe or frequent in the time periods studied.” To the contrary, they report that “overall, the number of negative significant trends pointing towards decreasing drought deficit volumes or fewer drought events exceeded the number of positive significant trends (increasing drought deficit volumes or more drought events).”

In conclusion, there is no evidence that droughts in Europe became more frequent or more severe due to global warming in the twentieth century. Additional information on this topic, including reviews of newer publications as they become available, can be found at <http://www.co2science.org/subject/d/droughteurope.php>.

## 6.1.4. North America

### 6.1.4.1. Canada

Gan (1998) performed several statistical tests on datasets pertaining to temperature, precipitation, spring snowmelt dates, streamflow, potential and actual evapotranspiration, and the duration, magnitude, and severity of drought throughout the Canadian Prairie Provinces of Alberta, Saskatchewan, and Manitoba. The results of these several tests suggest that the Prairies have become somewhat warmer and drier over the past four to five decades, although there are regional exceptions to this generality. After weighing all of the pertinent facts, however, Gan reports “there is no solid evidence to conclude that climatic warming, if it occurred, has caused the Prairie drought to become more severe,” further noting, “the evidence is insufficient to conclude that warmer climate will lead to more severe droughts in the Prairies.”

Working in the same general area, Quiring and Papakyriakou (2005) used an agricultural drought index (Palmer’s Z-index) to characterize the frequency, severity, and spatial extent of June-July moisture anomalies for 43 crop districts from the agricultural region of the Canadian prairies over the period 1920-99. This work revealed that for the 80-year period of their study, the single most severe June-July drought on the Canadian prairies occurred in 1961, and that the next most severe droughts, in descending order of severity, occurred in 1988, 1936, 1929, and 1937, for little net overall trend. Simultaneously, however, they say there was an upward trend in mean June-July moisture conditions. In addition, they note that “reconstructed July moisture conditions for the Canadian prairies demonstrate that droughts during the 18th and 19th centuries were more persistent than those of the 20th century (Sauchyn and Skinner, 2001).”

In a subsequent study that covered an even longer span of time, St. George and Nielsen (2002) used “a ringwidth chronology developed from living, historical and subfossil bur oak in the Red River basin to reconstruct annual precipitation in southern Manitoba since AD 1409.” They say that “prior to the 20th century, southern Manitoba’s climate was more extreme and variable, with prolonged intervals that were wetter and drier than any time following permanent Euro-Canadian settlement.” In other words, the twentieth century had more stable climatic conditions with fewer hydrologic extremes (floods

and droughts) than was typical of prior conditions. St. George and Nielsen conclude that “climatic case studies in regional drought and flood planning based exclusively on experience during the 20th century may dramatically underestimate true worst-case scenarios.” They also indicate that “multidecadal fluctuations in regional hydroclimate have been remarkably coherent across the northeastern Great Plains during the last 600 years,” and that “individual dry years in the Red River basin were usually associated with larger scale drought across much of the North American interior,” which suggests that their results for the Red River basin are likely representative of this entire larger region.

Taking an even longer look back in time, Campbell (2002) analyzed the grain sizes of sediment cores obtained from Pine Lake, Alberta, Canada to derive a non-vegetation-based high-resolution record of climate variability over the past 4,000 years. Throughout this record, periods of both increasing and decreasing moisture availability, as determined from grain size, were evident at decadal, centennial, and millennial time scales, as was also found by Laird *et al.* (2003) in a study of diatom assemblages in sediment cores taken from three additional Canadian lakes. Over the most recent 150 years, however, the grain size of the Pine Lake study generally remained above the 4,000-year average, indicative of relatively stable and less droughty conditions than the mean of the past four millennia.

Also working in eastern Canada, Girardin *et al.* (2004) developed a 380-year reconstruction of the Canadian Drought Code (CDC, a daily numerical rating of the average moisture content of deep soil organic layers in boreal conifer stands that is used to monitor forest fire danger) for the month of July, based on 16 well-replicated tree-ring chronologies from the Abitibi Plains of eastern Canada just below James Bay. Cross-continuous wavelet transformation analyses of these data, in their words, “indicated coherency in the 8-16 and 17-32-year per cycle oscillation bands between the CDC reconstruction and the Pacific Decadal Oscillation prior to 1850,” while “following 1850, the coherency shifted toward the North Atlantic Oscillation.” These results led them to suggest that “the end of [the] ‘Little Ice Age’ over the Abitibi Plains sector corresponded to a decrease in the North Pacific decadal forcing around the 1850s,” and that “this event could have been followed by an inhibition of the Arctic air outflow and an incursion of more humid air masses from the subtropical Atlantic climate sector,” which may have

helped reduce fire frequency and drought severity. In this regard, they note that several other paleo-climate and ecological studies have suggested that “climate in eastern Canada started to change with the end of the ‘Little Ice Age’ (~1850),” citing the works of Tardif and Bergeron (1997, 1999), Bergeron (1998, 2000) and Bergeron *et al.* (2001), while further noting that Bergeron and Archambault (1993) and Hofgaard *et al.* (1999) have “speculated that the poleward retreat of the Arctic air mass starting at the end of the ‘Little Ice Age’ contributed to the incursion of moister air masses in eastern Canada.”

Moving back towards the west, Wolfe *et al.* (2005) conducted a multi-proxy hydro-ecological analysis of Spruce Island Lake in the northern Peace sector of the Peace-Athabasca Delta in northern Alberta. Their research revealed that hydro-ecological conditions in that region varied substantially over the past 300 years, especially in terms of multi-decadal dry and wet periods. More specifically, they found that (1) recent drying in the region was not the product of Peace River flow regulation that began in 1968, but rather the product of an extended drying period that was initiated in the early to mid-1900s, (2) the multi-proxy hydro-ecological variables they analyzed were well correlated with other reconstructed records of natural climate variability, and (3) hydro-ecological conditions after 1968 have remained well within the broad range of natural variability observed over the past 300 years, with the earlier portion of the record actually depicting “markedly wetter and drier conditions compared to recent decades.”

Moving to the Pacific coast of North America (Heal Lake near the city of Victoria on Canada’s Vancouver Island), Zhang and Hebda (2005) conducted dendroclimatological analyses of 121 well-preserved subfossil logs discovered at the bottom of the lake plus 29 Douglas-fir trees growing nearby that led to the development of an ~ 4,000-year chronology exhibiting sensitivity to spring precipitation. In doing so, they found that “the magnitude and duration of climatic variability during the past 4000 years are not well represented by the variation in the brief modern period.” As an example of this fact, they note that spring droughts represented by ring-width departures exceeding two standard deviations below the mean in at least five consecutive years occurred in the late AD 1840s and mid 1460s, as well as the mid 1860s BC, and were more severe than any drought of the twentieth century. In addition, the most persistent drought occurred during the 120-year period between

about AD 1440 and 1560. Other severe droughts of multi-decadal duration occurred in the mid AD 760s-800s, the 540s-560s, the 150s-late 190s, and around 800 BC. Wavelet analyses of the tree-ring chronology also revealed a host of natural oscillations on timescales of years to centuries, demonstrating that the twentieth century was in no way unusual in this regard, as there were many times throughout the prior 4,000 years when it was both wetter and drier than it was during the last century of the past millennium.

### 6.1.4.2. Mexico

Stahle *et al.* (2000) developed a long-term history of drought over much of North America from reconstructions of the Palmer Drought Severity Index, based on analyses of many lengthy tree-ring records. This history reveals the occurrence of a sixteenth century drought in Mexico that persisted from the 1540s to the 1580s. Writing of this anomalous period of much reduced precipitation, they say that “the ‘megadrought’ of the sixteenth century far exceeded any drought of the 20th century.”

Diaz *et al.* (2002) constructed a history of winter-spring (November-April) precipitation—which accounts for one-third of the yearly total—for the Mexican state of Chihuahua for the period 1647-1992, based on earlywood width chronologies of

more than 300 Douglas fir trees growing at four locations along the western and southern borders of Chihuahua and at two locations in the United States just above Chihuahua's northeast border. On the basis of these reconstructions, they note that "three of the 5 worst winter-spring drought years in the past three-and-a-half centuries are estimated to have occurred during the 20th century." Although this observation tends to make the twentieth century look highly anomalous in this regard, it is not, for two of those three worst drought years occurred during a period of average to slightly above-average precipitation.

Diaz *et al.* also note that "the longest drought indicated by the smoothed reconstruction lasted 17 years (1948-1964)," which is again correct and seemingly indicative of abnormally dry conditions during the twentieth century. However, for several of the 17 years of that below-normal-precipitation interval, precipitation values were only slightly below normal. For all practical purposes, there were four very similar dry periods interspersed throughout the preceding two-and-a-half centuries: one in the late 1850s and early 1860s, one in the late 1790s and early 1800s, one in the late 1720s and early 1730s, and one in the late 1660s and early 1670s.

With respect to the twentieth century alone, there was also a long period of high winter-spring precipitation that stretched from 1905 to 1932; following the major drought of the 1950s, precipitation remained at or just slightly above normal for the remainder of the record. Finally, with respect to the entire 346 years, there is no long-term trend in the data, nor is there any evidence of any sustained departure from that trend over the course of the twentieth century.

Cleaveland *et al.* (2003) constructed a winter-spring (November-March) precipitation history for the period 1386-1993 for Durango, Mexico, based on earlywood width chronologies of Douglas-fir tree rings collected at two sites in the Sierra Madre Occidental. They report that this record "shows droughts of greater magnitude and longer duration than the worst historical drought that occurred in the 1950s and 1960s." These earlier dramatic droughts include the long dry spell of the 1850s-1860s and what they call the megadrought of the mid- to late-sixteenth century. Their work clearly demonstrates that the worst droughts of the past 600 years did *not* occur during the period of greatest warmth. Instead, they occurred during the Little Ice Age, which was perhaps the coldest period of the current interglacial.

Investigating the same approximate time period, Hodell *et al.* (2005b) analyzed a 5.1-m sediment core they retrieved from Aguada X'caamal, a small sinkhole lake in northwest Yucatan, Mexico, finding that an important hydrologic change occurred there during the fifteenth century AD, as documented by the appearance of *A. beccarii* in the sediment profile, a decline in the abundance of charophytes, and an increase in the  $\delta^{18}\text{O}$  of gastropods and ostracods. In addition, they report that "the salinity and  $^{18}\text{O}$  content of the lake water increased as a result of reduced precipitation and/or increased evaporation in the mid- to late 1500s." These several changes, as well as many others they cite, were, as they describe it, "part of a larger pattern of oceanic and atmospheric change associated with the Little Ice Age that included cooling throughout the subtropical gyre (Lund and Curry, 2004)." Their assessment of the situation was that the "climate became drier on the Yucatan Peninsula in the 15th century AD near the onset of the Little Ice Age," as is also suggested by Maya and Aztec chronicles that "contain references to cold, drought and famine in the period AD 1441-1460."

Going back even further in time, Hodell *et al.* (1995) had provided evidence for a protracted drought during the Terminal Classic Period of Mayan civilization (AD 800-1000), based on their analysis of a single sediment core retrieved in 1993 from Lake Chichanacanab in the center of the northern Yucatan Peninsula of Mexico. Subsequently, based on two additional sediment cores retrieved from the same location in 2000, Hodell *et al.* (2001) determined that the massive drought likely occurred in two distinct phases (750-875 and 1000-1075). Reconstructing the climatic history of the region over the past 2,600 years and applying spectral analysis to the data also revealed a significant recurrent drought periodicity of 208 years that matched well with a cosmic ray-produced  $^{14}\text{C}$  record preserved in tree rings, which is believed to reflect variations in solar activity. Because of the good correspondence between the two datasets, they concluded that "a significant component of century-scale variability in Yucatan droughts is explained by solar forcing."

Hodell *et al.* (2005a) returned to Lake Chichanacanab in March 2004 and retrieved a number of additional sediment cores in some of the deeper parts in the lake, with multiple cores being taken from its deepest point, from which depth profiles of bulk density were obtained by means of gamma-ray attenuation, as were profiles of reflected red, green, and blue light via a digital color line-scan camera. As

they describe their findings, “the data reveal in great detail the climatic events that comprised the Terminal Classic Drought and coincided with the demise of Classic Maya civilization.” In this regard, they again report that “the Terminal Classic Drought was not a single, two-century-long megadrought, but rather consisted of a series of dry events separated by intervening periods of relatively moister conditions,” and that it “included an early phase (ca 770-870) and late phase (ca 920-1100).” Last of all, they say that “the bipartite drought history inferred from Chichancanab is supported by oxygen isotope records from nearby Punta Laguna,” and that “the general pattern is also consistent with findings from the Cariaco Basin off northern Venezuela (Haug *et al.*, 2003), suggesting that the Terminal Classic Drought was a widespread phenomenon and not limited to north-central Yucatan.”

Concurrent with the study of Hodell *et al.* (2005a), Almeida-Lenero *et al.* (2005) analyzed pollen profiles derived from sediment cores retrieved from Lake Zempoala and nearby Lake Quila in the central Mexican highlands about 65 km southwest of Mexico City, determining that it was generally more humid than at present in the central Mexican highlands during the mid-Holocene. Thereafter, however, there was a gradual drying of the climate; their data from Lake Zempoala indicate that “the interval from 1300 to 1100 cal yr BP was driest and represents an extreme since the mid-Holocene,” noting further that this interval of 200 years “coincides with the collapse of the Maya civilization.” Likewise, they report that their data from Lake Quila are also “indicative of the most arid period reported during the middle to late Holocene from c. 1300 to 1100 cal yr BP.” In addition, they note that “climatic aridity during this time was also noted by Metcalfe *et al.* (1991) for the Lerma Basin [central Mexico],” that “dry climatic conditions were also reported from Lake Patzcuaro, central Mexico by Watts and Bradbury (1982),” and that “dry conditions were also reported for [Mexico’s] Zacapu Basin (Metcalfe, 1995) and for [Mexico’s] Yucatan Peninsula (Curtis *et al.*, 1996, 1998; Hodell *et al.*, 1995, 2001).”

Based on the many results described above, it is evident that throughout much of Mexico some of the driest conditions and worst droughts of the Late Holocene occurred during the Little Ice Age and the latter part of the Dark Ages Cold Period. These observations do much to discredit the model-based claim that droughts will get worse as air temperatures

rise. All of the Mexican droughts of the twentieth century (when the IPCC claims the planet warmed at a rate and to a level that were unprecedented over the past two millennia) were much milder than many of the droughts that occurred during much colder centuries.

Additional information on this topic, including reviews of newer publications as they become available, can be found at <http://www.co2science.org/subject/d/droughtmexico.php>.

#### 6.1.4.3. United States

##### 6.1.4.3.1. Central United States

Starting at the U.S.-Canadian border and working our way south, we begin with the study of Fritz *et al.* (2000), who utilized data derived from sediment cores retrieved from three North Dakota lakes to reconstruct a 2,000-year history of drought in this portion of the Northern Great Plains. This work suggested, in their words, “that droughts equal or greater in magnitude to those of the Dust Bowl period were a common occurrence during the last 2000 years.”

Also working in the Northern Great Plains, but extending down into South Dakota, Shapley *et al.* (2005) developed a 1,000-year hydroclimate reconstruction from local bur oak tree-ring records and various lake sediment cores. Based on this record, they determined that prior to 1800, “droughts tended towards greater persistence than during the past two centuries,” suggesting that droughts of the region became shorter-lived as opposed to longer-lasting as the earth gradually recovered from the cold temperatures of the Little Ice Age.

The above observations are significant because the United States’ Northern Great Plains is an important agricultural region, providing a significant source of grain for both local and international consumption. However, the region is susceptible to periodic extreme droughts that tend to persist longer than those in any other part of the country (Karl *et al.*, 1987; Soule, 1992). Because of this fact, Laird *et al.* (1998) examined the region’s historical record of drought in an attempt to establish a baseline of natural drought variability that could help in attempts to determine if current and future droughts might be anthropogenically influenced.

Working with a high-resolution sediment core obtained from Moon Lake, North Dakota, which provided a sub-decadal record of salinity (drought) over the past 2,300 years, Laird *et al.* discovered that the U.S. Northern Great Plains were relatively wet during the final 750 years of this period. Throughout the 1,550 prior years, they determined that “recurring severe droughts were more the norm,” and that they were “of much greater intensity and duration than any in the 20th century,” including the great Dust Bowl event of the 1930s. There were, as they put it, “no modern equivalents” to Northern Great Plains droughts experienced prior to AD 1200, which means the human presence has not led to unusual drought conditions in this part of the world.

Continuing our southward trek, we encounter the work of Forman *et al.* (2005), who note that “periods of dune reactivation reflect sustained moisture deficits for years to decades and reflect broader environmental change with diminished surface- and ground-water resources.” This observation prompted them to focus on “the largest dune system in North America, the Nebraska Sand Hills,” where they utilized “recent advances in optically stimulated luminescence dating (Murray and Wintle, 2000) to improve chronologic control on the timing of dune reactivation.” They also linked landscape response to drought over the past 1,500 years to tree-ring records of aridity.

Forman *et al.* identified six major aeolian depositional events in the past 1,500 years, all but one of which (the 1930s “Dust Bowl” drought) occurred prior to the twentieth century. Moving backwards in time from the Dust Bowl, the next three major events occurred during the depths of the Little Ice Age, the next one near the Little Ice Age’s inception, and the earliest one near the end of the Dark Ages Cold Period. As for how the earlier droughts compare with those of the past century, the researchers say the

1930s drought (the twentieth century's worst depositional event) was less severe than the others, especially the one that has come to be known as the sixteenth century megadrought. Forman *et al.* thus conclude that the aeolian landforms they studied "are clear indicators of climate variability beyond twentieth century norms, and signify droughts of greater severity and persistence than thus far instrumentally recorded."

In a study that covered the entirety of the U.S. Great Plains, Daniels and Knox (2005) analyzed the alluvial stratigraphic evidence for an episode of major channel incision in tributaries of the upper Republican River that occurred between 1,100 and 800 years ago, after which they compared their findings with proxy drought records from 28 other locations throughout the Great Plains and surrounding regions. This work revealed that channel incision in the Republican River between about AD 900 and 1200 was well correlated with a multi-centennial episode of widespread drought, which in the words of Daniels and Knox, "coincides with the globally recognized Medieval Warm Period." Of great interest, however, is the fact that modern twentieth century warming has *not* led to a repeat of those widespread drought conditions.

Working in pretty much the same area some seven years earlier, Woodhouse and Overpeck (1998) reviewed what we know about the frequency and severity of drought in the central United States over the past two thousand years based upon empirical evidence of drought from various proxy indicators. Their study indicated the presence of numerous "multidecadal- to century-scale droughts," leading them to conclude that "twentieth-century droughts are not representative of the full range of drought variability that has occurred over the last 2000 years." In addition, they noted that the twentieth century was characterized by droughts of "moderate severity and comparatively short duration, relative to the full range of past drought variability."

With respect to the causes of drought, Woodhouse and Overpeck suggest a number of different possibilities that either directly or indirectly induce changes in atmospheric circulation and moisture transport. However, they caution that "the causes of droughts with durations of years (i.e., the 1930s) to decades or centuries (i.e., paleodroughts) are not well understood." They conclude that "the full range of past natural drought variability, deduced from a comprehensive review of the paleoclimatic literature, suggests that droughts more severe than those of the 1930s and 1950s are likely to occur in the

future," whatever the air's CO<sub>2</sub> concentration or temperature might.

Mauget (2004) looked for what he called "initial clues" to the commencement of the great drying of the U.S. Heartland that had been predicted to occur in response to CO<sub>2</sub>-induced global warming by Manabe and Wetherald (1987), Rind *et al.* (1990), Rosenzweig and Hillel (1993), and Manabe *et al.* (2004), which Mauget reasoned would be apparent in the observational streamflow record of the region. In this endeavor, he employed data obtained from the archives of the U.S. Geological Survey's Hydro-Climatic Data Network, which come from 42 stations covering the central third of the United States that stretch from the Canadian border on the north to the Gulf of Mexico on the south, with the most dense coverage being found within the U.S. Corn Belt.

Mauget reports finding "an overall pattern of low flow periods before 1972, and high flow periods occurring over time windows beginning after 1969." Of the 42 stations' high flow periods, he says that "34 occur during 1969-1998, with 25 of those periods ending in either 1997 or 1998," and that "of those 25 stations 21 are situated in the key agricultural region known as the Corn Belt." He also reports that "among most of the stations in the western portions of the Corn Belt during the 1980s and 1990s there is an unprecedented tendency toward extended periods of daily high flow conditions, which lead to marked increases in the mean annual frequency of hydrological surplus conditions relative to previous years." What is more, he notes that "in 15 of the 18 Corn Belt gage stations considered here at daily resolution, a more than 50 percent reduction in the mean annual incidence of hydrological drought conditions is evident during those periods." Last, Mauget reports that "the gage station associated with the largest watershed area—the Mississippi at Vicksburg—shows more than a doubling of the mean annual frequency of hydrological surplus days during its 1973-1998 high flow period relative to previous years, and more than a 50% reduction in the mean annual incidence of hydrological drought condition."

In summarizing his findings, Mauget states that the overall pattern of climate variation "is that of a reduced tendency to hydrological drought and an increased incidence of hydrological surplus over the Corn Belt and most of the Mississippi River basin during the closing decades of the 20th century," noting further that "some of the most striking evidence of a transition to wetter conditions in the streamflow analyses is found among streams and

rivers situated along the Corn Belt's climatologically drier western edge.”

Mauget states that the streamflow data “suggest a fundamental climate shift, as the most significant incidence of high ranked annual flow was found over relatively long time scales at the end of the data record.” In other words, the shift is *away from* the droughty conditions predicted by the IPCC to result from CO<sub>2</sub>-induced global warming in this important agricultural region of the United States.

### 6.1.4.3.2. Eastern United States

Cronin *et al.* (2000) studied the salinity gradient across sediment cores from Chesapeake Bay, the largest estuary in the United States, in an effort to examine precipitation variability in the surrounding watershed over the past millennium. Their work revealed the existence of a high degree of decadal and multidecadal variability between wet and dry conditions throughout the 1,000-year record, where regional precipitation totals fluctuated by 25 to 30 percent, often in “extremely rapid [shifts] occurring over about a decade.” In addition, precipitation over the past two centuries of the record was found to be generally greater than it was during the previous eight centuries, with the exception of the Medieval Warm Period (AD 1250-1350) when the [local] climate was found to be “extremely wet.” Equally significant was the 10 researchers’ finding that the region had experienced several “mega-droughts” that had lasted for 60 to 70 years, several of which they judged to have been “more severe than twentieth century droughts.”

Building upon the work of Cronin *et al.* were Willard *et al.* (2003), who examined the last 2,300 years of the Holocene record of Chesapeake Bay and the adjacent terrestrial ecosystem “through the study

of fossil dinoflagellate cysts and pollen from sediment cores.” In doing so, they found that “several dry periods ranging from decades to centuries in duration are evident in Chesapeake Bay records.” The first of these periods of lower-than-average precipitation (200 BC-AD 300) occurred during the latter part of the Roman Warm Period, while the next such period (~AD 800-1200), according to Willard *et al.*, “corresponds to the ‘Medieval Warm Period’.” In addition, they identified several decadal-scale dry intervals that spanned the years AD 1320-1400 and 1525-1650.

In discussing their findings, Willard *et al.* note that “mid-Atlantic dry periods generally correspond to central and southwestern USA ‘megadroughts’, which are described by Woodhouse and Overpeck (1998) as major droughts of decadal or more duration that probably exceeded twentieth-century droughts in severity.” Emphasizing this important point, they additionally indicate that “droughts in the late sixteenth century that lasted several decades, and those in the ‘Medieval Warm Period’ and between ~AD 50 and AD 350 spanning a century or more have been indicated by Great Plains tree-ring (Stahle *et al.*, 1985; Stahle and Cleaveland, 1994), lacustrine diatom and ostracode (Fritz *et al.*, 2000; Laird *et al.*, 1996a, 1996b) and detrital clastic records (Dean, 1997).” Their work in the eastern United States, together with the work of other researchers in still other parts of the country, demonstrates that twentieth century global warming has not led to the occurrence of unusually strong wet or dry periods.

Quiring (2004) introduced his study of the subject by describing the drought of 2001-2002, which had produced anomalously dry conditions along most of the east coast of the U.S., including severe drought conditions from New Jersey to northern Florida that forced 13 states to ration water. Shortly after the drought began to subside in October 2002, however, moist conditions returned and persisted for about a year, producing the wettest growing-season of the instrumental record. These observations, in Quiring’s words, “raise some interesting questions,” including the one we are considering here. As he phrased the call to inquiry, “are moisture conditions in this region becoming more variable?”

Using an 800-year tree-ring-based reconstruction of the Palmer Hydrological Drought Index to address this question, Quiring documented the frequency, severity, and duration of growing-season moisture anomalies in the southern mid-Atlantic region of the United States. Among other things, this work

revealed, in Quiring’s words, that “conditions during the 18th century were much wetter than they are today, and the droughts that occurred during the sixteenth century tended to be both longer and more severe.” He concluded that “the recent growing-season moisture anomalies that occurred during 2002 and 2003 can only be considered rare events if they are evaluated with respect to the relatively short instrumental record (1895-2003),” for when compared to the 800-year reconstructed record, he notes that “neither of these events is particularly unusual.” In addition, Quiring reports that “although climate models predict decreases in summer precipitation and significant increases in the frequency and duration of extreme droughts, the data indicate that growing-season moisture conditions during the 20th century (and even the last 19 years) appear to be near normal (well within the range of natural climate variability) when compared to the 800-year record.”

#### 6.1.4.3.3. Western United States

Is there evidence of more severe and longer-lasting droughts in the western United States? We begin our journey of inquiry just below Canada, in the U.S. Pacific Northwest, from whence we gradually wend our way to the U.S./Mexico border.

Knapp *et al.* (2002) created a 500-year history of severe single-year Pacific Northwest droughts from a study of 18 western juniper tree-ring chronologies that they used to identify what they call extreme Climatic Pointer Years or CPYs, which are indicative of severe single-year droughts. As they describe it, this procedure revealed that “widespread and extreme CPYs were concentrated in the 16th and early part of the 17th centuries,” while “both the 18th and 19th centuries were largely characterized by a paucity of drought events that were severe and widespread.” Thereafter, however, they say that “CPYs became more numerous during the 20th century,” although the number of twentieth century extreme CPYs (26) was still substantially less than the mean of the number of sixteenth and seventeenth century extreme CPYs (38), when the planet was colder. The data of this study fail to support the IPCC’s claim that global warming increases the frequency of severe droughts.

Gedalof *et al.* (2004) used a network of 32 drought-sensitive tree-ring chronologies to reconstruct mean water-year flow on the Columbia River at The Dalles in Oregon since 1750. This study of the second-largest drainage basin in the United States is stated by them to have been done “for the purpose of assessing the representativeness of recent observations, especially with respect to low frequency changes and extreme events.” When finished, it revealed, in their words, that “persistent low flows during the 1840s were probably the most severe of the

past 250 years,” and that “the drought of the 1930s is probably the second most severe.”

More recent droughts, in the words of the researchers, “have led to conflicts among uses (e.g., hydroelectric production versus protecting salmon runs), increased costs to end users (notably municipal power users), and in some cases the total loss of access to water (in particular junior water rights holders in the agricultural sector).” Nevertheless, they say that “these recent droughts were not exceptional in the context of the last 250 years and were of shorter duration than many past events.” In fact, they say, “the period from 1950 to 1987 is anomalous in the context of this record for having no notable multiyear drought events.”

Working in the Bighorn Basin of north-central Wyoming and south-central Montana, Gray *et al.* (2004a) used cores and cross sections from 79 Douglas fir and limber pine trees at four different sites to develop a proxy for annual precipitation spanning the period AD 1260-1998. This reconstruction, in their words, “exhibits considerable nonstationarity, and the instrumental era (post-1900) in particular fails to capture the full range of precipitation variability experienced in the past ~750 years.” More specifically, they say that “both single-year and decadal-scale dry events were more severe before 1900,” and that “dry spells in the late thirteenth and sixteenth centuries surpass both [the] magnitude and duration of any droughts in the Bighorn Basin after 1900.” They say that “single- and multi-year droughts regularly surpassed the severity and magnitude of the ‘worst-case scenarios’ presented by the 1930s and 1950s droughts.” If twentieth century global warming had any effect at all on Bighorn Basin precipitation, it was to make it less extreme rather than more extreme.

Moving further south, Benson *et al.* (2002) developed continuous high-resolution  $\delta^{18}\text{O}$  records from cored sediments of Pyramid Lake, Nevada, which they used to help construct a 7,600-year history of droughts throughout the surrounding region. Oscillations in the hydrologic balance that were evident in this record occurred, on average, about every 150 years, but with significant variability. Over the most recent 2,740 years, for example, intervals between droughts ranged from 80 to 230 years; while drought durations ranged from 20 to 100 years, with some of the larger ones forcing mass migrations of indigenous peoples from lands that could no longer support them. In contrast, historical droughts typically have lasted less than a decade.

In another study based on sediment cores extracted from Pyramid Lake, Nevada, Mensing *et al.* (2004) analyzed pollen and algal microfossils deposited there over the prior 7,630 years that allowed them to infer the hydrologic history of the area over that time period. Their results indicated that “sometime after 3430 but before 2750 cal yr B.P., climate became cool and wet,” but, paradoxically, that “the past 2500 yr have been marked by recurring persistent droughts.” The longest of these droughts, according to them, “occurred between 2500 and 2000 cal yr B.P.,” while others occurred “between 1500 and 1250, 800 and 725, and 600 and 450 cal yr B.P.,” with none recorded in more recent warmer times.

The researchers also note that “the timing and magnitude of droughts identified in the pollen record compares favorably with previously published  $\delta^{18}\text{O}$  data from Pyramid Lake” and with “the ages of submerged rooted stumps in the Eastern Sierra Nevada and woodrat midden data from central Nevada.” Noting that Bond *et al.* (2001) “found that over the past 12,000 yr, decreases in [North Atlantic] drift ice abundance corresponded to increased solar output,” they report that when they “compared the pollen record of droughts from Pyramid Lake with the stacked petrologic record of North Atlantic drift ice ... nearly every occurrence of a shift from ice maxima (reduced solar output) to ice minima (increased solar output) corresponded with a period of prolonged drought in the Pyramid Lake record.” As a result, Mensing *et al.* concluded that “changes in solar irradiance may be a possible mechanism influencing century-scale drought in the western Great Basin [of the United States].”

Only a state away, Gray *et al.* (2004b) used samples from 107 piñon pines at four different sites to develop a proxy record of annual precipitation spanning the AD 1226- 2001 interval for the Uinta Basin watershed of northeastern Utah. This effort revealed, in their words, that “single-year dry events before the instrumental period tended to be more severe than those after 1900,” and that decadal-scale dry events were longer and more severe prior to 1900 as well. In particular, they found that “dry events in the late 13th, 16th, and 18th Centuries surpass the magnitude and duration of droughts seen in the Uinta Basin after 1900.”

At the other end of the moisture spectrum, Gray *et al.* report that the twentieth century was host to two of the strongest wet intervals (1938-1952 and 1965-1987), although these two periods were only the seventh and second most intense wet regimes,

respectively, of the entire record. Hence, it would appear that in conjunction with twentieth century global warming, precipitation extremes (both high and low) within northeastern Utah’s Uinta Basin have become more attenuated as opposed to more amplified.

Working in the central and southern Rocky Mountains, Gray *et al.* (2003) examined 15 tree ring-width chronologies that had been used in previous reconstructions of drought for evidence of low-frequency variations in five regional composite precipitation histories. In doing so, they found that “strong multidecadal phasing of moisture variation was present in all regions during the late 16th-century megadrought,” and that “oscillatory modes in the 30-70 year domain persisted until the mid-19th century in two regions, and wet-dry cycles were apparently synchronous at some sites until the 1950s drought.” They thus speculate that “severe drought conditions across consecutive seasons and years in the central and southern Rockies may ensue from coupling of the cold phase Pacific Decadal Oscillation with the warm phase Atlantic Multidecadal Oscillation,” which is something they envision as having happened in both the severe 1950s drought and the late sixteenth century megadrought. Hence, there is reason to believe that episodes of extreme dryness in this part of the country may be driven in part by naturally recurring climate “regime shifts” in the Pacific and Atlantic Oceans.

Hidalgo *et al.* (2000) used a new form of principal components analysis to reconstruct a history of streamflow in the Upper Colorado River Basin based on information obtained from tree-ring data, after which they compared their results to those of Stockton and Jacoby (1976). In doing so, they found the two approaches to yield similar results, except that Hidalgo *et al.*’s approach responded with more intensity to periods of below-average streamflow or regional drought. Hence, it was easier for them to determine there has been “a near-centennial return period of extreme drought events in this region,” going all the way back to the early 1500s. It is reasonable to assume that if such an extreme drought were to commence today, it would not be related to either the air’s  $\text{CO}_2$  content or its temperature.

Woodhouse *et al.* (2006) also generated updated proxy reconstructions of water-year streamflow for the Upper Colorado River Basin, based on four key gauges (Green River at Green River, Utah; Colorado near Cisco, Utah; San Juan near Bluff, Utah; and Colorado at Lees Ferry, Arizona) and using an

expanded tree-ring network and longer calibration records than in previous efforts. The results of this program indicated that the major drought of 2000-2004, “as measured by 5-year running means of water-year total flow at Lees Ferry ... is not without precedence in the tree ring record,” and that “average reconstructed annual flow for the period 1844-1848 was lower.” They also report that “two additional periods, in the early 1500s and early 1600s, have a 25% or greater chance of being as dry as 1999-2004,” and that six other periods “have a 10% or greater chance of being drier.” In addition, their work revealed that “longer duration droughts have occurred in the past,” and that “the Lees Ferry reconstruction contains one sequence each of six, eight, and eleven consecutive years with flows below the 1906-1995 average.”

“Overall,” in the words of the three researchers, “these analyses demonstrate that severe, sustained droughts are a defining feature of Upper Colorado River hydroclimate.” In fact, they conclude from their work that “droughts more severe than any 20th to 21st century event occurred in the past,” meaning the preceding few centuries.

Moving closer still to the U.S. border with Mexico, Ni *et al.* (2002) developed a 1,000-year history of cool-season (November-April) precipitation for each climate division of Arizona and New Mexico from a network of 19 tree-ring chronologies. They determined that “sustained dry periods comparable to the 1950s drought” occurred in “the late 1000s, the mid 1100s, 1570-97, 1664-70, the 1740s, the 1770s, and the late 1800s.” They also note that although the 1950s drought was large in both scale and severity, “it only lasted from approximately 1950 to 1956,” whereas the sixteenth century mega-drought lasted more than four times longer.

With respect to the opposite of drought, Ni *et al.* report that “several wet periods comparable to the wet conditions seen in the early 1900s and after 1976” occurred in “1108-20, 1195-1204, 1330-45, the 1610s, and the early 1800s,” and they add that “the most persistent and extreme wet interval occurred in the 1330s.” Consequently, for the particular part of the world covered by Ni *et al.*'s study, there appears to be nothing unusual about the extremes of both wetness and dryness experienced during the twentieth century.

Also working in New Mexico, Rasmussen *et al.* (2006) derived a record of regional relative moisture from variations in the annual band thickness and mineralogy of two columnar stalagmites collected

from Carlsbad Cavern and Hidden Cave in the Guadalupe Mountains near the New Mexico/Texas border. From this work they discovered that both records “suggest periods of dramatic precipitation variability over the last 3000 years, exhibiting large shifts unlike anything seen in the modern record.”

We come now to two papers that deal with the western United States as a whole. In the first, Cook *et al.* (2004) developed a 1,200-year history of drought for the western half of the country and adjacent parts of Canada and Mexico (hereafter the “West”), based on annually resolved tree-ring records of summer-season Palmer Drought Severity Index that were derived for 103 points on a 2.5° x 2.5° grid, 68 of which grid points (66 percent of them) possessed data that extended back to AD 800. This reconstruction, in the words of Cook *et al.*, revealed “some remarkable earlier increases in aridity that dwarf [our italics] the comparatively short-duration current drought in the ‘West’.” Interestingly, they report that “the four driest epochs, centered on AD 936, 1034, 1150 and 1253, all occur during a ~400 year interval of overall elevated aridity from AD 900 to 1300,” which they say is “broadly consistent with the Medieval Warm Period.”

Commenting on their findings, the five scientists say “the overall coincidence between our megadrought epoch and the Medieval Warm Period suggests that anomalously warm climate conditions during that time may have contributed to the development of more frequent and persistent droughts in the ‘West’,” as well as the megadrought that was discovered by Rein *et al.* (2004) to have occurred in Peru at about the same time (AD 800-1250); and after citing nine other studies that provide independent evidence of drought during this time period for various sub-regions of the West, they warn that “any trend toward warmer temperatures in the future could lead to a serious long-term increase in aridity over western North America,” noting that “future droughts in the ‘West’ of similar duration to those seen prior to AD 1300 would be disastrous.”

While we agree with Cook *et al.*'s conclusion, we cannot help but note that the droughts that occurred during the Medieval Warm Period were obviously not CO<sub>2</sub>-induced. If the association between global warmth and drought in the western United States is robust, it suggests that current world temperatures are still well below those experienced during large segments of the Medieval Warm Period.

The last of the two papers to cover the western United States as a whole is that of Woodhouse

(2004), who reports what is known about natural hydroclimatic variability throughout the region via descriptions of several major droughts that occurred there over the past three millennia, all but the last century of which had atmospheric CO<sub>2</sub> concentrations that never varied by more than about 10 ppm from a mean value of 280 ppm.

For comparative purposes, Woodhouse begins by noting that “the most extensive U.S. droughts in the 20th century were the 1930s Dust Bowl and the 1950s droughts.” The first of these lasted “most of the decade of the 1930s” and “occurred in several waves,” while the latter “also occurred in several waves over the years 1951-1956.” More severe than either of these two droughts was what has come to be known as the Sixteenth Century Megadrought, which lasted from 1580 to 1600 and included northwestern Mexico in addition to the southwestern United States and the western Great Plains. Then there was what is simply called The Great Drought, which spanned the last quarter of the thirteenth century and was actually the last in a series of three thirteenth century droughts, the first of which may have been even more severe than the last. In addition, Woodhouse notes there was a period of remarkably sustained drought in the second half of the twelfth century.

It is evident from these observations, according to Woodhouse, that “the 20th century climate record contains only a subset of the range of natural climate variability in centuries-long and longer paleoclimatic records.” This subset, as it pertains to water shortage, does not approach the level of drought severity and duration experienced in prior centuries and millennia. A drought much more extreme than the most extreme droughts of the twentieth century would be required to propel the western United States and adjacent portions of Canada and Mexico into a truly unprecedented state of dryness.

#### 6.1.4.3.4. Entire United States

Andreadis and Lettenmaier (2006) examined twentieth century trends in soil moisture, runoff, and drought over the conterminous United States with a hydro-climatological model forced by real-world measurements of precipitation, air temperature, and wind speed over the period 1915-2003. This work revealed, in their words, that “droughts have, for the most part, become shorter, less frequent, less severe, and cover a smaller portion of the country over the last century.”

Using the self-calibrating Palmer (1965) drought severity index (SCPDSI), as described by Wells *et al.* (2004), Van der Schrier *et al.* (2006) constructed maps of summer moisture availability across a large portion of North America (20-50°N, 130-60°W) for the period 1901-2002 with a spatial latitude/longitude resolution of 0.5° x 0.5°. This operation revealed, in their words, that over the area as a whole, “the 1930s and 1950s stand out as times of persistent and exceptionally dry conditions, whereas the 1970s and the 1990s were generally wet.” However, they say that “no statistically significant trend was found in the mean summer SCPDSI over the 1901-2002 period, nor in the area percentage with moderate or severe moisture excess or deficit.” In fact, they could not find a single coherent area within the SCPDSI maps that “showed a statistically significant trend over the 1901-2002 period.”

Going back considerably further in time, Fye *et al.* (2003) developed gridded reconstructions of the summer (June-August) basic Palmer Drought Severity Index over the continental United States, based on “annual proxies of drought and wetness provided by 426 climatically sensitive tree-ring chronologies.” This work revealed that the greatest twentieth century

moisture anomalies across the United States were the 13-year pluvial over the West in the early part of the century, and the epic droughts of the 1930s (the Dust Bowl years) and 1950s, which lasted 12 and 11 years, respectively.

The researchers found the 13-year pluvial from 1905 to 1917 had three earlier analogs: an extended 16-year pluvial from 1825 to 1840, a prolonged 21-year wet period from 1602 to 1622, and a 10-year pluvial from 1549 to 1558. The 11-year drought from 1946 to 1956, on the other hand, had at least 12 earlier analogs in terms of location, intensity, and duration; but the Dust Bowl drought was greater than all of them, except for a sixteenth century “megadrought” which lasted some 18 years and was, in the words of Fye *et al.*, “the most severe sustained drought to impact North America in the past 500 to perhaps 1000 years.”

In another long-term study, Stahle *et al.* (2000) developed a long-term history of North American drought from reconstructions of the Palmer Drought Severity Index based on analyses of many lengthy tree-ring records. This history also revealed that the 1930s Dust Bowl drought in the United States was eclipsed in all three of these categories by the sixteenth century megadrought. This incredible period of dryness, as they describe it, persisted “from the 1540s to 1580s in Mexico, from the 1550s to 1590s over the [U.S.] Southwest, and from the 1570s to 1600s over Wyoming and Montana.” In addition, it “extended across most of the continental United States during the 1560s,” and it recurred with greater intensity over the Southeast during the 1580s to 1590s. So horrendous were its myriad impacts, Stahle *et al.* unequivocally state that “the ‘megadrought’ of the sixteenth century far exceeded any drought of the 20th century.” They state that a “precipitation reconstruction for western New Mexico suggests that the sixteenth century drought was the most extreme prolonged drought in the past 2000 years.”

Last, we come to the intriguing study of Herweijer *et al.* (2006), who begin the report of their work by noting that “drought is a recurring major natural hazard that has dogged civilizations through time and remains the ‘world’s costliest natural disaster’.” With respect to the twentieth century, they report that the “major long-lasting droughts of the 1930s and 1950s covered large areas of the interior and southern states and have long served as paradigms for the social and economic cost of sustained drought in the USA.” However, they add that “these events are not unique to the twentieth

century,” and they go on to describe three periods of widespread and persistent drought in the latter half of the nineteenth century—1856-1865 (the “Civil War” drought), 1870-1877 and 1890-1896—based on evidence obtained from proxy, historical, and instrumental data.

With respect to the first of these impressive mid-to late-nineteenth century droughts, Herweijer *et al.* say it “is likely to have had a profound ecological and cultural impact on the interior USA, with the persistence and severity of drought conditions in the Plains surpassing those of the infamous 1930s Dust Bowl drought.” In addition, they report that “drought conditions during the Civil War, 1870s and 1890s droughts were not restricted to the summer months, but existed year round, with a large signal in the winter and spring months.”

Taking a still longer look back in time, the three researchers cite the work of Cook and Krusic (2004), who constructed a North American Drought Atlas using hundreds of tree-ring records. This atlas reveals what Herweijer *et al.* describe as “a ‘Mediaeval Megadrought’ that occurred from AD 900 to AD 1300,” along with “an abrupt shift to wetter conditions after AD 1300, coinciding with the ‘Little Ice Age’, a time of globally cooler temperatures” that ultimately gave way to “a return to more drought-prone conditions beginning in the nineteenth century.”

The broad picture that emerges from these observations is one where the most severe North American droughts of the past millennium were associated with the globally warmer temperatures of the Medieval Warm Period plus the initial stage of the globally warmer Current Warm Period. Superimposed upon this low-frequency behavior, however, Herweijer *et al.* find evidence for a “linkage between a colder eastern equatorial Pacific and persistent North American drought over the last 1000 years,” noting further that “Rosby wave propagation from the cooler equatorial Pacific amplifies dry conditions over the USA.” In addition, they report that after using “published coral data for the last millennium to reconstruct a NINO 3.4 history,” they applied “the modern-day relationship between NINO 3.4 and North American drought ... to recreate two of the severest Mediaeval ‘drought epochs’ in the western USA.”

But how is it that simultaneous global-scale warmth and regional-scale cold combine to produce the most severe North American droughts? One possible answer is variable solar activity. When solar

activity is in an ascending mode, the globe as a whole warms; but at the same time, to quote from Herweijer *et al.*’s concluding sentence, increased irradiance typically “corresponds to a colder eastern equatorial Pacific and, by extension, increased drought occurrence in North America and other mid-latitude continental regions.”

An important implication of these observations is that the most severe North American droughts should occur during major multi-centennial global warm periods, as has in fact been observed to be the case. Since the greatest such droughts of the Current Warm Period have not yet approached the severity of those that occurred during the Medieval Warm Period, it seems a good bet that the global temperature of the Current Warm Period is not yet as high as the global temperature that prevailed throughout the Medieval Warm Period.

## 6.2. Floods

In the midst of 2002's massive flooding in Europe, Gallus Cadonau, the managing director of the Swiss Greina Foundation, called for a punitive tariff on U.S. imports to force cooperation on reducing greenhouse gas emissions, claiming that the flooding "definitely has to do with global warming" and stating that "we must change something now" (Hooper, 2002). Cadonau was joined in this sentiment by Germany's environment minister, Jurgen Trittin, who implied much the same thing when he said "if we don't want this development to get worse, then we must continue with the consistent reduction of environmentally harmful greenhouse gasses" (Ibid.).

The IPCC seems to agree with Cadonau and Trittin. Its authors report "a catastrophic flood occurred along several central European rivers in August 2002. The floods resulting from extraordinarily high precipitation were enhanced by the fact that the soils were completely saturated and the river water levels were already high because of previous rain. Hence, it was part of a pattern of weather over an extended period" (IPCC, 2007-I, p. 311). While admitting "there is no significant trend in flood occurrences of the Elbe within the last 500 years," the IPCC nevertheless says the "observed increase in precipitation variability at a majority of German precipitation stations during the last century is indicative of an enhancement of the probability of both floods and droughts" (Ibid.)

In evaluating these claims it is instructive to see how flood activity has responded to the global warming of the past century. In the sections below we review studies of the subject that have been conducted in Asia, Europe, and North America.

Additional information on this topic, including reviews on floods not discussed here, can be found at [http://www.co2science.org/subject/f/subject\\_f.php](http://www.co2science.org/subject/f/subject_f.php) under the heading Floods.

### 6.2.1. Asia

In a study that covered the entire continent, Cluis and Laberge (2001) analyzed the flow records of 78 rivers distributed throughout the Asia-Pacific region to see if there had been any enhancement of earth's hydrologic cycle coupled with an increase in variability that might have led to more floods between the mean beginning and end dates of the flow records:  $1936 \pm 5$  years and  $1988 \pm 1$  year, respectively. Over this period, the two scientists determined that mean river discharges were unchanged in 67 percent of the cases investigated; where there were trends, 69 percent of them were downward. In addition, maximum river discharges were unchanged in 77 percent of the cases investigated; where there were trends, 72 percent of them were downward. Consequently, the two researchers observed no changes in both of these flood characteristics in the majority of the rivers they studied; where there were changes, more of them were of the type that typically leads to less flooding and less severe floods.

Two years later, Kale *et al.* (2003) conducted geomorphic studies of slackwater deposits in the bedrock gorges of the Tapi and Narmada Rivers of central India, which allowed them to assemble long chronologies of large floods of these rivers. In doing so, they found that "since 1727 at least 33 large floods have occurred on the Tapi River and the largest on the river occurred in 1837." With respect to large floods on the Narmada River, they reported at least nine or 10 floods between the beginning of the Christian era and AD 400; between AD 400 and 1000 they documented six to seven floods; between AD 1000 and 1400 eight or nine floods; and after 1950 three more such floods. In addition, on the basis of texture, elevation, and thickness of the flood units, they concluded that "the periods AD 400-1000 and post-1950 represent periods of extreme floods."

What do these findings imply about the effects of global warming on central India flood events? The post-1950 period would likely be claimed by the IPCC to have been the warmest of the past millennium; it has indeed experienced some extreme floods. However, the flood characteristics of the AD 400-1000 period are described in equivalent terms, and this was a rather cold climatic interval known as the Dark Ages Cold Period. See, for example, McDermott *et al.* (2001) and Andersson *et al.* (2003). In addition, the most extreme flood in the much shorter record of the Tapi River occurred in 1837, near the beginning of one of the colder periods of the

Little Ice Age. There appears to be little correlation between the flood characteristics of the Tapi and Narmada Rivers of central India and the thermal state of the global climate.

Focusing on the much smaller area of southwestern Turkey, Touchan *et al.* (2003) developed two reconstructions of spring (May-June) precipitation from tree-ring width measurements, one of them (1776-1998) based on nine chronologies of *Cedrus libani*, *Juniperus excelsa*, *Pinus brutia* and *Pinus nigra*, and the other one (1339-1998) based on three chronologies of *Juniperus excelsa*. These reconstructions, in their words, “show clear evidence of multi-year to decadal variations in spring precipitation,” with both wet and dry periods of 1-2 years duration being well distributed throughout the record. However, in the case of more extreme hydrologic events, they found that all of the wettest five-year periods preceded the Industrial Revolution, manifesting themselves at times when the air’s carbon dioxide content was largely unaffected by anthropogenic CO<sub>2</sub> emissions.

Two years later, Jiang *et al.* (2005) analyzed pertinent historical documents to produce a 1,000-year time series of flood and drought occurrence in the Yangtze Delta of Eastern China (30 to 33°N, 119 to 122°E), which with a nearly level plain that averages only two to seven meters above sea level across 75 percent of its area is vulnerable to flooding and maritime tidal hazards. This work demonstrated that alternating wet and dry episodes occurred throughout the 1,000-year period, with the most rapid and strongest of these fluctuations occurring during the Little Ice Age (1500-1850).

The following year, Davi *et al.* (2006) developed a reconstruction of streamflow that extended from 1637 to 1997, based on absolutely dated tree-ring-width chronologies from five sampling sites in west-central Mongolia, all of which sites were in or near the Selenge River basin, the largest river in Mongolia. Of the 10 wettest five-year periods, only two occurred during the twentieth century (1990-1994 and 1917-1921, the second and eighth wettest of the 10 extreme periods, respectively), once again indicative of a propensity for less flooding during the warmest portion of the 360-year period.

The year 2007 produced a second study of the Yangtze Delta of Eastern China, when Zhang *et al.* (2007) developed flood and drought histories of the past thousand years “from local chronicles, old and very comprehensive encyclopaedia, historic agricultural registers, and official weather reports,”

after which “continuous wavelet transform was applied to detect the periodicity and variability of the flood/drought series” and, finally, the results of the entire set of operations were compared with 1,000-year temperature histories of northeastern Tibet and southern Tibet. This work revealed, in the words of the researchers, that “colder mean temperature in the Tibetan Plateau usually resulted in higher probability of flood events in the Yangtze Delta region.”

Contemporaneously, Huang *et al.* (2007) constructed a complete catalog of Holocene overbank flooding events at a watershed scale in the headwater region of the Sushui River within the Yuncheng Basin in the southeast part of the middle reaches of China’s Yellow River, based on pedo-sedimentary records of the region’s semiarid piedmont alluvial plains, including the color, texture, and structure of the sediment profiles, along with determinations of particle-size distributions, magnetic susceptibilities, and elemental concentrations. This work revealed there were six major episodes of overbank flooding. The first occurred at the onset of the Holocene, the second immediately before the mid-Holocene Climatic Optimum, and the third in the late stage of the mid-Holocene Climatic Optimum, while the last three episodes coincided with “the cold-dry stages during the late Holocene,” according to the six scientists. Speaking of the last of the overbank flooding episodes, they note that it “corresponds with the well documented ‘Little Ice Age,’ when “climate departed from its long-term average conditions and was unstable, irregular, and disastrous,” which is pretty much like the Little Ice Age has been described in many other parts of the world as well.

The history of floods in Asia provides no evidence of increased frequency or severity during the Current Warm Period. Additional information on this topic, including reviews of newer publications as they become available, can be found at <http://www.co2science.org/subject/f/floodsasiasia.php>.

## 6.2.2. Europe

Nesje *et al.* (2001) analyzed a sediment core from a lake in southern Norway in an attempt to determine the frequency and magnitude of floods in that region. The last thousand years of the record revealed “a period of little flood activity around the Medieval period (AD 1000-1400),” which was followed by a period of extensive flood activity that was associated with the “post-Medieval climate deterioration characterized by lower air temperature, thicker and more long-lasting snow cover, and more frequent storms associated with the ‘Little Ice Age.’” This particular study suggests that the post-Little Ice Age warming the earth has experienced for the past century or two—and which could well continue for some time to come—should be leading this portion of the planet into a period of less-extensive floods.

Pirazzoli (2000) analyzed tide-gauge and meteorological data over the period 1951-1997 for the northern portion of the Atlantic coast of France, discovering that the number of atmospheric depressions and strong surge winds in this region “are becoming less frequent.” The data also revealed that “ongoing trends of climate variability show a decrease in the frequency and hence the gravity of coastal flooding,” which is what would be expected in view of the findings of Nesje *et al.*

Reynard *et al.* (2001) used a continuous flow simulation model to assess the impacts of potential climate and land use changes on flood regimes of the UK’s Thames and Severn Rivers; and, as might have been expected of a model study, it predicted modest increases in the magnitudes of 50-year floods on these rivers when the climate was forced to change as predicted for various global warming scenarios. However, when the modelers allowed forest cover to rise concomitantly, they found that this land use change “acts in the opposite direction to the climate changes and under some scenarios is large enough to fully compensate for the shifts due to climate.” As the air’s  $\text{CO}_2$  content continues to rise, there will be a natural impetus for forests to expand their ranges and grow in areas where grasses now dominate the landscape. If public policies cooperate, forests will indeed expand their presence on the river catchments in question and neutralize any predicted increases in flood activity in a future high- $\text{CO}_2$  world.

Starkel (2002) reviewed what is known about the relationship between extreme weather events and the thermal climate of Europe during the Holocene. This review demonstrated that more extreme fluvial activity was typically associated with cooler time intervals. In recovering from one such period (the Younger Dryas), for example, temperatures in Germany and Switzerland rose by 3-5°C over several decades; “this fast shift,” in Starkel’s words, “caused a rapid expansion of forest communities, [a] rise in the upper treeline and higher density of vegetation cover,” which led to a “drastic” reduction in sediment delivery from slopes to river channels.

Mudelsee *et al.* (2003) analyzed historical documents from the eleventh century to 1850, plus subsequent water stage and daily runoff records from then until 2002, for two of the largest rivers in central Europe: the Elbe and Oder Rivers. The team of German scientists reported that “for the past 80 to 150 years”—which the IPCC claims was a period of unprecedented global warming—“we find a decrease in winter flood occurrence in both rivers, while

summer floods show no trend, consistent with trends in extreme precipitation occurrence.” As the world has recovered from the global chill of the Little Ice Age, flooding of the Elbe and Oder rivers has not materially changed in summer and has actually decreased in winter. Blaming anthropogenic CO<sub>2</sub> emissions for the European flooding of 2002, then, is not a reasoned deduction based on scientific evidence.

On September 8 and 9, 2002, extreme flooding of the Gardon River in southern France occurred as a result of half-a-year’s rainfall being received in approximately 20 hours. Floods claimed the lives of a number of people and caused much damage to towns and villages situated adjacent to its channel. The event elicited much coverage in the press; in the words of Sheffer *et al.* (2003), “this flood is now considered by the media and professionals to be ‘the largest flood on record’,” which record extends all the way back to 1890. Coincidentally, Sheffer *et al.* were in the midst of a study of prior floods of the Gardon River, so they had data spanning a much longer time period. They report that “the extraordinary flood of September 2002 was not the largest by any means,” noting that “similar, and even larger floods have occurred several times in the recent past,” with three of the five greatest floods they had identified to that point in time occurring over the period AD 1400-1800 during the Little Ice Age. Commenting on these facts, Sheffer *et al.* stated that “using a longer time scale than human collective memory, paleoflood studies can put in perspective the occurrences of the extreme floods that hit Europe and other parts of the world during the summer of 2002.”

Lindstrom and Bergstrom (2004) analyzed runoff and flood data from more than 60 discharge stations scattered throughout Sweden, some of which provide information stretching to the early- to mid-1800s, when Sweden and the world were still experiencing the cold of the Little Ice Age. This analysis led them to discover that the last 20 years of the past century were indeed unusually wet, with a runoff anomaly of +8 percent compared with the century average. But they also found that “the runoff in the 1920s was comparable to that of the two latest decades,” and that “the few observation series available from the 1800s show that the runoff was even higher than recently.” What is more, they note that “flood peaks in old data are probably underestimated,” which “makes it difficult to conclude that there has really been a significant increase in average flood levels.” In addition, they say “no increased frequency of floods

with a return period of 10 years or more, could be determined.”

With respect to the generality of their findings, Lindstrom and Bergstrom say that conditions in Sweden “are consistent with results reported from nearby countries: e.g. Forland *et al.* (2000), Bering Ovesen *et al.* (2000), Klavins *et al.* (2002) and Hyvarinen (2003),” and that, “in general, it has been difficult to show any convincing evidence of an increasing magnitude of floods (e.g. Roald, 1999) in the near region, as is the case in other parts of the world (e.g. Robson *et al.*, 1998; Lins and Slack, 1999; Douglas *et al.*, 2000; McCabe and Wolock, 2002; Zhang *et al.*, 2001).”

It is clear that for most of Europe, there are no compelling real-world data to support the claim that the global warming of the past two centuries led to more frequent or severe flooding. Additional information on this topic, including reviews of newer publications as they become available, can be found at <http://www.co2science.org/subject/f/floodseuro.php>.

### 6.2.3. North America

Lins and Slack (1999) analyzed secular streamflow trends in 395 different parts of the United States that were derived from more than 1,500 individual streamgauges, some of which had continuous data stretching to 1914. In the mean, they found that “the conterminous U.S. is getting wetter, but less extreme.” That is to say, as the near-surface air temperature of the planet gradually rose throughout the course of the twentieth century, the United States became wetter in the mean but less variable at the extremes, which is where floods and droughts occur, leading to what could well be called the best of both worlds, i.e., more water with fewer floods and droughts.

In a similar but more regionally focused study, Molnar and Ramirez (2001) conducted a detailed analysis of precipitation and streamflow trends for the period 1948-1997 in the semiarid Rio Puerco Basin of New Mexico. At the annual timescale, they reported finding “a statistically significant increasing trend in precipitation,” which was driven primarily by an increase in the number of rainy days in the moderate rainfall intensity range, with essentially no change at the high-intensity end of the spectrum. In the case of streamflow, there was no trend at the annual timescale, but monthly totals increased in low-flow months and decreased in high-flow months, once again reducing the likelihood of both floods and droughts.

Knox (2001) identified an analogous phenomenon in the more mesic Upper Mississippi River Valley, but with a slight twist. Since the 1940s and early 1950s, the magnitudes of the largest daily flows in this much wetter region have been decreasing at the same time that the magnitude of the average daily baseflow has been increasing, once again manifesting simultaneous trends towards lessened flood and drought conditions.

Much the same story is told by the research of Garbrecht and Rossel (2002), who studied the nature of precipitation throughout the U.S. Great Plains over the period 1895-1999. For the central and southern Great Plains, the last two decades of this period were found to be the longest and wettest of the entire 105 years of record, due primarily to a reduction in the number of dry years and an increase in the number of wet years. Once again, however, the number of very wet years—which would be expected to produce flooding—“did not increase as much and even showed a decrease for many regions.”

The northern and northwestern Great Plains also experienced a precipitation increase near the end of Garbrecht and Rossel’s 105-year record, but it was primarily confined to the final decade of the twentieth century. And again, as they report, “fewer dry years over the last 10 years, as opposed to an increase in very wet years, were the leading cause of the observed wet conditions.”

In spite of the general tendencies described in these several papers, there still were some significant floods during the last decade of the past century, such as the 1997 flooding of the Red River of the North, which devastated Grand Forks, North Dakota, as well as parts of Canada. However, as Haque (2000) reports, although this particular flood was indeed the largest experienced by the Red River over the past

century, it was not the largest to occur in historic times. In 1852 there was a slightly larger Red River flood, and in 1826 there was a flood that was nearly 40 percent greater than the flood of 1997. The temperature of the globe was colder at the times of these earlier catastrophic floods than it was in 1997, indicating that one cannot attribute the strength of the 1997 flood to higher temperatures that year or the warming of the preceding decades. We also note that Red River flooding is also linked to snow melt and ice jams because it flows northward into frozen areas.

Olsen *et al.* (1999) report that some upward trends in flood-flows have been found in certain places along the Mississippi and Missouri Rivers, which is not at all surprising, as there will always be exceptions to the general rule. They note that many of the observed upward trends were highly dependent upon the length of the data record and when the trends began and ended. They say of these trends that they “were not necessarily there in the past and they may not be there tomorrow.”

Expanding the scope of our survey to much longer intervals of time is Fye *et al.* (2003), who developed multi-century reconstructions of summer (June-August) Palmer Drought Severity Index over the continental United States from annual proxies of moisture status provided by 426 climatically sensitive tree-ring chronologies. This exercise indicated that the greatest twentieth century wetness anomaly across the United States was a 13-year period in the early part of the century when it was colder than it is now. Fye *et al.*'s analysis also revealed the existence of a 16-year pluvial from 1825 to 1840 and a prolonged 21-year wet period from 1602 to 1622, both of which anomalies occurred during the Little Ice Age, when, of course, it was colder still.

St. George and Nielsen (2002) used “a ringwidth chronology developed from living, historical and subfossil bur oak (*Quercus macrocarpa* (Michx.)) in the Red River basin to reconstruct annual precipitation in southern Manitoba since A.D. 1409.” Their analysis indicated, in their words, that “prior to the 20th century, southern Manitoba's climate was more extreme and variable, with prolonged intervals that were wetter and drier than any time following permanent Euro-Canadian settlement.”

Also working with tree-ring chronologies, Ni *et al.* (2002) developed a 1,000-year history of cool-season (November-April) precipitation for each climate division in Arizona and New Mexico, USA. In doing so, they found that several wet periods comparable to the wet conditions seen in the early

1900s and post-1976 occurred in 1108-20, 1195-1204, 1330-45 (which they denominate “the most persistent and extreme wet interval”), the 1610s, and the early 1800s, all of which wet periods are embedded in the long cold expanse of the Little Ice Age, which is clearly revealed in the work of Esper *et al.* (2002).

Doubling the temporal extent of Ni *et al.*'s investigation, Schimmelmann *et al.* (2003) analyzed gray clay-rich flood deposits in the predominantly olive varved sediments of the Santa Barbara Basin off the coast of California, USA, which they accurately dated by varve-counting. Their analysis indicated that six prominent flood events occurred at approximately AD 212, 440, 603, 1029, 1418, and 1605, “suggesting,” in their words, “a quasi-periodicity of ~200 years,” with “skipped” flooding just after AD 800, 1200, and 1800. They further note that “the floods of ~AD 1029 and 1605 seem to have been associated with brief cold spells,” that “the flood of ~AD 440 dates to the onset of the most unstable marine climatic interval of the Holocene (Kennett and Kennett, 2000),” and that “the flood of ~AD 1418 occurred at a time when the global atmospheric circulation pattern underwent fundamental reorganization at the beginning of the ‘Little Ice Age’ (Kreutz *et al.*, 1997; Meeker and Mayewski, 2002).” As a result, they hypothesize that “solar-modulated climatic background conditions are opening a ~40-year window of opportunity for flooding every ~200 years,” and that “during each window, the danger of flooding is exacerbated by additional climatic and environmental cofactors.” They also note that “extrapolation of the ~200-year spacing of floods into the future raises the uncomfortable possibility for historically unprecedented flooding in southern California during the first half of this century.” Consequently, if such flooding does occur in the near future, there will be no need to suppose it came as a consequence of what the IPCC calls the unprecedented warming of the past century.

Once again doubling the length of time investigated, Campbell (2002) analyzed the grain sizes of sediment cores obtained from Pine Lake, Alberta, Canada, to provide a non-vegetation-based high-resolution record of streamflow variability for this part of North America over the past 4,000 years. This work revealed that the highest rates of stream discharge during this period occurred during the Little Ice Age, approximately 300-350 years ago, at which time grain sizes were about 2.5 standard deviations above the 4,000-year mean. In contrast, the lowest

rates of streamflow were observed around AD 1100, during the Medieval Warm Period, when median grain sizes were nearly 2.0 standard deviations below the 4,000-year mean.

Further extending the temporal scope of our review, Brown *et al.* (1999) analyzed various properties of cored sequences of hemipelagic muds deposited in the northern Gulf of Mexico for evidence of variations in Mississippi River outflow over the past 5,300 years. This group of researchers found evidence of seven large megafloods, which they describe as “almost certainly larger than historical floods in the Mississippi watershed.” In fact, they say these fluvial events were likely “episodes of multidecadal duration,” five of which occurred during cold periods similar to the Little Ice Age.

Last, in a study that covered essentially the entire Holocene, Noren *et al.* (2002) employed several techniques to identify and date terrigenous in-wash layers found in sediment cores extracted from 13 small lakes distributed across a 20,000-km<sup>2</sup> region in Vermont and eastern New York that depict the frequency of storm-related floods. They found that “the frequency of storm-related floods in the northeastern United States has varied in regular cycles during the past 13,000 years (13 kyr), with a characteristic period of about 3 kyr.” Specifically, they found there were four major peaks in the data during this period, with the most recent upswing in storm-related floods beginning “at about 600 yr BP [Before Present], coincident with the beginning of the Little Ice Age.” In addition, they note that several “independent records of storminess and flooding from around the North Atlantic show maxima that correspond to those that characterize our lake records [Brown *et al.*, 1999; Knox, 1999; Lamb, 1979; Liu and Fearn, 2000; Zong and Tooley, 1999].”

Taken together, the research described in this section suggests that North American flooding tends to become both less frequent and less severe when the planet warms, although there have been some exceptions to this general rule. We would expect that any further warming of the globe would tend to further reduce both the frequency and severity of flooding in North America.

### 6.3. Tropical Cyclones

The IPCC contends that global warming is likely to increase the frequency and intensity of hurricanes. For example, it states “it is *likely* that future tropical cyclones (typhoons and hurricanes) will become more intense, with larger peak wind speeds and more heavy precipitation associated with ongoing increases of tropical sea surface temperatures [*italics in the original*]” (IPCC, 2007-I, p. 15). However, numerous peer-reviewed studies suggest otherwise. In the following sections we examine such claims as they pertain to hurricane activity in the Atlantic, Pacific, and Indian Ocean basins, and the globe as a whole.

#### 6.3.1. Atlantic Ocean

##### 6.3.1.1. Intensity

Free *et al.* (2004) write that “increases in hurricane intensity are expected to result from increases in sea surface temperature and decreases in tropopause-level temperature accompanying greenhouse warming (Emanuel, 1987; Henderson-Sellers *et al.*, 1998; Knutson *et al.*, 1998),” but that “because the predicted increase in intensity for doubled CO<sub>2</sub> is only 5%-20%, changes over the past 50 years would likely be less than 2%—too small to be detected easily.” They report that “studies of observed frequencies and maximum intensities of tropical cyclones show no consistent upward trend (Landsea *et al.*, 1996; Henderson-Sellers *et al.*, 1998; Solow and Moore, 2002),” and set out to find increases in what they call “potential” hurricane intensity, because, as they describe it, “changes in potential intensity (PI) can be estimated from thermodynamic principles as shown in Emanuel (1986, 1995) given a record of SSTs [sea surface temperatures] and profiles of atmospheric temperature and humidity.” Using radiosonde and SST data from 14 island radiosonde stations in the tropical Atlantic and Pacific Oceans, they compare their results with those of Bister and Emanuel (2002) at grid points near the selected stations. They report that their results “show no significant trend in potential intensity from 1980 to 1995 and no consistent trend from 1975 to 1995.” What is more, they report that between 1975 and 1980, “while SSTs rose, PI decreased, illustrating the hazards of predicting changes in hurricane intensity from projected SST changes alone.”

In the following year, some important new studies once again promoted the IPCC’s claim that warming would enhance tropical cyclone intensity (Emanuel, 2005; Webster *et al.*, 2005), but a new review of the subject once again cast doubt on this contention. Pielke *et al.* (2005) began their discussion by noting

that “globally there has been no increase in tropical cyclone frequency over at least the past several decades,” citing the studies of Lander and Guard (1998), Elsner and Kocher (2000) and Webster *et al.* (2005). They noted that research on possible future changes in hurricane frequency due to global warming has produced studies that “give such contradictory results as to suggest that the state of understanding of tropical cyclogenesis provides too poor a foundation to base any projections about the future.”

With respect to hurricane intensity, Pielke *et al.* noted that Emanuel (2005) claimed to have found “a very substantial upward trend in power dissipation (i.e., the sum over the life-time of the storm of the maximum wind speed cubed) in the North Atlantic and western North Pacific.” However, they report that “other studies that have addressed tropical cyclone intensity variations (Landsea *et al.*, 1999; Chan and Liu, 2004) show no significant secular trends during the decades of reliable records.” In addition, they indicate that although early theoretical work by Emanuel (1987) “suggested an increase of about 10% in wind speed for a 2°C increase in tropical sea surface temperature,” more recent work by Knutson and Tuleya (2004) points to only a 5 percent increase in hurricane windspeeds by 2080, and that Michaels *et al.* (2005) conclude that even this projection is likely twice as great as it should be.

By 2050, Pielke *et al.* report that “for every additional dollar in damage that the Intergovernmental Panel on Climate Change expects to result from the effects of global warming on tropical cyclones, we should expect between \$22 and \$60 of increase in damage due to population growth and wealth,” citing the findings of Pielke *et al.* (2000) in this regard. Based on this evidence, they state without equivocation that “the primary factors that govern the magnitude and patterns of future damages and casualties are how society develops and prepares for storms rather than any presently conceivable future changes in the frequency and intensity of the storms.”

In concluding their review, Pielke *et al.* note that massive reductions of anthropogenic CO<sub>2</sub> emissions “simply will not be effective with respect to addressing future hurricane impacts,” and that “there are much, much better ways to deal with the threat of hurricanes than with energy policies (e.g., Pielke and Pielke, 1997).”

Michaels *et al.* (2006) subsequently analyzed Emanuel’s (2005) and Webster *et al.*’s (2005) claims

that “rising sea surface temperatures (SSTs) in the North Atlantic hurricane formation region are linked to recent increases in hurricane intensity, and that the trend of rising SSTs during the past 3 to 4 decades bears a strong resemblance to that projected to occur from increasing greenhouse gas concentrations.” The researchers used weekly averaged 1° latitude by 1° longitude SST data together with hurricane track data of the National Hurricane Center that provide hurricane-center locations (latitude and longitude in tenths of a degree) and maximum 1-minute surface wind speeds (both at six-hour intervals) for all tropical storms and hurricanes in the Atlantic basin that occurred between 1982 (when the SST dataset begins) through 2005. Plotting maximum cyclone wind speed against the maximum SST that occurred prior to (or concurrent with) the maximum wind speed of each of the 270 Atlantic tropical cyclones of their study period, they found that for each 1°C increase in SST between 21.5°C and 28.25°C, the maximum wind speed attained by Atlantic basin cyclones rises, in the mean, by 2.8 m/s, and that thereafter, as SSTs rise still further, the first category-3-or-greater storms begin to appear. However, they report “there is no significant relationship between SST and maximum winds at SST exceeding 28.25°C.”

From these observations, Michaels *et al.* conclude that “while crossing the 28.25°C threshold is a virtual necessity for attaining category 3 or higher winds, SST greater than 28.25°C does not act to further increase the intensity of tropical cyclones.” The comparison of SSTs actually encountered by individual storms performed by Michaels *et al.*—as opposed to the comparisons of Emanuel (2005) and Webster *et al.* (2005), which utilized basin-wide averaged monthly or seasonal SSTs—refutes the idea that anthropogenic activity has detectably influenced the severity of Atlantic basin hurricanes over the past quarter-century.

Simultaneously, Balling and Cerveny (2006) examined temporal patterns in the frequency of intense tropical cyclones (TCs), the rates of rapid intensification of TCs, and the average rate of intensification of hurricanes in the North Atlantic Basin, including the tropical and subtropical North Atlantic, Caribbean Sea, and Gulf of Mexico, where they say there was “a highly statistically significant warming of 0.12°C decade<sup>-1</sup> over the period 1970-2003 ... based on linear regression analysis and confirmed by a variety of other popular trend identification techniques.” In doing so, they found

“no increase in a variety of TC intensification indices,” and that “TC intensification and/or hurricane intensification rates ... are not explained by current month or antecedent sea surface temperatures (despite observed surface warming over the study period).” They concluded that “while some researchers have hypothesized that increases in long-term sea surface temperature may lead to marked increases in TC storm intensity, our findings demonstrate that various indicators of TC intensification show no significant trend over the recent three decades.”

Klotzbach and Gray (2006) note that still other papers question the validity of the findings of Emanuel (2005) and Webster *et al.* (2005) “due to potential bias-correction errors in the earlier part of the data record for the Atlantic basin (Landsea, 2005),” and that “while major hurricane activity in the Atlantic has shown a large increase since 1995, global tropical-cyclone activity, as measured by the accumulated cyclone energy index, has decreased slightly during the past 16 years (Klotzbach, 2006).” And as a result of these and other data and reasoning described in their paper, they “attribute the heightened Atlantic major hurricane activity of the 2004 season as well as the increased Atlantic major hurricane activity of the previous nine years to be a consequence of multidecadal fluctuations in the strength of the Atlantic multidecadal mode and strength of the Atlantic Ocean thermohaline circulation.” In this regard, they say “historical records indicate that positive and negative phases of the Atlantic multidecadal mode and thermohaline circulation last about 25-30 years (typical period ~50-60 years; Gray *et al.*, 1997; Latif *et al.*, 2004),” and “since we have been in this new active thermohaline circulation period for about 11 years, we can likely expect that most of the next 15-20 hurricane seasons will also be active, particularly with regard to increased major hurricane activity.”

Vecchi and Soden (2007a) explored twenty first century projected changes in vertical wind shear (VS) over the tropical Atlantic and its ties to the Pacific Walker circulation via a suite of coupled ocean-atmosphere models forced by emissions scenario A1B (atmospheric CO<sub>2</sub> stabilization at 720 ppm by 2100) of the Intergovernmental Panel on Climate Change’s Fourth Assessment Report, where VS is defined as the magnitude of the vector difference between monthly mean winds at 850 and 200 hPa, and where changes are computed between the two 20-year periods 2001-2020 and 2081-2100. The 18-model mean result indicated a prominent increase in VS over

the tropical Atlantic and East Pacific (10°N-25°N). Noting that “the relative amplitude of the shear increase in these models is comparable to or larger than model-projected changes in other large-scale parameters related to tropical cyclone activity,” the two researchers went on to state that the projected changes “would not suggest a strong anthropogenic increase in tropical Atlantic or Pacific hurricane activity during the 21<sup>st</sup> Century,” and that “in addition to impacting cyclogenesis, the increase in SER [shear enhancement region] shear could act to inhibit the intensification of tropical cyclones as they traverse from the MDR [main development region] to the Caribbean and North America.” Consequently, and in addition to the growing body of empirical evidence that indicates global warming has little to no impact on the intensity of hurricanes (Donnelly and Woodruff, 2007; Nyberg *et al.*, 2007), there is now considerable up-to-date model-based evidence for the same conclusion.

In a closely related paper, Vecchi and Soden (2007b) used both climate models and observational reconstructions “to explore the relationship between changes in sea surface temperature and tropical cyclone ‘potential intensity’—a measure that provides an upper bound on cyclone intensity and can also reflect the likelihood of cyclone development.” They found “changes in local sea surface temperature are inadequate for characterizing *even the sign* [our italics] of changes in potential intensity.” Instead, they report that “long-term changes in potential intensity are closely related to the regional structure of warming,” such that “regions that warm more than the tropical average are characterized by increased potential intensity, and vice versa.” Using this relationship to reconstruct changes in potential intensity over the twentieth century, based on observational reconstructions of sea surface temperature, they further found that “even though tropical Atlantic sea surface temperatures are currently at a historical high, Atlantic potential intensity probably peaked in the 1930s and 1950s,” noting that “recent values are near the historical average.” The two scientists’ conclusion was that the response of tropical cyclone activity to natural climate variations “may be larger than the response to the more uniform patterns of greenhouse-gas-induced warming.”

Also in the year 2007, and at the same time Vecchi and Soden were conducting their studies of the subject, Latif *et al.* (2007) were analyzing the 1851-2005 history of Accumulated Cyclone Energy

(ACE) Index for the Atlantic basin, which parameter, in their words, “takes into account the number, strength and duration of all tropical storms in a season,” after which they “analyzed the results of an atmospheric general circulation model forced by the history of observed global monthly sea surface temperatures for the period 1870-2003.”

With respect to the first part of their study, they report that “the ACE Index shows pronounced multidecadal variability, with enhanced tropical storm activity during the 1890s, 1950s and at present, and mostly reduced activity in between, but no sustained long-term trend,” while with respect to the second part of their study, they report that “a clear warming trend is seen in the tropical North Atlantic sea surface temperature,” but that this warming trend “does not seem to influence the tropical storm activity.”

This state of affairs seemed puzzling at first, because a warming of the tropical North Atlantic is known to reduce vertical wind shear there and thus promote the development of tropical storms. However, Latif *et al.*'s modeling work revealed that a warming of the tropical Pacific enhances the vertical wind shear over the Atlantic, as does a warming of the tropical Indian Ocean. Consequently, they learned, as they describe it, that “the response of the vertical wind shear over the tropical Atlantic to a warming of all three tropical oceans, as observed during the last decades, will depend on the warming of the Indo-Pacific relative to that of the tropical North Atlantic,” and “apparently,” as they continue, “the warming trends of the three tropical oceans cancel with respect to their effects on the vertical wind shear over the tropical North Atlantic, so that the tropical cyclone activity [has] remained rather stable and mostly within the range of the natural multidecadal variability.”

Nevertheless, a striking exception to this general state of affairs occurred in 2005, when the researchers report that “the tropical North Atlantic warmed more rapidly than the Indo-Pacific,” which reduced vertical wind shear over the North Atlantic, producing the most intense Atlantic hurricane season of the historical record. By contrast, they say that the summer and fall of 2006 were “characterized by El Niño conditions in the Indo-Pacific, leading to a rather small temperature difference between the tropical North Atlantic and the tropical Indian and Pacific Oceans,” and they say that “this explains the weak tropical storm activity [of that year].”

Latif *et al.* say “the future evolution of Atlantic tropical storm activity will critically depend on the

warming of the tropical North Atlantic relative to that in the Indo-Pacific region,” and “changes in the meridional overturning circulation and their effect on tropical Atlantic sea surface temperatures have to be considered,” and that “changes in ENSO statistics in the tropical Pacific may become important.” Consequently, it is anyone's guess as to what would actually occur in the real world if the earth were to experience additional substantial warming. However, since the global temperature rise of the twentieth century—which the IPCC contends was unprecedented over the past two millennia—did not lead to a sustained long-term increase in hurricane intensity, there is little reason to believe any further warming would do so.

In one final concurrent study, Scileppi and Donnelly (2007) note that “when a hurricane makes landfall, waves and storm surge can overtop coastal barriers, depositing sandy overwash fans on backbarrier salt marshes and tidal flats,” and that long-term records of hurricane activity are thus formed “as organic-rich sediments accumulate over storm-induced deposits, preserving coarse overwash layers.” Based on this knowledge, they refined and lengthened the hurricane record of the New York City area by first calibrating the sedimentary record of surrounding backbarrier environments to documented hurricanes—including those of 1893, 1821, 1788, and 1693—and then extracting several thousand additional years of hurricane history from this important sedimentary archive.

As a result of these efforts, the two researchers determined that “alternating periods of quiescent conditions and frequent hurricane landfall are recorded in the sedimentary record and likely indicate that climate conditions may have modulated hurricane activity on millennial timescales.” Of special interest in this regard, as they describe it, is the fact that “several major hurricanes occur in the western Long Island record during the latter part of the Little Ice Age (~1550-1850 AD) when sea surface temperatures were generally colder than present,” but that “no major hurricanes have impacted this area since 1893,” when the earth experienced the warming that took it from the Little Ice Age to the Current Warm Period.

Noting that Emanuel (2005) and Webster *et al.* (2005) had produced analyses that suggest that “cooler climate conditions in the past may have resulted in fewer strong hurricanes,” but that their own findings suggest just the opposite, Scileppe and Donnelly concluded that “other climate phenomena, such as atmospheric circulation, may have been

favorable for intense hurricane development despite lower sea surface temperatures” prior to the development of the Current Warm Period.

Last, Briggs (2008) developed Bayesian statistical models for the number of tropical cyclones, the rate at which these cyclones became hurricanes, and the rate at which the hurricanes became category 4+ storms in the North Atlantic, based on data from 1966 to 2006; this work led him to conclude that there is “no evidence that the distributional mean of individual storm intensity, measured by storm days, track length, or individual storm power dissipation index, has changed (increased or decreased) through time.”

In light of the many real-world observations (as well as certain modeling work) discussed above, it would appear that even the supposedly unprecedented global warming of the past century or more has not led to an increase in the intensity of Atlantic hurricanes.

### 6.3.1.2. Frequency

#### 6.3.1.2.1. The Past Few Millennia

Has the warming of the past century increased the yearly number of intense Atlantic Basin hurricanes? We offer a brief review of some studies that have explored this question via thousand-year reconstructions of the region's intense hurricane activity.

Liu and Fearn (1993) analyzed sediment cores retrieved from the center of Lake Shelby in Alabama (USA) to determine the history of intense (category 4 and 5) hurricane activity there over the past 3,500 years. This work revealed that over the period of their study, "major hurricanes of category 4 or 5 intensity directly struck the Alabama coast ... with an average recurrence interval of ~600 years." They also report that the last of these hurricane strikes occurred about 700 years ago. Hence, it would appear that twentieth century global warming has not accelerated the occurrence of such severe storm activity.

Seven years later, Liu and Fearn (2000) conducted a similar study based on 16 sediment cores retrieved from Western Lake, Florida (USA), which they used to produce a proxy record of intense hurricane strikes for this region of the Gulf of Mexico that covered the past 7,000 years. In this study, 12 major hurricanes of category 4 or 5 intensity were found to have struck the Western Lake region. Nearly all of these events were centered on a 2,400-year period between 1,000 and 3,400 years ago, when 11 of the 12 events were recorded. In contrast, between 0 to 1,000 and 3,400 to 7,000 years ago, only one and zero major hurricane strikes were recorded, respectively. According to the two researchers, a probable explanation for the "remarkable increase in hurricane frequency and intensity" that affected the Florida Panhandle and the Gulf Coast after 1400 BC would have been a continental-scale shift in circulation patterns that caused the jet stream to shift south and the Bermuda High southwest of their earlier Holocene positions, such as would be expected with

global cooling, giving strength to their contention that “paleohurricane records from the past century or even the past millennium are not long enough to capture the full range of variability of catastrophic hurricane activities inherent in the Holocene climatic regime.”

Last, we have the study of Donnelly and Woodruff (2007), who state that “it has been proposed that an increase in sea surface temperatures caused by anthropogenic climate change has led to an increase in the frequency of intense tropical cyclones,” citing the studies of Emanuel (2005) and Webster *et al.* (2005). Donnelly and Woodruff developed “a record of intense [category 4 and greater] hurricane activity in the western North Atlantic Ocean over the past 5,000 years based on sediment cores from a Caribbean lagoon [Laguna Playa Grande on the island of Vieques, Puerto Rico] that contains coarse-grained deposits associated with intense hurricane landfalls.”

Based on this work, the two researchers from the Woods Hole Oceanographic Institution detected three major intervals of intense hurricane strikes: one between 5,400 and 3,600 calendar years before present (yr BP, where “present” is AD 1950), one between 2,500 and 1,000 yr BP, and one after 250 yr BP. They also report that coral-based sea surface temperature (SST) data from Puerto Rico “indicate that mean annual Little Ice Age (250-135 yr BP or AD 1700-1815) SSTs were 2-3°C cooler than they are now,” and they say that “an analysis of Caribbean hurricanes documented in Spanish archives indicates that 1766-1780 was one of the most active intervals in the period between 1500 and 1800 (Garcia-Herrera *et al.*, 2005), when tree-ring-based reconstructions indicate a negative (cooler) phase of the Atlantic Multidecadal Oscillation (Gray *et al.*, 2004).”

In light of these findings, Donnelly and Woodruff concluded that “the information available suggests that tropical Atlantic SSTs were probably not the principal driver of intense hurricane activity over the past several millennia.” Indeed, there is no compelling reason to believe that the current level of intense hurricane activity is in any way unprecedented or that it has been caused by global warming. Quite to the contrary, the two researchers write that “studies relying on recent climatology indicate that North Atlantic hurricane activity is greater during [cooler] La Niña years and suppressed during [warmer] El Niño years (Gray, 1984; Bove *et al.*, 1998), due primarily to increased vertical wind shear in strong El Niño years hindering hurricane development.”

In summary, millennial-scale reconstructions of intense hurricane activity within the Atlantic Basin provide no support for the claim that global warming will lead to the creation of more intense Atlantic hurricanes that will batter the east, southeast, and southern coasts of the United States. In fact, they suggest just the opposite.

### 6.3.1.2.2. *The Past Few Centuries*

Has the warming of the past century, which rescued the world from the extreme cold of the Little Ice Age, led to the formation of more numerous Atlantic Basin tropical storms and hurricanes? We review several studies that have broached this question with sufficiently long databases to provide reliable answers.

Elsner *et al.* (2000) provided a statistical and physical basis for understanding regional variations in major hurricane activity along the U.S. coastline on long timescales; in doing so, they presented data on major hurricane occurrences in 50-year intervals for Bermuda, Jamaica, and Puerto Rico. These data revealed that hurricanes occurred at lower frequencies in the last half of the twentieth century than they did in the preceding five 50-year periods, at all three of the locations studied. From 1701 to 1850, for example, when the earth was locked in the icy grip of the Little Ice Age, major hurricane frequency was 2.77 times greater at Bermuda, Jamaica, and Puerto Rico than it was from 1951 to 1998; from 1851 to 1950, when the planet was in transition from Little Ice Age to current conditions, the three locations experienced a mean hurricane frequency that was 2.15 times greater than what they experienced from 1951 to 1998.

Boose *et al.* (2001) used historical records to reconstruct hurricane damage regimes for an area composed of the six New England states plus adjoining New York City and Long Island for the period 1620-1997. In describing their findings, they wrote that “there was no clear century-scale trend in the number of major hurricanes.” At lower damage levels, however, fewer hurricanes were recorded in the seventeenth and eighteenth centuries than in the nineteenth and twentieth centuries; but the three researchers concluded that “this difference is probably the result of improvements in meteorological observations and records since the early 19<sup>th</sup> century.” Confining ourselves to the better records of the past 200 years, we note that the cooler nineteenth century had five of the highest-damage storms, while the warmer twentieth century had only one such storm.

Nyberg *et al.* (2007) developed a history of major (category 3-5) Atlantic hurricanes over the past 270 years based on proxy records of vertical wind shear and sea surface temperature that they derived from corals and a marine sediment core. These parameters are the primary controlling forces that set the stage for

the formation of major hurricanes in the main development region westward of Africa across the tropical Atlantic and Caribbean Sea between latitudes 10 and 20°N, where 85 percent of all major hurricanes and 60 percent of all non-major hurricanes and tropical storms of the Atlantic are formed. This effort resulted in their discovering that the average frequency of major Atlantic hurricanes “decreased gradually from the 1760s until the early 1990s, reaching anomalously low values during the 1970s and 1980s.” More specifically, they note that “a gradual downward trend is evident from an average of ~4.1 (1775-1785) to ~1.5 major hurricanes [per year] during the late 1960s to early 1990s,” and that “the current active phase (1995-2005) is unexceptional compared to the other high-activity periods of ~1756-1774, 1780-1785, 1801-1812, 1840-1850, 1873-1890 and 1928-1933.” They conclude that the recent ratcheting up of Atlantic major hurricane activity appears to be simply “a recovery to normal hurricane activity.” In a commentary on Nyberg *et al.*'s paper, Elsner (2007) states that “the assumption that hurricanes are simply passive responders to climate change should be challenged.”

Also noting that “global warming is postulated by some researchers to increase hurricane intensity in the north basin of the Atlantic Ocean,” with the implication that “a warming ocean may increase the frequency, intensity, or timing of storms of tropical origin that reach New York State,” Vermette (2007) employed the Historical Hurricane Tracks tool of the National Oceanic and Atmospheric Administration's Coastal Service Center to document all Atlantic Basin tropical cyclones that reached New York State between 1851 and 2005, in order to assess the degree of likelihood that twentieth century global warming might be influencing these storms, particularly for hurricanes but also for tropical storms, tropical depressions and extratropical storms.

This work revealed, in Vermette's words, that “a total of 76 storms of tropical origin passed over New York State between 1851 and 2005,” and that of these storms, 14 were hurricanes, 27 were tropical storms, seven were tropical depressions and 28 were extratropical storms. For Long Island, he further reports that “the average frequency of hurricanes and storms of tropical origin (all types) is one in every 11 years and one in every 2 years, respectively.” Also of note is his finding that storm activity was greatest in both the late nineteenth century and the late twentieth century, and the fact that “the frequency and intensity of storms in the late 20<sup>th</sup> century are similar to those

of the late 19<sup>th</sup> century.” As a result, Vermette concludes that “rather than a linear change, that may be associated with a global warming, the changes in recent time are following a multidecadal cycle and returning to conditions of the latter half of the 19<sup>th</sup> century.” He also concludes that “yet unanswered is whether a warmer global climate of the future will take hurricane activity beyond what has been experienced in the observed record.”

In a similar study, Mock (2008) developed a “unique documentary reconstruction of tropical cyclones for Louisiana, U.S.A. that extends continuously back to 1799 for tropical cyclones, and to 1779 for hurricanes.” This record—which was derived from daily newspaper accounts, private diaries, plantation diaries, journals, letters, and ship records, and which was augmented “with the North Atlantic hurricane database as it pertains to all Louisiana tropical cyclones up through 2007”—is, in Mock’s words, “the longest continuous tropical cyclone reconstruction conducted to date for the United States Gulf Coast.” And this record reveals that “the 1820s/early 1830s and the early 1860s are the most active periods for the entire record.”

In discussing his findings, the University of South Carolina researcher says that “the modern records which cover just a little over a hundred years is too short to provide a full spectrum of tropical cyclone variability, both in terms of frequency and magnitude.” In addition, he states that “if a higher frequency of major hurricanes occurred in the near future in a similar manner as the early 1800s or in single years such as in 1812, 1831, and 1860, [they] would have devastating consequences for New Orleans, perhaps equaling or exceeding the impacts such as in hurricane Katrina in 2005.” We also observe that the new record clearly indicates that the planet’s current high levels of air temperature and CO<sub>2</sub> concentration cannot be blamed for the 2005 Katrina catastrophe, as both parameters were much lower when tropical cyclone and hurricane activity in that region were much higher in the early- to mid-1800s.

Around the same time, Wang and Lee (2008) used the “improved extended reconstructed” sea surface temperature (SST) data described by Smith and Reynolds (2004) for the period 1854-2006 to examine historical temperature changes over the global ocean, after which they regressed vertical wind shear—“calculated as the magnitude of the vector difference between winds at 200 mb and 850 mb during the Atlantic hurricane season (June to

November), using NCEP-NCAR reanalysis data”—onto a temporal variation of global warming defined by the SST data. This work led to their discovery that warming of the surface of the global ocean is typically associated with a secular increase of tropospheric vertical wind shear in the main development region (MDR) for Atlantic hurricanes, and that the long-term increased wind shear of that region has coincided with a weak but robust downward trend in U.S. landfalling hurricanes. However, this relationship has a pattern to it, whereby local ocean warming in the Atlantic MDR actually reduces the vertical wind shear there, while “warmings in the tropical Pacific and Indian Oceans produce an opposite effect, i.e., they increase the vertical wind shear in the MDR for Atlantic hurricanes.”

In light of these findings, the two researchers conclude that “the tropical oceans compete with one another for their impacts on the vertical wind shear over the MDR for Atlantic hurricanes,” and they say that to this point in time, “warmings in the tropical Pacific and Indian Oceans win the competition and produce increased wind shear which reduces U.S. landfalling hurricanes.” As for the years and decades ahead, they write that “whether future global warming increases the vertical wind shear in the MDR for Atlantic hurricanes will depend on the relative role induced by secular warmings over the tropical oceans.”

Vecchi and Knutson (2008) write in the introduction to their study of the subject that “there is currently disagreement within the hurricane/climate community on whether anthropogenic forcing (greenhouse gases, aerosols, ozone depletion, etc.) has caused an increase in Atlantic tropical storm or hurricane frequency.” In further exploring this question, they derived an estimate of the expected number of North Atlantic tropical cyclones (TCs) that were missed by the observing system in the pre-satellite era (1878-1965), after which they analyzed trends of both reconstructed TC numbers and duration over various time periods and looked at how they may or may not have been related to trends in sea surface temperature over the main development region of North Atlantic TCs. This work revealed, in their words, that “the estimated trend for 1900-2006 is highly significant (+~4.2 storms century<sup>-1</sup>),” but they say that the trend “is strongly influenced by a minimum in 1910-30, perhaps artificially enhancing significance.” When using their base case adjustment for missed TCs and considering the entire 1878-2006

record, they find that the trend in the number of TCs is only “weakly positive” and “not statistically significant,” while they note that the trend in average TC duration over the 1878-2006 period “is negative and highly significant.”

Elsner (2008), in his summary of the *International Summit on Hurricanes and Climate Change* held in May 2007 on the Greek island of Crete, said the presence of more hurricanes in the northeastern Caribbean Sea “during the second half of the Little Ice Age when sea temperatures near Puerto Rico were a few degrees (Celsius) cooler than today” provides evidence that “today’s warmth is not needed for increased storminess.”

In conclusion, the bulk of the evidence that has been accumulated to date over multi-century timescales indicates that late twentieth century yearly hurricane numbers were considerably lower than those observed in colder prior centuries. It is by no means clear that further global warming, due to any cause, would lead to an increase or decrease in U.S. landfalling hurricanes. All we can say is that up to this point in time, global warming appears to have had a weak negative impact on their numbers.

### 6.3.1.2.3. The Past Century

Have tropical storms and hurricanes of the Atlantic Ocean become more numerous over the past century, in response to what the IPCC describes as unprecedented global warming? This became a matter of intense speculation following a spike of storm occurrences in 2004-2005, but once again it is instructive to approach the question by starting with the findings of earlier research.

Bove *et al.* (1998) examined the characteristics of all recorded landfalling U.S. Gulf Coast hurricanes—defined as those whose eyes made landfall between Cape Sable, Florida and Brownsville, Texas—from 1896 to 1995. They found that the first half of this period saw considerably more hurricanes than the last half: 11.8 per decade vs. 9.4 per decade. The same was true for intense hurricanes of category 3 or more on the Saffir-Simpson storm scale: 4.8 vs. 3.6. The numbers of all hurricanes and the numbers of intense hurricanes both tended downward from 1966 to the end of the period investigated, with the decade 1986-1995 exhibiting the fewest intense hurricanes of the entire century. The three researchers concluded that “fears of increased hurricane activity in the Gulf of Mexico are premature.”

Noting that the 1995 Atlantic hurricane season was one of near-record tropical storm and hurricane activity, but that during the preceding four years (1991-94) such activity over the Atlantic basin was the lowest since the keeping of reliable records began in the mid-1940s, Landsea *et al.* (1998) studied the meteorological characteristics of the two periods to determine what might have caused the remarkable upswing in storm activity in 1995. In doing so, they found that “perhaps the primary factor for the increased hurricane activity during 1995 can be attributed to a favorable large-scale pattern of

extremely low vertical wind shear throughout the main development region.” They also noted that “in addition to changes in the large-scale flow fields, the enhanced Atlantic hurricane activity has also been linked to below-normal sea-level pressure, abnormally warm ocean waters, and very humid values of total precipitable water.”

An additional factor that may have contributed to the enhanced activity of the 1995 Atlantic hurricane season was the westerly phase of the stratospheric quasi-biennial oscillation, which is known to enhance Atlantic basin storm activity. Possibly the most important factor of all, however, was what Landsea *et al.* called the “dramatic transition from the prolonged late 1991-early 1995 warm episode (El Niño) to cold episode (La Niña) conditions,” which contributed to what they described as “the dramatic reversal” of weather characteristics “which dominated during the [prior] four hurricane seasons.”

“Some have asked,” in the words of the four researchers, “whether the increase in hurricanes during 1995 is related to the global surface temperature increases that have been observed over the last century, some contribution of which is often ascribed to increases in anthropogenic ‘greenhouse’ gases.” In reply, they stated that “such an interpretation is not warranted,” because the various factors noted above seem sufficient to explain the observations. “Additionally,” as they further wrote, “Atlantic hurricane activity has actually decreased significantly in both frequency of intense hurricanes and mean intensity of all named storms over the past few decades,” and “this holds true even with the inclusion of 1995’s Atlantic hurricane season.”

In a major synthesis of Atlantic basin hurricane indices published the following year, Landsea *et al.* (1999) reported long-term variations in tropical cyclone activity for this region (North Atlantic Ocean, Gulf of Mexico, and Caribbean Sea). Over the period 1944-1996, decreasing trends were found for (1) the total number of hurricanes, (2) the number of intense hurricanes, (3) the annual number of hurricane days, (4) the maximum attained wind speed of all hurricane storms averaged over the course of a year, and (5) the highest wind speed associated with the strongest hurricane recorded in each year. In addition, they reported that the total number of Atlantic hurricanes making landfall in the United States had decreased over the 1899-1996 time period, and that normalized trends in hurricane damage in the United States between 1925 and 1996 revealed such damage to be decreasing at a rate of \$728 million per decade.

In a similar study that included a slightly longer period of record (1935-1998), Parisi and Lund (2000) conducted a number of statistical tests on all Atlantic Basin hurricanes that made landfall in the contiguous United States, finding that “a simple linear regression of the yearly number of landfalling hurricanes on the years of study produces a trend slope estimate of  $-0.011 \pm 0.0086$  storms per year.” To drive home the significance of that result, they expressly called attention to the fact that “the estimated trend slope is negative,” which means, of course, that the yearly number of such storms is decreasing, which is just the opposite of what they described as the “frequent hypothesis ... that global warming is causing increased storm activity.” Their statistical analysis indicates that “the trend slope is not significantly different from zero.”

Contemporaneously, Easterling *et al.* (2000) noted that the mean temperature of the globe rose by about  $0.6^{\circ}\text{C}$  over the past century, and they thus looked for possible impacts of this phenomenon on extreme weather events, which if found to be increasing, as they describe it, “would add to the body of evidence that there is a discernable human affect on the climate.” Their search, however, revealed few changes of significance, although they did determine that “the number of intense and landfalling Atlantic hurricanes has declined.”

Lupo and Johnston (2000) found “there has been relatively little trend in the overall occurrence of hurricanes within the Atlantic Ocean Basin (62 year period),” reflecting an upward trend in category 1 hurricanes which is countered by downward or weak trends in the occurrence of category 2-5 hurricanes. Stratifying by hurricane genesis region indicated the tendency for more hurricanes to form in La Niña years during PDO1 (1977-1999) was strongly influenced by more storms being generated in the Caribbean and Eastern Atlantic. Only two storms formed in these regions during El Niño years. During PDO2 (1947-1976) there was a weak tendency for more (fewer) storms forming in the Gulf and Caribbean (West and East Atlantic) sub-regions during La Niña years, while the reverse occurred for El Niño years.

Three years later, Balling and Cerveny (2003) wrote that “many numerical modeling papers have appeared showing that a warmer world with higher sea surface temperatures and elevated atmospheric moisture levels could increase the frequency, intensity, or duration of future tropical cyclones,” but that empirical studies had failed to reveal any such

relationships. They also noted that “some scientists have suggested that the buildup of greenhouse gases can ultimately alter other characteristics of tropical cyclones, ranging from timing of the active season to the location of the events,” and that these relationships have not been thoroughly studied with historical real-world data. They proceeded to fill this void by conducting such a study for tropical storms in the Caribbean Sea, the Gulf of Mexico, and the western North Atlantic Ocean.

More specifically, the two Arizona State University climatologists constructed a daily database of tropical storms that occurred within their study area over the period 1950-2002, generating “a variety of parameters dealing with duration, timing, and location of storm season,” after which they tested for trends in these characteristics, attempting to explain the observed variances in the variables using regional, hemispheric, and global temperatures. In doing so, they “found no trends related to timing and duration of the hurricane season and geographic position of storms in the Caribbean Sea, Gulf of Mexico and tropical sector of the western North Atlantic Ocean.” Likewise, they said they “could find no significant trends in these variables and generally no association with them and the local ocean, hemispheric, and global temperatures.”

Elsner *et al.* (2004) conducted a change-point analysis of time series of annual major North Atlantic hurricane counts and annual major U.S. hurricane counts for the twentieth century, which technique, in their words, “quantitatively identifies temporal shifts in the mean value of the observations.” This work revealed that “major North Atlantic hurricanes have become more frequent since 1995,” but at “a level reminiscent of the 1940s and 1950s.” In actuality, however, they had not quite reached that level, nor had they maintained it for as long a time. Their data indicate that the mean annual hurricane count for the seven-year period 1995-2001 was 3.86, while the mean count for the 14-year period 1948-1961 was 4.14. They also reported that, “in general, twentieth-century U.S. hurricane activity shows no abrupt shifts,” noting, however, that there was an exception over Florida, “where activity decreased during the early 1950s and again during the late 1960s.” Last, they found that “El Niño events tend to suppress hurricane activity along the entire coast with the most pronounced effects over Florida.”

In contradiction of the IPCC’s claim that global warming leads to more intense hurricane activity, the results of Elsner *et al.*’s study found that not only did

North Atlantic hurricane activity not increase over the entire twentieth century, hurricane activity also did not increase in response to the more sporadic warming associated with periodic El Niño conditions.

Two years later, things got a bit more interesting. “The 2005 hurricane season,” in the words of Virmani and Weisberg (2006), “saw an unprecedented number of named tropical storms since records began in 1851.” Moreover, they said it followed “on the heels of the unusual 2004 hurricane season when, in addition to the first South Atlantic hurricane, a record-breaking number of major hurricanes made landfall in the United States, also causing destruction on the Caribbean islands in their path.” The question they thus posed was whether these things occurred in response to recent global warming or if they bore sufficient similarities with hurricane seasons of years past to preclude such an attribution.

The two researchers determined that “latent heat loss from the tropical Atlantic and Caribbean was less in late spring and early summer 2005 than preceding years due to anomalously weak trade winds associated with weaker sea-level pressure,” which phenomenon “resulted in anomalously high sea surface temperatures” that “contributed to earlier and more intense hurricanes in 2005.” However, they went on to note that “these conditions in the Atlantic and Caribbean during 2004 and 2005 were not unprecedented and were equally favorable during the active hurricane seasons of 1958, 1969, 1980, 1995 and 1998.” In addition, they said there was “not a clear link between the Atlantic Multidecadal Oscillation or the long term trend [of temperature] and individual active hurricane years, confirming the importance of other factors in hurricane formation.”

The following year, Mann and Emanuel (2006) used quantitative records stretching back to the mid-nineteenth century to develop a positive correlation between sea surface temperatures and Atlantic basin tropical cyclone frequency for the period 1871-2005, while Holland and Webster (2007) had analyzed Atlantic tropical cyclone frequency back to 1855 and found a doubling of the number of tropical cyclones over the past 100 years. Both of these papers linked these changes to anthropogenic greenhouse warming. In a compelling rebuttal of those conclusions, however, Landsea (2007) cited a number of possible biases that may exist in the cyclone frequency trends derived in the two studies, concluding that “improved monitoring in recent years is responsible for most, if not all, of the observed trend in increasing frequency of tropical cyclones.”

Parisi and Lund (2008) calculated return periods of Atlantic-basin U.S. landfalling hurricanes based on “historical data from the 1900 to 2006 period via extreme value methods and Poisson regression techniques” for each of the categories (1-5) of the Saffir-Simpson Hurricane Scale. This work revealed that return periods (in years) for these hurricanes were, in ascending Saffir-Simpson Scale category order: (1) 0.9, (2) 1.3, (3) 2.0, (4) 4.7, and (5) 23.1. In addition, the two researchers reported that corresponding non-encounter probabilities in any one hurricane season were calculated to be (1) 0.17, (2) 0.37, (3) 0.55, (4) 0.78, and (5) 0.95. They stated that the hypothesis that U.S. hurricane strike frequencies are “increasing in time” is “statistically rejected.”

Lupo *et al.* (2008) added data for seven more years to the data originally analyzed by Lupo and Johnston (2000) and found it “did not change the major findings.” The authors hypothesized that the Atlantic hurricane season of 2005 was so active, not only because of the recent increase in hurricane activity which may be associated with the PDO, but also possibly due to decreased upper tropospheric shear over the Atlantic which may have been associated with a stronger easterly phase of the quasi-biennial oscillation along with warmer-than-normal SSTs.

In light of the long history of multi-decadal to century-scale analyses that have come to the same conclusion, we must reject the oft-heard claim that Atlantic hurricanes have increased in frequency in response to twentieth century global warming.

### 6.3.1.2.4. The El Niño Effect

How does the frequency of Atlantic basin hurricanes respond to increases in ocean temperature? In exploring this important question one has to look not only at Atlantic Ocean temperatures, but also those in the eastern tropical Pacific, in particular during La Niña and El Niño conditions. Wilson (1999) utilized data from the last half of the twentieth century to determine that the probability of having three or more

intense Atlantic hurricanes was only 14 percent during an El Niño year (warm temperatures in the eastern tropical Pacific), but fully 53 percent during a La Niña year (cold ocean temperatures in the eastern tropical Pacific). When ocean temperatures warm in the eastern tropical Pacific, they cause stronger upper level winds in the tropical Atlantic and a greater likelihood that storms would become sheared, and hence weaker. The opposite (weaker upper level winds) occurs during La Niña years.

Muller and Stone (2001) conducted a similar study of tropical storm and hurricane strikes along the southeast U.S. coast from South Padre Island (Texas) to Cape Hatteras (North Carolina), using data from the entire past century. For tropical storms and hurricanes together, they found an average of 3.3 strikes per La Niña season, 2.6 strikes per neutral season, and 1.7 strikes per El Niño season. For hurricanes alone, the average rate of strike occurrence ranged from 1.7 per La Niña season to 0.5 per El Niño season, which represents a frequency-of-occurrence decline of fully 70 percent in going from cooler La Niña conditions to warmer El Niño conditions. Likewise, Elsner *et al.* (2001)—who also worked with data from the entire past century—found that when there are below normal sea surface temperatures in the equatorial Pacific, “the probability of a U.S. hurricane increases.”

Lyons (2004) also conducted a number of analyses of U.S. landfalling tropical storms and hurricanes, dividing them into three different groupings: the 10 highest storm and hurricane landfall years, the nine lowest such years, and all other years. These groupings revealed, in Lyons’ words, that “La Niña conditions occurred 19% more often during high U.S. landfall years than during remaining years,” and that “El Niño conditions occurred 10% more often during low U.S. landfall years than during remaining years.” In addition, it was determined that “La Niña (El Niño) conditions were 18% (25%) more frequent during high (low) U.S. landfall years than during low (high) U.S. landfall years.”

An analogous approach was used by Pielke and Landsea (1999) to study the effect of warming on the intensity of Atlantic basin hurricanes, using data from the period 1925 to 1997. In their analysis, they first determined that 22 years of this period were El Niño years, 22 were La Niña years, and 29 were neither El Niño nor La Niña years. Then, they compared the average hurricane wind speed of the cooler La Niña years with that of the warmer El Niño years, finding that in going from the cooler climatic state to the

warmer climatic state, average hurricane wind speed dropped by about 6 meters per second.

Independent confirmation of these findings was provided by Pielke and Landsea’s assessment of concurrent hurricane damage in the United States: El Niño years experienced only half the damage of La Niña years. And in a 10-year study of a Mediterranean waterbird (Cory’s Shearwater) carried out on the other side of the Atlantic, Brichetti *et al.* (2000) determined—contrary to their own expectation—that survival rates during warmer El Niño years were greater than during cooler La Niña years.

In another pertinent study, Landsea *et al.* (1998) analyzed the meteorological circumstances associated with the development of the 1995 Atlantic hurricane season, which was characterized by near-record tropical storm and hurricane activity after four years (1991-94) that had exhibited the lowest such activity since the keeping of reliable records began. They determined that the most important factor behind this dramatic transition from extreme low to extreme high tropical storm and hurricane activity was what they called the “dramatic transition from the prolonged late 1991-early 1995 warm episode (El Niño) to cold episode (La Niña) conditions.”

Last, in a twentieth century change-point analysis of time series of major North Atlantic and U.S. annual hurricane counts, which in the words of its authors, “quantitatively identifies temporal shifts in the mean value of the observations,” Elsner *et al.* (2004) found that “El Niño events tend to suppress hurricane activity along the entire coast with the most pronounced effects over Florida.”

### 6.3.2. Indian Ocean

Singh *et al.* (2000, 2001) analyzed 122 years of tropical cyclone data from the North Indian Ocean over the period 1877-1998. Since this was the period of time during which the planet recovered from the global chill of the Little Ice Age, it is logical to assume that their findings would be indicative of changes in hurricane characteristics we might expect if the earth were to warm by that amount again, which is what the IPCC is projecting.

Singh *et al.* found that on an annual basis, there was a slight decrease in tropical cyclone frequency, such that the North Indian Ocean, on average, experienced about one less hurricane per year at the end of the 122-year record in 1998 than it did at its start in 1877. In addition, based on data from the Bay of Bengal, they found that tropical cyclone numbers dropped during the months of most severe cyclone formation (November and May), when the El Niño-Southern Oscillation was in a warm phase. In light of these real-world observations, it would thus appear that if tropical cyclones of the North Indian Ocean were to change at all in response to global warming, their overall frequency and the frequency of the most intense such storms would likely decrease.

Hall (2004) analyzed characteristics of cyclones occurring south of the equator from longitude 90°E to 120°W in the South Pacific and southeast Indian

Oceans, concentrating on the 2001-2002 cyclone season and comparing the results with those of the preceding four years and the 36 years before that. This work revealed that “the 2001-2002 tropical cyclone season in the South Pacific and southeast Indian Ocean was one of the quietest on record, in terms of both the number of cyclones that formed, and the impact of those systems on human affairs.” In the southeast Indian Ocean, for example, Hall determined that “the overall number of depressions and tropical cyclones was below the long-term mean.” Further east, he found that broad-scale convection was near or slightly above normal, but that “the proportion of tropical depressions and weak cyclones developing into severe cyclones was well below average,” which result represented “a continuation of the trend of the previous few seasons.” What is more, Hall writes that “in the eastern Australian region, the four-year period up to 2001-2002 was by far the quietest recorded in the past 41 years.”

Raghavan and Rajesh (2003) reviewed the general state of scientific knowledge relative to trends in the frequency and intensity of tropical cyclones throughout the world, giving special attention to the Indian state of Andhra Pradesh, which borders on the Bay of Bengal. For the North Indian Ocean (NIO), comprising both the Bay of Bengal and the Arabian Sea, they report that for the period 1891-1997 there was a significant decreasing trend (at the 99 percent confidence level) in the frequency of cyclones with the designation of “cyclonic storm” and above, and that “the maximum decrease was in the last four decades,” citing the work of Srivastava *et al.* (2000). In addition, they note that Singh and Khan (1999), who studied 122 years of data, also found the annual frequency of NIO-basin tropical cyclones to be decreasing.

As in other parts of the world, they found increasing impacts of tropical cyclones; but their economic analysis led them to conclude that “increasing damage due to tropical cyclones over Andhra Pradesh, India, is attributable mainly to economic and demographic factors and not to any increase in frequency or intensity of cyclones.” With no equivocation, they state that “inflation, growth in population, and the increased wealth of people in the coastal areas (and not global warming) are the factors contributing to the increased impact.”

Commenting on their findings, the researchers say “there is a common perception in the media, and even government and management circles, that

[increased property damage from tropical cyclones] is due to an increase in tropical cyclone frequency and perhaps in intensity, probably as a result of global climate change.” However, as they continue, “studies all over the world show that though there are decadal variations, there is no definite long-term trend in the frequency or intensity of tropical cyclones.” They confidently state that “the specter of tropical cyclones increasing alarmingly due to global climate change, portrayed in the popular media and even in some more serious publications, does not therefore have a sound scientific basis.”

### 6.3.3. Pacific Ocean

Chu and Clark (1999) analyzed the frequency and intensity of tropical cyclones that either originated in or entered the central North Pacific (0-70°N, 140-180°W) over the 32-year period 1966-1997. They

determined that “tropical cyclone activity (tropical depressions, tropical storms, and hurricanes combined) in the central North Pacific [was] on the rise.” This increase, however, appears to have been due to a step-change that led to the creation of “fewer cyclones during the first half of the record (1966-81) and more during the second half of the record (1982-1997),” and accompanying the abrupt rise in tropical cyclone numbers was a similar abrupt increase in maximum hurricane intensity. Chu and Clark say the observed increase in tropical cyclone activity cannot be due to CO<sub>2</sub>-induced global warming, because, in their words, “global warming is a gradual process” and “it cannot explain why there is a steplike change in the tropical cyclone incidences in the early 1980s.”

Clearly, a much longer record of tropical cyclone activity is needed to better understand the nature of the variations documented by Chu and Clark, as well as their relationship to mean global air temperature. The beginnings of such a history were presented by Liu *et al.* (2001), who meticulously waded through a wealth of weather records from Guangdong Province in southern China, extracting data pertaining to the landfall of typhoons there since AD 975. Calibrating the historical data against instrumental observations over the period 1884-1909, they found the trends of the two datasets to be significantly correlated ( $r = 0.71$ ). This observation led them to conclude that “the time series reconstructed from historical documentary evidence contains a reliable record of variability in typhoon landfalls.” They proceeded to conduct a spectral analysis of the Guangdong time series and discovered an approximate 50-year cycle in the frequency of typhoon landfall that “suggests an external forcing mechanism, which remains to be identified.” They also found that “the two periods of most frequent typhoon strikes in Guangdong (AD 1660-1680, 1850-1880) coincide with two of the coldest and driest periods in northern and central China during the Little Ice Age.”

Looking even further back in time into the Southern Hemisphere, Hayne and Chappell (2001) studied a series of storm ridges at Curacoa Island, which were deposited over the past 5,000 years on the central Queensland shelf (18°40'S; 146°33'E), in an attempt to create a long-term history of major cyclonic events that have impacted that area. One of their stated reasons for doing so was to test the climate-model-based hypothesis that “global warming leads to an increase of cyclone frequency or intensity.” They found that “cyclone frequency was statistically constant over the last 5,000 years.” In

addition, they could find “no indication that cyclones have changed in intensity,” a finding that is inconsistent with the climate-model-based hypothesis.

In a similar study, Nott and Hayne (2001) produced a 5,000-year record of tropical cyclone frequency and intensity along a 1,500-km stretch of coastline in northeast Australia located between latitudes 13 and 24°S by geologically dating and topographically surveying landform features left by historic hurricanes, and running numerical models to estimate storm surge and wave heights necessary to reach the landform locations. These efforts revealed that several “super-cyclones” with central pressures less than 920 hPa and wind speeds in excess of 182 kilometers per hour had occurred over the past 5,000 years at intervals of roughly 200 to 300 years in all parts of the region of their study. They also report that the Great Barrier Reef “experienced at least five such storms over the past 200 years, with the area now occupied by Cairns experiencing two super-cyclones between 1800 and 1870.” The twentieth century, however, was *totally devoid* of such storms, “with only one such event (1899) since European settlement in the mid-nineteenth century.”

Also noting that “many researchers have suggested that the buildup of greenhouse gases (Watson *et al.*, 2001) will likely result in a rise in sea surface temperature (SST), subsequently increasing both the number and maximum intensity of tropical cyclones (TCs),” Chan and Liu (2004) explored the validity of this assertion via an examination of pertinent real-world data. As they put it, “if the frequency of TC occurrence were to increase with increasing global air temperature, one would expect to see an increase in the number of TCs during the past few decades.” Their efforts, which focused on the last four decades of the twentieth century, resulted in their finding that a number of parameters related to SST and TC activity in the Western North Pacific (WNP) “have gone through large interannual as well as interdecadal variations,” and that “they also show a slight decreasing trend.” In addition, they say that “no significant correlation was found between the typhoon activity parameters and local SST,” and “an increase in local SST does not lead to a significant change of the number of intense TCs in the WNP, which is contrary to the results produced by many of the numerical climate models.” Instead, they found that “the interannual variation of annual typhoon activity is mainly constrained by the ENSO phenomenon through the alteration of the large-scale circulation induced by the ENSO event.”

In discussing their results, Chan and Liu write that the reason for the discrepancies between their real-world results and those of many of the numerical climate models likely lies in the fact that the models assume TCs are generated primarily from energy from the oceans and that a higher SST therefore would lead to more energy being transferred from the ocean to the atmosphere. “In other words,” as they say, “the typhoon activity predicted in these models is almost solely determined by thermodynamic processes, as advocated by Emanuel (1999),” whereas “in the real atmosphere, dynamic factors, such as the vertical variation of the atmospheric flow (vertical wind shear) and the juxtaposition of various flow patterns that lead to different angular momentum transports, often outweigh the thermodynamic control in limiting the intensification process.” Their final conclusion is that “at least for the western North Pacific, observational evidence does not support the notion that increased typhoon activity will occur with higher local SSTs.”

Much the same thing was found by Free *et al.* (2004), who looked for increases in potential hurricane intensity, as they put it, “estimated from thermodynamic principles as shown in Emanuel (1986, 1995) given a record of SSTs and profiles of atmospheric temperature and humidity.” This they did using radiosonde and SST data from 14 island radiosonde stations in both the tropical Pacific and Atlantic Oceans, after which they compared their results with those of Bister and Emanuel (2002) at grid points near the selected stations. They found “no significant trend in potential intensity from 1980 to 1995 and no consistent trend from 1975 to 1995.” What is more, they report that between 1975 and 1980, “while SSTs rose, PI decreased, illustrating the hazards of predicting changes in hurricane intensity from projected SST changes alone.”

Hall (2004) reviewed the characteristics of cyclones occurring south of the equator and eastward from longitude 90°E to 120°W in the South Pacific and southeast Indian Oceans, concentrating on the 2001-2002 cyclone season and comparing the results with those of the preceding four years and the 36 years before that. This analysis indicated that “the 2001-2002 tropical cyclone season in the South Pacific and southeast Indian Ocean was one of the quietest on record, in terms of both the number of cyclones that formed, and the impact of those systems on human affairs.” In the southeast Indian Ocean, for example, he writes that “the overall number of depressions and tropical cyclones was below the long-

term mean,” while further east he found that broad-scale convection was near or slightly above normal, but that “the proportion of tropical depressions and weak cyclones developing into severe cyclones was well below average,” which result represented “a continuation of the trend of the previous few seasons.” Hall writes that “in the eastern Australian region, the four-year period up to 2001-2002 was by far the quietest recorded in the past 41 years.”

Noting that “according to Walsh and Ryan (2000), future global climate trends may result in an increased incidence of cyclones,” and realizing that “understanding the behavior and frequency of severe storms in the past is crucial for the prediction of future events,” Yu *et al.* (2004) devised a way to decipher the history of severe storms in the southern South China Sea. Working at Youngshu Reef (9°32'–9°42'N, 112°52'–113°04'E), they used standard radiocarbon dating together with TIMS U-series dating to determine the times of occurrence of storms that were strong enough to relocate large *Porites* coral blocks that are widespread on the reef flats there. This program revealed that “during the past 1000 years, at least six exceptionally strong storms occurred,” which they dated to approximately AD 1064 ± 30, 1218 ± 5, 1336 ± 9, 1443 ± 9, 1682 ± 7, and 1872 ± 15, yielding an average recurrence time of 160 years. Interestingly, none of these six severe storms occurred during the past millennium’s last century, which the IPCC claims was the warmest such period of that thousand-year interval.

Noting that Emanuel (2005) and Webster *et al.* (2005) have claimed that “tropical cyclone intensity has increased markedly in recent decades,” and saying that because they specifically argued that “tropical cyclone activity over the western North Pacific has been changed in response to the ongoing global warming,” Ren *et al.* (2006) decided to see if any increases in tropical cyclone activity had occurred over China between 1957 and 2004. This they did by analyzing tropical cyclone (TC) precipitation (P) data from 677 Chinese weather stations for the period 1957 to 2004, searching for evidence of long-term changes in TCP and TC-induced torrential precipitation events. This search indicated, in their words, that “significant downward trends are found in the TCP volume, the annual frequency of torrential TCP events, and the contribution of TCP to the annual precipitation over the past 48 years.” Also, they say that the downward trends were accompanied by “decreases in the numbers of TCs and typhoons that affected China during the period 1957-2004.” In

a conclusion that consequently differs dramatically from the claims of Emanuel (2005) and Webster *et al.* (2005) relative to inferred increases in tropical cyclone activity over the western North Pacific in recent decades, Ren *et al.* say their findings “strongly suggest that China has experienced decreasing TC influence over the past 48 years, especially in terms of the TCP.”

Nott *et al.* (2007) developed a 777-year-long annually resolved record of landfalling tropical cyclones in northeast Australia based on analyses of isotope records of tropical cyclone rainfall in an annually layered carbonate stalagmite from Chillagoe (17.2°S, 144.6°E) in northeast Queensland. Perhaps their most important discovery in doing so was their finding that “the period between AD 1600 to 1800”—when the Little Ice Age held sway throughout the world—“had many more intense or hazardous cyclones impacting the site than the post AD 1800 period,” when the planet gradually began to warm.

Li *et al.* (2007) analyzed real-world tropical cyclone data pertaining to the western North Pacific basin archived in the *Yearbook of Typhoon* published by the China Meteorological Administration for the period 1949-2003, together with contemporaneous atmospheric information obtained from the National Center for Environmental Protection reanalysis dataset for the period 1951-2003. Following this endeavor, they used their empirical findings to infer future tropical cyclone activity in the region based upon climate-model simulations of the state of the general circulation of the atmosphere over the next half-century. This protocol revealed, first, that there were “more tropical cyclones generated over the western North Pacific from the early 1950s to the early 1970s in the 20th century and less tropical cyclones from the mid-1970s to the present.” They further found that “the decadal changes of tropical cyclone activities are closely related to the decadal changes of atmospheric general circulation in the troposphere, which provide favorable or unfavorable conditions for the formation of tropical cyclones.” Based on simulations of future occurrences of these favorable and unfavorable conditions derived from “a coupled climate model under the [A2 and B2] schemes of the Intergovernmental Panel on Climate Change special report on emission scenarios,” they then determined that “the general circulation of the atmosphere would become unfavorable for the formation of tropical cyclones as a whole and the frequency of tropical cyclone formation would likely decrease by 5% within the next half century, although

more tropical cyclones would appear during a short period of it.”

Last, an analysis by Lupo *et al.* (2008) of 69 years of East Pacific tropical cyclone activity (1970 – 2007) found that there were 16.3 storms per year (9.0 hurricanes and 7.3 tropical storms), which was a greater amount of activity than found in the Atlantic Ocean basin. The long-term trend showed a slight decrease (not statistically significant) in East Pacific tropical cyclone activity. An examination of the interannual variability demonstrated that there were more East Pacific tropical cyclones during El Niño years, and that this was mainly accounted for by more storms becoming intense hurricanes than during La Niña years. The tropical cyclone season was one or two months longer in El Niño years, while more storms formed in the southeast and southwest part of the East Pacific Ocean Basin. This is likely due to the fact that ENSO years bring warmer waters to the East Pacific region. When breaking down the ENSO years by phase of the PDO, the ENSO-related differences in occurrence and intensity and geographic formation region are accentuated in PDO1 years (1977-1999), but were blurred in PDO2 (1947-1976) years. This ENSO and PDO related variability is similar to that occurring in the Atlantic (LJ00), except that in the Atlantic more storms occurred in La Niña years and they were more intense.

### 6.3.4. Global

Although some climate models suggest the intensity and frequency of tropical cyclones on a global scale may be significantly reduced in response to global warming (Bengtsson *et al.*, 1996), thus implying a “decrease in the global total number of tropical cyclones on doubling CO<sub>2</sub>,” as noted by Sugi *et al.* (2002), most of them suggest otherwise. Free *et al.* (2004) state that “increases in hurricane intensity are expected to result from increases in sea surface temperature and decreases in tropopause-level temperature accompanying greenhouse warming (Emanuel, 1987; Henderson-Sellers *et al.*, 1998; Knutson *et al.*, 1998).”

In an early review of empirical evidence related to the subject, Walsh and Pittcock (1998) concluded that “the effect of global warming on the number of tropical cyclones is presently unknown,” and “there is little relationship between SST (sea surface temperature) and tropical cyclone numbers in several regions of the globe.” They opined there was “little evidence that changes in SSTs, by themselves, could cause change in tropical cyclone numbers.”

In a second early analysis of the topic, Henderson-Sellers *et al.* (1998) determined that (1) “there are no discernible global trends in tropical cyclone number, intensity, or location from historical data analyses,” (2) “global and mesoscale-model-based predictions for tropical cyclones in greenhouse conditions have not yet demonstrated prediction skill,” and (3) “the popular belief that the region of cyclogenesis will expand with the 26°C SST isotherm is a fallacy.”

Six years later, Free *et al.* (2004) looked for increases in “potential” hurricane intensity and found “no significant trend in potential intensity from 1980 to 1995 and no consistent trend from 1975 to 1995.”

What is more, they report that between 1975 and 1980, “while SSTs rose, PI decreased, illustrating the hazards of predicting changes in hurricane intensity from projected SST changes alone.”

In another review of what real-world data have to say about the subject, Walsh (2004) was once again forced to report “there is as yet no convincing evidence in the observed record of changes in tropical cyclone behavior that can be ascribed to global warming.” Nevertheless, Walsh continued to believe that (1) “there is likely to be some increase in maximum tropical cyclone intensities in a warmer world,” (2) “it is probable that this would be accompanied by increases in mean tropical cyclone intensities,” and (3) “these increases in intensities are likely to be accompanied by increases in peak precipitation rates of about 25%,” putting the date of possible detection of these increases “some time after 2050,” little knowing that two such claims would actually be made the very next year.

Emanuel (2005) claimed to have found that a hurricane power dissipation index had increased by approximately 50 percent for both the Atlantic basin and the Northwest Pacific basin since the mid 1970s, and Webster *et al.* (2005) contended the numbers of Category 4 and 5 hurricanes for all tropical cyclone basins had nearly doubled between an earlier (1975-1989) and a more recent (1990-2004) 15-year period. However, in a challenge to both of these claims, Klotzbach (2006) wrote that “many questions have been raised regarding the data quality in the earlier part of their analysis periods,” and he thus proceeded to perform a new analysis based on a “near-homogeneous” global dataset for the period 1986-2005.

Klotzbach first tabulated global tropical cyclone (TC) activity using best track data—which he describes as “the best estimates of the locations and intensities of TCs at six-hour intervals produced by the international warning centers”—for all TC basins (North Atlantic, Northeast Pacific, Northwest Pacific, North Indian, South Indian, and South Pacific), after which he determined trends of worldwide TC frequency and intensity over the period 1986-2005, during which time global SSTs are purported to have risen by about 0.2-0.4°C. This work did indeed indicate, in his words, “a large increasing trend in tropical cyclone intensity and longevity for the North Atlantic basin,” but it also indicated “a considerable decreasing trend for the Northeast Pacific.” Combining these observations with the fact that “all other basins showed small trends,” he determined

there had been “no significant change in global net tropical cyclone activity” over the past two decades. With respect to Category 4 and 5 hurricanes, however, he found there had been a “small increase” in their numbers from the first half of the study period (1986-1995) to the last half (1996-2005); but he noted that “most of this increase is likely due to improved observational technology.” Klotzbach said his findings were “contradictory to the conclusions drawn by Emanuel (2005) and Webster *et al.* (2005),” in that the global TC data did “not support the argument that global TC frequency, intensity and longevity have undergone increases in recent years.”

Following close on the heels of Klotzbach’s study came the paper of Kossin *et al.* (2007), who wrote that “the variability of the available data combined with long time-scale changes in the availability and quality of observing systems, reporting policies, and the methods utilized to analyze the data make the best track records inhomogeneous,” and stated that this “known lack of homogeneity in both the data and techniques applied in the post-analyses has resulted in skepticism regarding the consistency of the best track intensity estimates.” Consequently, as an important first step in resolving this problem, Kossin *et al.* “constructed a more homogeneous data record of hurricane intensity by first creating a new consistently analyzed global satellite data archive from 1983 to 2005 and then applying a new objective algorithm to the satellite data to form hurricane intensity estimates,” after which they analyzed the resultant homogenized data for temporal trends over the period 1984-2004 for all major ocean basins and the global ocean as a whole.

The five scientists who conducted the work said that “using a homogeneous record, we were not able to corroborate the presence of upward trends in hurricane intensity over the past two decades in any basin other than the Atlantic.” Therefore, noting that “the Atlantic basin accounts for less than 15% of global hurricane activity,” they concluded that “this result poses a challenge to hypotheses that directly relate globally increasing tropical sea surface temperatures to increases in long-term mean global hurricane intensity.” They deliver another major blow to the contentions of Emanuel (2005) and Webster *et al.* (2005) when they say “the question of whether hurricane intensity is globally trending upwards in a warming climate will likely remain a point of debate in the foreseeable future.”

As a result of the many investigations of the subject that have been conducted over the past several

years, there currently appears to be no factual basis for claiming that planet-wide hurricane frequency and/or intensity will rise in response to potential future global warming. Nevertheless, parties pushing for restrictions on anthropogenic CO<sub>2</sub> emissions continue to do so, citing the now-rebutted claims of Emanuel (2005) and Webster *et al.* (2005).

## 6.4. ENSO

Computer model simulations have given rise to three claims regarding the influence of global warming on El Niño/Southern Oscillation (ENSO) events: (1) global warming will increase the frequency of ENSO events, (2) global warming will increase the intensity of ENSO events, and (3) weather-related disasters will be exacerbated under El Niño conditions. Here, we test the validity of these assertions, demonstrating they are in conflict with the observational record. We begin by highlighting studies that suggest the virtual world of ENSO, as simulated by state-of-the-art climate models, is at variance with reality.

Additional information on this topic, including reviews on ENSO not discussed here, can be found at [http://www.co2science.org/subject/e/subject\\_e.php](http://www.co2science.org/subject/e/subject_e.php) under the heading ENSO.

### 6.4.1. Model Inadequacies

In a comparison of 24 coupled ocean-atmosphere climate models, Latif *et al.* (2001) report that “almost all models (even those employing flux corrections) still have problems in simulating the SST [sea surface temperature] climatology.” They also note that “only a few of the coupled models simulate the El Niño/Southern Oscillation (ENSO) in terms of gross equatorial SST anomalies realistically.” And they state that “no model has been found that simulates

realistically all aspects of the interannual SST variability.” Because “changes in sea surface temperature are both the cause and consequence of wind fluctuations,” and because these phenomena figure prominently in the El Niño-La Niña oscillation, it is not surprising that Fedorov and Philander (2000) conclude that current climate models do not do a good job of determining the potential effects of global warming on ENSO.

Human ignorance likely also plays a role in the models’ failure to simulate ENSO. According to Overpeck and Webb (2000), there is evidence that “ENSO may change in ways that we do not yet understand,” which “ways” have clearly not yet been modeled. White *et al.* (2001), for example, found that “global warming and cooling during earth’s internal mode of interannual climate variability [the ENSO cycle] arise from fluctuations in the global hydrological balance, not the global radiation balance,” and that these fluctuations are the result of no known forcing of either anthropogenic or extraterrestrial origin, although Cerveny and Shaffer (2001) make a case for a lunar forcing of ENSO activity, which also is not included in any climate model.

Another example of the inability of today’s most sophisticated climate models to properly describe El Niño events is provided by Landsea and Knaff (2000), who employed a simple statistical tool to evaluate the skill of 12 state-of-the-art climate models in real-time predictions of the development of the 1997-98 El Niño. They found that the models exhibited essentially no skill in forecasting this very strong event at lead times ranging from 0 to eight months. They also determined that no models were able to anticipate even one-half of the actual amplitude of the El Niño’s peak at a medium range lead-time of six to 11 months. They state that “since no models were able to provide useful predictions at the medium and long ranges, *there were no models that provided both useful and skillful forecasts for the entirety of the 1997-98 El Niño*” [italics in the original].

Given the inadequacies listed above, it is little wonder several scientists have criticized model simulations of current ENSO behavior, including Walsh and Pittock (1998), who say “there is insufficient confidence in the predictions of current models regarding any changes in ENSO,” and Fedorov and Philander (2000), who say “at this time, it is impossible to decide which, if any, are correct.” As a result, there is also little reason to believe that

current climate models can correctly predict ENSO behavior under future conditions of changed climate.

- Changnon (1999) determined that adverse weather events attributed to the El Niño of 1997-98 negatively affected the United States economy to the tune of \$4.5 billion and contributed to the loss of 189 lives, which is serious indeed. On the other hand, he determined that El Niño-related benefits amounted to approximately \$19.5 billion—resulting primarily from reduced energy costs, increased industry sales, and the lack of normal hurricane damage—and that a total of 850 lives were *saved* due to the reduced amount of bad winter weather. Thus, the net effect of the 1997-98 El Niño on the United States, according to Changnon, was “surprisingly positive,” in stark contrast to what was often reported in the media and by some commentators who tend, in his words, “to focus only on the negative outcomes.”
- Another of the “surprisingly positive” consequences of El Niños is their tendency to moderate Atlantic hurricane frequencies. Working with data from 1950 to 1998, Wilson (1999) determined that the probability of having three or more intense hurricanes during a warmer El Niño year was approximately 14 percent, while during a cooler non-El Niño year the probability jumped to 53 percent. Similarly, in a study of tropical storm and hurricane strikes along the southeast coast of the United States over the entire last century, Muller and Stone (2001) determined that “more tropical storm and hurricane events can be anticipated during La Niña seasons [3.3 per season] and fewer during El Niño seasons [1.7 per season].” And in yet another study of Atlantic basin hurricanes, this one over the period 1925 to 1997, Pielke and Landsea (1999) reported that average hurricane wind speeds during warmer El Niño years were about six meters per second lower than during cooler La Niña years. In addition, they reported that hurricane damage during cooler La Niña years was twice as great as during warmer El Niño years. These year-to-year variations thus indicate that, if anything, hurricane frequency and intensity—as well as damage—tend to decrease under warmer El Niño conditions.
- Much the same story is being said of other parts of the world. In the North Indian Ocean, Singh *et al.* (2000) studied tropical cyclone data pertaining to the period 1877-1998, finding that tropical cyclone frequency there declined during the months of most severe cyclone formation—November and May—when ENSO was in a warm phase. In New Zealand, De Lange and Gibb (2000) studied storm surge events recorded by several tide gauges in Tauranga Harbor over the period 1960-1998, finding a considerable decline in both the annual number of such events and their magnitude in the latter (warmer) half of the nearly four-decade-long record, additionally noting that La Niña seasons typically experienced more storm surge days than El Niño seasons. And in Australia, Kuhnel and Coates (2000) found that over the period 1876-1991, yearly fatality event-days due to floods, bushfires, and heatwaves were greater in cooler La Niña years than in warmer El Niño years.

### 6.4.2. Relationship to Extreme Weather

Changnon (1999) determined that adverse weather events attributed to the El Niño of 1997-98 negatively affected the United States economy to the tune of \$4.5 billion and contributed to the loss of 189 lives, which is serious indeed. On the other hand, he determined that El Niño-related benefits amounted to approximately \$19.5 billion—resulting primarily from reduced energy costs, increased industry sales, and the lack of normal hurricane damage—and that a total of 850 lives were *saved* due to the reduced

Zuki and Lupo (2008), when examining Southern South China Sea (SSCS) data on tropical storms and cyclones for interannual variability, found La Niña years were more active and El Niño years were less active than other years, and this result was significant at the 95 percent confidence level when examining the total sample. The variability of tropical storms and tropical cyclones of local origin was similar to that of the total sample. There was no apparent climatic variability (statistically significant) in the SSCS that could be attributed to interdecadal variability such as the PDO. A spectral analysis of the filtered climatological background variables such as SST, SLP, 200–850 hPa wind shear, 850 hPa divergence and 850 hPa vorticity showed that there was significant variability found in the 3–7 year period, which is consistent with that of the ENSO period.

Zuki and Lupo then examined a subset of the most active years (all La Niña and “cold” neutral years) versus those years with no tropical cyclone activity for the five years of warmest SSTs (predominantly El Niño years) and coolest SSTs. They found that during warm non-active SST years, tropical cyclone activity was likely suppressed as the low-level relative vorticity was considerably more anticyclonic, even though SSTs were about one standard deviation warmer and wind shears were similar to those of active years. The SSCS atmospheric environment for warm SST non-active years was drier than that of the active years, and did not exhibit a surface–500 hPa structure that would be as supportive of warm-core tropical cyclones. Most of these years were also ENSO years, and two thirds of all years with no activity were El Niño or warm neutral.

Apparently, even birds seem to know the dangers of La Niña vs. El Niño. In a study of breeding populations of Cory’s Shearwaters on the Tremeiti Islands of Italy, for example, Brichetti *et al.* (2000) found that, contrary to even their hypothesis, survival rates during El Niño years were greater than during La Niña years.

### 6.4.3. Relationship to Global Warming

All of the claims regarding the influence of global warming on ENSO events are derived from climate model simulations. Timmermann *et al.* (1999), for example, developed a global climate model which, according to them, operates with sufficient resolution to address the issue of whether “human-induced ‘greenhouse’ warming affects, or will affect, ENSO.” When running this model with increasing greenhouse-gas concentrations, more frequent El-Niño-like conditions do indeed occur. However, this is not what observational data reveal to be the case. The frequent

and strong El Niño activity of the recent past is no different from that of a number of other such episodes of prior centuries, when it was colder than it is today, as described in several of the papers highlighted below. And in many instances, the El Niño activity of the recent past is shown to be inferior to that of colder times.

Evans *et al.* (2002) reconstructed gridded Pacific Ocean sea surface temperatures from coral stable isotope ( $\delta^{18}\text{O}$ ) data, from which they assessed ENSO activity over the period 1607-1990. The results of their analysis showed that a period of relatively vigorous ENSO activity over the colder-than-present period of 1820-1860 was “similar to [that] observed in the past two decades.” Likewise, in a study that was partly based upon the instrumental temperature record for the period 1876-1996, Allan and D’Arrigo (1999) found four persistent El Niño sequences similar to that of the 1990s; using tree-ring proxy data covering the period 1706 to 1977, they found several other ENSO events of prolonged duration. There were four or five persistent El Niño sequences in each of the eighteenth and nineteenth centuries, which were both significantly colder than the final two decades of the twentieth century, leading them to conclude there is “no evidence for an enhanced greenhouse influence in the frequency or duration of ‘persistent’ ENSO event sequences.”

Brook *et al.* (1999) analyzed the layering of couplets of inclusion-rich calcite over inclusion-free calcite, and darker aragonite over clear aragonite, in two stalagmites from Anjohibe Cave in Madagascar, comparing their results with historical records of El Niño events and proxy records of El Niño events and sea surface temperatures derived from ice core and coral data. This exercise revealed that the cave-derived record of El Niño events compared well with the historical and proxy ice core and coral records; these data indicated, in Brook *et al.*’s words, that “the period 1700-50 possibly witnessed the highest frequency of El Niño events in the last four and a half centuries while the period 1780-1930 was the longest period of consistently high El Niño occurrences,” both of which periods were cooler than the 1980s and 1990s.

In another multi-century study, Meyerson *et al.* (2003) analyzed an annually dated ice core from the South Pole that covered the period 1487-1992, specifically focusing on the marine biogenic sulfur species methanesulfonate (MS), after which they used orthogonal function analysis to calibrate the high-resolution MS series with associated environmental

series for the period of overlap (1973-92). This procedure allowed them to derive a five-century history of ENSO activity and southeastern Pacific sea-ice extent, the latter of which parameters they say “is indicative of regional temperatures within the Little Ice Age period in the southeastern Pacific sea-ice sector.”

In analyzing these records, Meyerson *et al.* noted a shift at about 1800 towards generally cooler conditions. This shift was concurrent with an increase in the frequency of El Niño events in the ice core proxy record, which is contrary to what is generally predicted by climate models. On the other hand, their findings were harmonious with the historical El Niño chronologies of both South America (Quinn and Neal, 1992) and the Nile region (Quinn, 1992; Diaz and Pulwarty, 1994), which depict, in their words, “increased El Niño activity during the period of the Little Ice Age (nominally 1400-1900) and decreased El Niño activity during the Medieval Warm Period (nominally 950-1250),” as per Anderson (1992) and de Putter *et al.*, 1998).

Taking a little longer look back in time were Cobb *et al.* (2003), who generated multi-century monthly resolved records of tropical Pacific climate variability over the last millennium by splicing together overlapping fossil-coral records from the central tropical Pacific, which exercise allowed them “to characterize the range of natural variability in the tropical Pacific climate system with unprecedented fidelity and detail.” In doing so, they discovered that “ENSO activity in the seventeenth-century sequence [was] not only stronger, but more frequent than ENSO activity in the late twentieth century.” They also found “there [were] 30-yr intervals during both the twelfth and fourteenth centuries when ENSO activity [was] greatly reduced relative to twentieth-century observations.” Once again, we have evidence of a situation where ENSO activity was much greater and more intense during the cold of the Little Ice Age than the warmth of the late twentieth century.

Inching still further back in time, Eltahir and Wang (1999) used water-level records of the Nile River as a proxy for El Niño episodes over the past 14 centuries. This approach indicated that although the frequency of El Niño events over the 1980s and 1990s was high, it was not without precedent, being similar to values observed near the start of the twentieth century and much the same as those “experienced during the last three centuries of the first millennium,” which latter period, according to Esper

*et al.* (2002), was also cooler than the latter part of the twentieth century.

Woodroffe *et al.* (2003) found pretty much the same thing, but over an even longer period of time. Using oxygen isotope ratios obtained from *Porites* microatolls at Christmas Island in the central Pacific to provide high-resolution proxy records of ENSO variability since 3.8 thousand years ago (ka), they found, in their words, that “individual ENSO events in the late Holocene [3.8-2.8 ka] appear at least as intense as those experienced in the past two decades.” In addition, they note that “geoarcheological evidence from South America (Sandweiss *et al.*, 1996), Ecuadorian varved lake sediments (Rodbell *et al.*, 1999), and corals from Papua New Guinea (Tudhope *et al.*, 2001) indicate that ENSO events were considerably weaker or absent between 8.8 and 5.8 ka,” which was the warmest part of the Holocene. In fact, they report that “faunal remains from archeological sites in Peru (Sandweiss *et al.*, 2001) indicate that the onset of modern, rapid ENSO recurrence intervals was achieved only after ~4-3 ka,” or during the long cold interlude that preceded the Roman Warm Period (McDermott *et al.*, 2001).

Also concentrating on the mid to late Holocene were McGregor and Gagan (2004), who used several annually resolved fossil *Porites* coral  $\delta^{18}\text{O}$  records to investigate the characteristics of ENSO events over a period of time in which the earth cooled substantially. For comparison, study of a modern coral core provided evidence of ENSO events for the period 1950-1997, the results of which analysis suggest they occurred at a rate of 19 events/century. The mid-Holocene coral  $\delta^{18}\text{O}$  records, on the other hand, showed reduced rates of ENSO occurrence: 12 events/century for the period 7.6-7.1 ka, eight events/century for the period 6.1-5.4 ka, and six events/century at 6.5 ka. For the period 2.5-1.7 ka, however, the results were quite different, with all of the coral records revealing, in the words of McGregor and Gagan, “large and protracted  $\delta^{18}\text{O}$  anomalies indicative of particularly severe El Niño events.” They note specifically that “the 2.5 ka Madang PNG coral records a protracted 4-year El Niño, like the 1991-1994 event, but almost twice the amplitude of [the] 1997-1998 event (Tudhope *et al.*, 2001).” In addition, they say that “the 2 ka Muschu Island coral  $\delta^{18}\text{O}$  record shows a severe 7-year El Niño, longer than any recorded Holocene or modern event.” And they add that “the 1.7 ka *Porites* microatoll of Woodroffe *et al.* (2003) also records an extreme El Niño that was twice the amplitude of the 1997-1998

event.” Taken together, these several sets of results portray what McGregor and Gagan describe as a “mid-Holocene El Niño suppression and late Holocene amplification.”

That there tend to be fewer and weaker ENSO events during warm periods has further been documented by Riedinger *et al.* (2002). In a 7,000-year study of ENSO activity in the vicinity of the Galapagos Islands, they determined that “mid-Holocene [7,130 to 4,600 yr BP] El Niño activity was infrequent,” when, of course, global air temperature was significantly warmer than it is now, but that both the “frequency and intensity of events increased at about 3100 yr BP,” when it finally cooled below current temperatures. Throughout the former 2,530-year warm period, their data revealed the existence of 23 strong to very strong El Niños and 56 moderate events; while throughout the most recent (and significantly colder) 3,100-year period, they identified 80 strong to very strong El Niños and 186 moderate events. These numbers correspond to rates of 0.9 strong and 2.2 moderate occurrences per century in the earlier warm period and 2.7 strong and 6.0 moderate occurrences per century in the latter cool period, suggestive of an approximate tripling of the rate of occurrence of both strong and moderate El Niños in going from the warmth of the Holocene “Climatic Optimum” to the colder conditions of the past three millennia.

Similar results have been reported by Andrus *et al.* (2002) and Moy *et al.* (2002). According to Andrus *et al.*, sea surface temperatures off the coast of Peru some 6,000 years ago were 3° to 4°C warmer than what they were over the decade of the 1990s and provided little evidence of any El Niño activity. Nearby, Moy *et al.* analyzed a sediment core from lake Laguna Pallcacocha in the southern Ecuadorian Andes, producing a proxy measure of ENSO over the past 12,000 years. For the moderate and strong ENSO events detected by their analytical techniques (weaker events are not registered), these researchers state that “the overall trend exhibited in the Pallcacocha record includes a low concentration of events in the early Holocene, followed by increasing occurrence after 7,000 cal. yr BP, with peak event frequency occurring at ~1,200 cal. yr BP,” after which the frequency of events declines dramatically to the present.

With respect to the last 1,200 years of this record, the decline in the frequency of ENSO events is anything but smooth. In coming out of the Dark Ages Cold Period, which was one of the coldest intervals of the Holocene (McDermott *et al.*, 2001), the number of

ENSO events experienced by the earth drops by an order of magnitude, from a high of approximately 33 events per 100 yr to a low of about three events per 100 yr, centered approximately on the year AD 1000, which is right in the middle of the Medieval Warm Period, as delineated by the work of Esper *et al.* (2002). Then, at approximately AD 1250, the frequency of ENSO events exhibits a new peak of approximately 27 events per 100 yr in the midst of the longest sustained cold period of the Little Ice Age, again as delineated by the work of Esper *et al.* Finally, ENSO event frequency declines in zigzag fashion to a low on the order of four to five events per 100 yr at the start of the Current Warm Period, which according to the temperature history of Esper *et al.* begins at about 1940.

Going even further back in time, in a study of a recently revised New England varve chronology derived from proglacial lakes formed during the recession of the Laurentide ice sheet some 17,500 to 13,500 years ago, Rittenour *et al.* (2000) determined that “the chronology shows a distinct interannual band of enhanced variability suggestive of El Niño-Southern Oscillation (ENSO) teleconnections into North America during the late Pleistocene, when the Laurentide ice sheet was near its maximum extent ... during near-peak glacial conditions.” But during the middle of the Holocene, when it was considerably warmer, even than it is today, Overpeck and Webb (2000) report that data from corals suggest that “interannual ENSO variability, as we now know it, was substantially reduced, or perhaps even absent.”

In summing up the available evidence pertaining to the effect of temperature on the frequency of occurrence and strength of ENSO events, we have one of the most sophisticated climate models ever developed to deal with the ENSO phenomenon implying that global warming will promote more frequent El Niño-like conditions. But we also have real-world observations demonstrating that El Niño-like conditions during the latter part of the twentieth century (claimed by the IPCC to be the warmest period of the past 1,300 years) are not much different from those that occurred during much colder times. In addition, we have a number of long-term records that suggest that when the earth was significantly warmer than it is currently, ENSO events were substantially reduced or perhaps even absent.

## 6.5. Precipitation Variability

The IPCC contends that global warming is responsible for causing greater variability in precipitation, leading to more droughts and floods. In this section we review empirical research on precipitation patterns in Africa, Asia, and North America.

Additional information on this topic, including reviews on precipitation not discussed here, can be found at [http://www.co2science.org/subject/p/subject\\_p.php](http://www.co2science.org/subject/p/subject_p.php) under the heading Precipitation.

### 6.5.1. Africa

Nicholson and Yin (2001) described climatic and hydrologic conditions in equatorial East Africa from the late 1700s to close to the present, based on histories of the levels of 10 major African lakes. They also used a water balance model to infer changes in rainfall associated with the different conditions, concentrating most heavily on Lake Victoria. This work revealed “two starkly contrasting climatic episodes.” The first, which began sometime prior to 1800 and was characteristic of Little Ice Age conditions, was one of “drought and desiccation throughout Africa.” This arid episode, which was most extreme during the 1820s and 1830s, was accompanied by extremely low lake levels. As the two researchers describe it, “Lake Naivash was reduced to a puddle ... Lake Chad was desiccated ... Lake Malawi was so low that local inhabitants traversed dry land where a deep lake now resides ... Lake Rukwa [was] completely desiccated ... Lake Chilwa, at its southern end, was very low and nearby Lake Chiuta almost dried up.” Throughout this period, they report that “intense droughts were ubiquitous.” Some were “long and severe enough to force the migration of peoples and create warfare among various tribes.”

As the Little Ice Age’s grip on the world began to loosen in the mid to latter part of the 1800s, however, things began to improve for most of the continent. Nicholson and Yin report that “semi-arid regions of

Mauritania and Mali experienced agricultural prosperity and abundant harvests ... the Niger and Senegal Rivers were continually high; and wheat was grown in and exported from the Niger Bend region.” Across the length of the northern Sahel, maps and geographical reports described the presence of “forests.” As the nineteenth century came to an end and the twentieth century began, there was a slight lowering of lake levels, but nothing like what had occurred a century earlier (i.e., variability was much reduced). And then, in the latter half of the twentieth century, things once again began to pick up for the Africans, with the levels of some of the lakes rivaling the high-stands characteristic of the years of transition to the Current Warm Period.

Concentrating on the more recent past, Nicholson (2001) says the most significant climatic change has been “a long-term reduction in rainfall in the semi-arid regions of West Africa,” which has been “on the order of 20 to 40% in parts of the Sahel.” There have been, she says, “three decades of protracted aridity,” and “nearly all of Africa has been affected ... particularly since the 1980s.” However, she goes on to note that “the rainfall conditions over Africa during the last 2 to 3 decades are not unprecedented,” and that “a similar dry episode prevailed during most of the first half of the 19th century.”

Describing the situation in more detail, Nicholson says “the 3 decades of dry conditions evidenced in the Sahel are not in themselves evidence of irreversible global change,” because a longer historical perspective indicates an even longer period of similar dry conditions occurred between 1800 and 1850. This remarkable dry period occurred when the earth was still in the clutches of the Little Ice Age, a period of cold that is without precedent in at least the past 6,500 years, even in Africa (Lee-Thorp *et al.*, 2001). There is no reason to think that the most recent two- to three-decade Sahelian drought was unusual or that it was caused by the higher temperatures of that period.

Also taking a longer view of the subject were Nguetsop *et al.* (2004), who developed a high-resolution proxy record of West African precipitation based on analyses of diatoms recovered from a sediment core retrieved from Lake Ossa, West Cameroon, which they describe as “the first paleohydrological record for the last 5500 years in the equatorial near-coastal area, east of the Guinean Gulf.” They reported that this record provides evidence for alternating periods of increasing and decreasing precipitation “at a millennial time scale for the last 5500 years,” which oscillatory behavior they

interpret as being “a result of south/northward shifts of the Intertropical Convergence Zone,” specifically noting that “a southward shift of the ITCZ, combined with strengthened northern trade winds, was marked by low and high precipitation at the northern subtropics and the subequatorial zone, respectively,” and that “these events occurred in coincidence with cold spells in the northern Atlantic.”

Most recently, Therrell *et al.* (2006) developed “the first tree-ring reconstruction of rainfall in tropical Africa using a 200-year regional chronology based on samples of *Pterocarpus angolensis* [a deciduous tropical hardwood known locally as Mukwa] from Zimbabwe.” This record revealed that “a decadal-scale drought reconstructed from 1882 to 1896 matches the most severe sustained drought during the instrumental period (1989-1995),” and that “an even more severe drought is indicated from 1859 to 1868 in both the tree-ring and documentary data.” They report, for example, that the year 1860, which exhibited the lowest reconstructed rainfall value during this period, was described in a contemporary account from Botswana (where part of their tree-ring chronology originated) as “a season of ‘severe and universal drought’ with ‘food of every description’ being ‘exceedingly scarce’ and the losses of cattle being ‘very severe’ (Nash and Endfield, 2002).” At the other end of the moisture spectrum, they report that “a 6-year wet period at the turn of the nineteenth century (1897-1902) exceeds any wet episode during the instrumental era.”

### 6.5.2. Asia

Pederson *et al.* (2001) developed tree-ring chronologies for northeastern Mongolia and used them to reconstruct annual precipitation and streamflow histories for the period 1651-1995. Working with both standard deviations and five-year intervals of extreme wet and dry periods, they found that “variations over the recent period of instrumental data are not unusual relative to the prior record.” They note, however, that their reconstructions “appear to show more frequent extended wet periods in more recent decades,” but they say that this observation “does not demonstrate unequivocal evidence of an increase in precipitation as suggested by some climate models.” Spectral analysis of the data also revealed significant periodicities around 12 and 20-24 years, which they suggested may constitute “possible evidence for solar influences in these reconstructions for northeastern Mongolia.”

Kripalani and Kulkarni (2001) studied seasonal summer monsoon (June-September) rainfall data from 120 east Asia stations for the period 1881-1998. A series of statistical tests they applied to these data revealed the presence of short-term variability in rainfall amounts on decadal and longer time scales, the longer “epochs” of which were found to last for about three decades over China and India and for approximately five decades over Japan. With respect to long-term trends, however, none was detected. Consequently, the history of summer rainfall trends in east Asia does not support claims of intensified monsoonal conditions in this region as a result of CO<sub>2</sub>-induced global warming. As for the decadal variability inherent in the record, the two researchers say it “appears to be just a part of natural climate variations.”

Taking a much longer look at the Asian monsoon were Ji *et al.* (2005), who used reflectance spectroscopy on a sediment core taken from a lake in

the northeastern part of the Qinghai-Tibetan Plateau to obtain a continuous high-resolution proxy record of the Asian monsoon over the past 18,000 years. This project indicated that monsoonal moisture since the late glacial period had been subject to “continual and cyclic variations,” among which was a “very abrupt onset and termination” of a 2,000-year dry spell that started about 4,200 years ago (yr BP) and ended around 2,300 yr BP. Other variations included the well-known centennial-scale cold and dry spells of the Dark Ages Cold Period (DACP) and Little Ice Age (LIA), which lasted from 2,100 yr BP to 1,800 yr BP and 780 yr BP to 400 yr BP, respectively, while sandwiched between them was the warmer and wetter Medieval Warm Period, and preceding the DACP was the Roman Warm Period. Time series analyses of the sediment record also revealed several statistically significant periodicities (123, 163, 200, and 293 years, all above the 95 percent level), with the 200-year cycle matching the de Vries or Suess solar cycle, implying that changes in solar activity are important triggers for some of the recurring precipitation changes in that part of Asia. It is clear that large and abrupt fluctuations in the Asian monsoon have occurred numerous times and with great regularity throughout the Holocene, and that the sun played an important role in orchestrating them.

Also working on the Tibetan Plateau were Shao *et al.* (2005), who used seven Qilian juniper ring-width chronologies from the northeastern part of the Qaidam Basin to reconstruct a thousand-year history of annual precipitation there. In doing so, they discovered that annual precipitation had fluctuated at various intervals and to various degrees throughout the entire past millennium. Wetter periods occurred between 1520 and 1633, as well as between 1933 and 2001, although precipitation has declined somewhat since the 1990s. Drier periods, on the other hand, occurred between 1429 and 1519 and between 1634 and 1741. With respect to variability, the scientists report that the magnitude of variation in annual precipitation was about 15 mm before 1430, increased to 30 mm between 1430 and 1850, and declined thereafter to the present.

Based on analyses of tree-ring width data and their connection to large-scale atmospheric circulation, Touchan *et al.* (2005) developed summer (May-August) precipitation reconstructions for several parts of the eastern Mediterranean region (Turkey, Syria, Lebanon, Cyprus, and Greece) that extend back in time anywhere from 115 to 600 years. Over the latter length of time, they found that May-

August precipitation varied on multiannual and decadal timescales, but that on the whole there were no long-term trends. The longest dry period occurred in the late sixteenth century (1591-1595), while there were two extreme wet periods: 1601-1605 and 1751-1755. In addition, both extremely strong and weak precipitation events were found to be more variable over the intervals 1520-1590, 1650-1670, and 1850-1930. The results of this study demonstrate there was nothing unusual or unprecedented about late twentieth century precipitation events in the eastern Mediterranean part of Asia that would suggest a CO<sub>2</sub> influence.

Last, Davi *et al.* (2006) used absolutely dated tree-ring-width chronologies obtained from five sampling sites in west-central Mongolia to derive individual precipitation models, the longest of which stretches from 1340 to 2002, additionally developing a reconstruction of streamflow that extends from 1637 to 1997. In the process of doing so, they discovered there was “much wider variation in the long-term tree-ring record than in the limited record of measured precipitation,” which for the region they studied covers the period from 1937 to 2003. In addition, they say their streamflow history indicates that “the wettest 5-year period was 1764-68 and the driest period was 1854-58,” while “the most extended wet period [was] 1794-1802 and ... extended dry period [was] 1778-83.” For this part of Mongolia, therefore, which the researchers say is “representative of the central Asian region,” there is no support to be found for the contention that the “unprecedented warming” of the twentieth century has led to increased variability in precipitation and streamflow.

These several findings suggest that either there is nothing unusual about Asia’s current degree of warmth, i.e., it is not unprecedented relative to that of the early part of the past millennium, or unprecedented warming need not lead to unprecedented precipitation or unprecedented precipitation variability ... or both of the above. We conclude that the findings of this study and of others reviewed in this section provide no support for the contention that global warming leads to greater and more frequent precipitation extremes in Asia.

### 6.5.3. North America

Cronin *et al.* (2000) studied salinity gradients across sediment cores extracted from Chesapeake Bay, the largest estuary in the United States, in an effort to determine precipitation variability in the surrounding watershed over the prior millennium. They discovered there was a high degree of decadal and multidecadal variability in moisture conditions over the 1,000-year period, with regional precipitation totals fluctuating by between 25 percent and 30 percent, often in extremely rapid shifts occurring over about a decade. They also determined that precipitation was generally greater over the past two centuries than it was over the eight previous centuries, with the exception of a portion of the Medieval Warm Period (AD 1250-1350), when the climate was extremely wet. In addition, they found that the region surrounding Chesapeake Bay had experienced several “mega-droughts” lasting from 60-70 years, some of which the researchers say “were more severe than twentieth

century droughts.” Likewise, across the continent, Haston and Michaelsen (1997) developed a 400-year history of precipitation for 29 stations in coastal and near-interior California between San Francisco Bay and the U.S.-Mexican border using tree-ring chronologies; their work also revealed that “region-wide precipitation during the last 100 years has been unusually high and less variable compared to other periods in the past.”

Crossing the continent yet again, and dropping down to the Caribbean Sea, Watanabe *et al.* (2001) analyzed delta  $^{18}\text{O}/^{16}\text{O}$  and Mg/Ca ratios in cores obtained from a coral in an effort designed to examine seasonal variability in sea surface temperature and salinity there during the Little Ice Age. In doing so, they found that sea surface temperatures during this period were about 2°C colder than they are currently, while sea surface salinity exhibited greater variability than it does now, indicating that during the Little Ice Age “wet and dry seasons were more pronounced.”

In Canada, Zhang *et al.* (2001) analyzed the spatial and temporal characteristics of extreme precipitation events for the period 1900-1998, using what they describe as “the most homogeneous long-term dataset currently available for Canadian daily precipitation.” This exercise indicated that decadal-scale variability was a dominant feature of both the frequency and intensity of extreme precipitation events, but it provided “no evidence of any significant long-term changes” in these indices during the twentieth century. Their analysis of precipitation totals (extreme and non-extreme) did reveal a slightly increasing trend across Canada during the period of study, but it was found to be due to increases in the number of non-heavy precipitation events. Consequently, the researchers concluded that “increases in the concentration of atmospheric greenhouse gases during the twentieth century have not been associated with a generalized increase in extreme precipitation over Canada.”

Dropping down into the Uinta Basin Watershed of northeastern Utah, Gray *et al.* (2004) used cores extracted from 107 piñon pines at four different sites to develop a proxy record of annual (June to June) precipitation spanning the period AD 1226-2001. They report that “single-year dry events before the instrumental period tended to be more severe than those after 1900,” and that decadal-scale dry events were longer and more severe prior to 1900 as well. In particular, they found that “dry events in the late 13th, 16th, and 18th centuries surpass the magnitude and duration of droughts seen in the Uinta Basin after

1900.” At the other end of the spectrum, they report that the twentieth century contained two of the strongest wet intervals (1938-1952 and 1965-1987), although the two periods were only the seventh and second most intense wet regimes, respectively, of the entire record. Hence, it would appear that in conjunction with twentieth century global warming, precipitation extremes (both high and low) within the Uinta Basin of northeastern Utah have become attenuated as opposed to amplified.

Last, we come to the study of Rasmussen *et al.* (2006), who had previously demonstrated that “speleothems from the Guadalupe Mountains in southeastern New Mexico are annually banded, and variations in band thickness and mineralogy can be used as a record of regional relative moisture (Asmerom and Polyak, 2004).” In their new study, they continued this tack, concentrating on “two columnar stalagmites collected from Carlsbad Cavern (BC2) and Hidden Cave (HC1) in the Guadalupe Mountains.”

The three researchers report that “both records, BC2 and HC1, suggest periods of dramatic precipitation variability over the last 3000 years, exhibiting large shifts *unlike anything seen in the modern record* [our italics].” Second, they report that the time interval from AD 900-1300 coincides with the well-known Medieval Warm Period and “shows dampened precipitation variability and overall drier conditions” that are “consistent with the idea of more frequent La Niña events and/or negative PDO phases causing elevated aridity in the region during this time.” Third, they indicate that the preceding and following colder centuries “show increased precipitation variability ... coinciding with increased El Niño flooding events.”

Clearly, moisture extremes in North America much greater than those observed in the modern era are neither unusual nor manmade; they are simply a normal part of earth’s natural climatic variability. In this regard, North America is like Africa and Asia: Precipitation variability in the Current Warm Period is no greater than what was experienced in earlier times.

Additional information on this topic, including reviews of newer publications as they become available, can be found at <http://www.co2science.org/subject/p/variabilnortham.php>.

## 6.6. Storms

Among the highly publicized changes in weather phenomena that are predicted to attend the ongoing rise in the air's  $\text{CO}_2$  content are increases in the frequency and severity of all types of storms. Many researchers have examined historical and proxy records in an attempt to determine how temperature changes over the past millennium or two have affected this aspect of earth's climate. This section reviews what some of them have learned about storm trends, focusing on Europe and North America.

A number of studies have reported increases in North Atlantic storminess over the last two decades of the twentieth century (Jones *et al.*, 1997; Gunther *et al.*, 1998; Dickson *et al.*, 2000). Since the IPCC claims this period was the warmest of the past millennium, this observation might appear to

vindicate their view of the subject. When much longer time periods are considered, however, the storminess of the twentieth century is found to be not uncommon and even mild compared to times when temperatures and  $\text{CO}_2$  levels were lower.

Dawson *et al.* (2002) searched daily meteorological records from Stornoway (Outer Hebrides), Lerwick (Shetland Islands), Wick (Caithness), and Fair Isle (west of the Shetland Islands) for all data pertaining to gale-force winds over the period 1876-1996, which they used to construct a history of storminess for that period for northern and northwestern Scotland. This history indicated that although North Atlantic storminess and associated wave heights had indeed increased over the prior two decades, storminess in the North Atlantic region "was considerably more severe during parts of the nineteenth century than in recent decades." In addition, whereas the modern increase in storminess appeared to be associated with a spate of substantial positive values of the North Atlantic Oscillation (NAO) index, they say "this was not the case during the period of exceptional storminess at the close of the nineteenth century." During that earlier period, the conditions that fostered modern storminess were apparently overpowered by something even more potent, i.e., cold temperatures, which in the view of Dawson *et al.* led to an expansion of sea ice in the Greenland Sea that expanded and intensified the Greenland anticyclone, which in turn led to the North Atlantic cyclone track being displaced farther south. Additional support for this view is provided by the hypothesis propounded by Clarke *et al.* (2002), who postulated that a southward spread of sea ice and polar water results in an increased thermal gradient between  $50^\circ\text{N}$  and  $65^\circ\text{N}$  that intensifies storm activity in the North Atlantic and supports dune formation in the Aquitaine region of southwest France.

The results of these two studies suggest that the increased storminess and wave heights observed in the European sector of the North Atlantic Ocean over the past two decades are not the result of global warming. Rather, they are associated with the most recent periodic increase in the NAO index. Furthermore, a longer historical perspective reveals that North Atlantic storminess was even more severe than it is now during the latter part of the nineteenth century, when it was significantly colder than it is now. In fact, the storminess of that much colder period was so great that it was actually decoupled from the NAO index. Hence, the long view of history suggests that the global warming of the past century

or so has actually led to an overall *decrease* in North Atlantic storminess.

Additional evidence for the recent century-long decrease in storminess in and around Europe comes from the study of Bijl *et al.* (1999), who analyzed long-term sea-level records from several coastal stations in northwest Europe. According to these researchers, “although results show considerable natural variability on relatively short (decadal) time scales,” there is “no sign of a significant increase in storminess ... over the complete time period of the data sets.” In the southern portion of the North Sea, however, where natural variability was more moderate, they did find a trend, but it was “a tendency towards a weakening of the storm activity over the past 100 years.”

Much the same results were obtained by Pirazzoli (2000), who analyzed tide-gauge, wind, and atmospheric pressure data over the period 1951-1997 for the northern portion of the Atlantic coast of France. In that study, the number of atmospheric depressions (storms) and strong surge winds were found to be decreasing in frequency. In addition, it was reported that “ongoing trends of climate variability show a decrease in the frequency and hence the gravity of coastal flooding.”

Tide-gauge data also have been utilized as proxies for storm activity in England. Based on high-water measurements made at the Liverpool waterfront over the period 1768-1999, Woodworth and Blackman (2002) found that the annual maximum surge-at-high-water declined at a rate of  $0.11 \pm 0.04$  meters per century, suggesting that the winds responsible for producing high storm surges were much stronger and/or more common during the early part of the record (colder Little Ice Age) than the latter part (Current Warm Period).

On a somewhat different front, and quite a ways inland, Bielec (2001) analyzed thunderstorm data from Cracow, Poland for the period 1896-1995, finding an average of 25 days of such activity per year, with a non-significant linear-regression-derived increase of 1.6 storm days from the beginning to the end of the record. From 1930 onward, however, the trend was negative, revealing a similarly derived decrease of 1.1 storm days. In addition, there was a decrease in the annual number of thunderstorms with hail over the entire period and a decrease in the frequency of storms producing precipitation in excess of 20 mm.

In introducing a study they conducted in Switzerland, Stoffel *et al.* (2005) noted that debris

flows are a type of mass movement that frequently causes major destruction in alpine areas; and they reported that since 1987 there had been an apparent above-average occurrence of such events in the Valais region of the Swiss Alps, which had prompted some researchers to suggest that the increase was the result of global warming (Rebetez *et al.*, 1997). Consequently, Stoffel *et al.* used dendrochronological methods to determine if the recent increase in debris-flow events was indeed unusual, and if it appeared that it was, to see if it made sense to attribute it to CO<sub>2</sub>-induced global warming.

In extending the history of debris-flow events (1922-2002) back to the year 1605, they found that “phases with accentuated activity and shorter recurrence intervals than today existed in the past, namely after 1827 and until the late nineteenth century.” What is more, the nineteenth century period of high-frequency debris flow was shown to coincide with a period of higher flood activity in major Swiss rivers, while less frequent debris flow activity after 1922 corresponded with lower flooding frequencies. In addition, debris flows from extremely large mass movement events, similar to what occurred in 1993, were found to have “repeatedly occurred” in the historical past, and to have been of such substantial magnitude that, in the opinion of Stoffel *et al.*, the “importance of the 1993 debris-flow surges has to be thoroughly revised.” They reported that debris flows occurred “ever more frequently in the nineteenth century than they do today” and concluded that “correlations between global warming and modifications in the number or the size of debris-flow events, as hypothesized by, e.g., Haeberli and Beniston (1998), cannot, so far, be confirmed in the study area.”

Noting that “a great amount of evidence for changing storminess over northwestern Europe is based on indirect data and reanalysis data rather than on station wind data,” Smits *et al.* (2005) investigated trends in storminess over the Netherlands based on hourly records of 10-m wind speed observations made at 13 meteorological stations scattered across the country that have uninterrupted records for the time period 1962-2002. This effort led to their discovery that “results for moderate wind events (that occur on average 10 times per year) and strong wind events (that occur on average twice a year) indicate a decrease in storminess over the Netherlands [of] between 5 and 10% per decade.”

Moving cross-continent to the south and west, Raicich (2003) analyzed 62 years of sea-level data for

the period 1 July 1939 to 30 June 2001 at Trieste, in the Northern Adriatic, to determine historical trends of surges and anomalies. This work revealed that weak and moderate positive surges did not exhibit any definite trends, while strong positive surges clearly became less frequent, even in the face of a gradually rising sea level, “presumably,” in the words of Raicich, “as a consequence of a general weakening of the atmospheric activity,” which was also found to have been the case for Brittany by Pirazzoli (2000).

Further north, Björck and Clemmensen (2004) extracted cores of peat from two raised bogs in the near-coastal part of southwest Sweden, from which they derived histories of wind-transported clastic material via systematic counts of quartz grains of various size classes that enabled them to calculate temporal variations in Aeolian Sand Influx (ASI), which has been shown to be correlated with winter wind climate in that part of the world. In doing so, they found that “the ASI records of the last 2500 years (both sites) indicate two timescales of winter storminess variation in southern Scandinavia.” Specifically, they note that “decadal-scale variation (individual peaks) seems to coincide with short-term variation in sea-ice cover in the North Atlantic and is thus related to variations in the position of the North Atlantic winter season storm tracks,” while “centennial-scale changes—peak families, like high peaks 1, 2 and 3 during the Little Ice Age, and low peaks 4 and 5 during the Medieval Warm Period—seem to record longer-scale climatic variation in the frequency and severity of cold and stormy winters.”

Björck and Clemmensen also found a striking association between the strongest of these winter storminess peaks and periods of reduced solar activity. They specifically note, for example, that the solar minimum between AD 1880 and 1900 “is almost exactly coeval with the period of increased storminess at the end of the nineteenth century, and the Dalton Minimum between AD 1800 and 1820 is almost coeval with the period of peak storminess reported here.” In addition, they say that an event of increased storminess they dated to AD 1650 “falls at the beginning of the Maunder solar minimum (AD 1645-1715),” while further back in time they report high ASI values between AD 1450 and 1550 with “a very distinct peak at AD 1475,” noting that this period coincides with the Spörer Minimum of AD 1420-1530. In addition, they call attention to the fact that the latter three peaks in winter storminess all occurred during the Little Ice Age and “are among the most prominent in the complete record.”

Last, the two researchers report that degree of humification (DOH) intervals “correlate well with the classic late-Holocene climatic intervals,” which they specifically state to include the Modern Climate Optimum (100-0 cal. yr BP), the Little Ice Age (600-100 cal. yr BP), the Medieval Warm Period (1,250-600 cal. yr BP), the Dark Ages Cold Period (1,550-1,250 cal. yr BP) and the Roman Climate Optimum (2,250-1,550 cal. yr BP). There would thus appear to be little doubt that winter storms throughout southern Scandinavia were more frequent and intense during the multi-century Dark Ages Cold Period and Little Ice Age than they were during the Roman Warm Period, the Medieval Warm Period, and the Current Warm Period, providing strong evidence to refute the IPCC’s contention that storminess tends to increase during periods of greater warmth. In the real world, just the opposite would appear to be the case.

Also working in Sweden were Barring and von Storch (2004), who say the occurrence of extreme weather events may “create the perception that ... the storms lately have become more violent, a trend that may continue into the future.” These two researchers analyzed long time series of pressure readings for Lund (since 1780) and Stockholm (since 1823), analyzing (1) the annual number of pressure observations below 980 hPa, (2) the annual number of absolute pressure tendencies exceeding 16 hPa/12h, and (3) intra-annual 95th and 99th percentiles of the absolute pressure differences between two consecutive observations. They determined that the storminess time series they developed “are remarkably stationary in their mean, with little variations on time scales of more than one or two decades.” They note that “the 1860s-70s was a period when the storminess indices showed general higher values,” as was the 1980s-90s, but that, subsequently, “the indices have returned to close to their long-term mean.”

Barring and von Storch conclude that their storminess proxies “show no indication of a long-term robust change towards a more vigorous storm climate.” In fact, during “the entire historical period,” in their words, storminess was “remarkably stable, with no systematic change and little transient variability.” We can conclude that for much of Sweden, at least, there was no warming-induced increase in windstorms over the entire transitional period between the Little Ice Age and the Current Warm Period.

Dawson *et al.* (2004b) examined the sedimentary characteristics of a series of Late Holocene coastal

windstorm deposits found on the Scottish Outer Hebrides, an island chain that extends across the latitudinal range 56-58°N. These deposits form part of the landward edges of coastal sand accumulations that are intercalated with peat, the radiocarbon dating of which was used to construct a local chronology of the windstorms. This work revealed that “the majority of the sand units were produced during episodes of climate deterioration both prior to and after the well-known period of Medieval warmth.” The researchers also say “the episodes of sand blow indicated by the deposits may reflect periods of increased cyclogenesis in the Atlantic associated with increased sea ice cover and an increase in the thermal gradient across the North Atlantic region.” In addition, they report that “dated inferred sand drift episodes across Europe show synchronicity with increased sand mobilization in SW France, NE England, SW Ireland and the Outer Hebrides, implying a regional response to storminess with increased sand invasion during the cool periods of the Little Ice Age,” citing the corroborative studies of Lamb (1995), Wintle *et al.* (1998), Gilbertson *et al.* (1999), and Wilson *et al.* (2001). Throughout a vast portion of the North Atlantic Ocean and adjacent Europe, therefore, storminess and wind strength appear to have been inversely related to mean global air temperature over most of the past two millennia, with the most frequent and intense events occurring both prior to and following the Medieval Warm Period.

Dawson *et al.* (2004a) examined 120- to 225-year records of gale-days per year from five locations scattered across Scotland, northwest Ireland, and Iceland, which they compared with a much longer 2,000-year record for the same general region. In doing so, they found that four of the five century-scale records showed a greater frequency of storminess in the cooler 1800s and early 1900s than throughout the remainder of the warmer twentieth century. In addition, they report that “considered over the last ca. 2000 years, it would appear that winter storminess and climate-driven coastal erosion was at a minimum during the Medieval Warm Period,” which again is just the opposite of what the IPCC forecasts, i.e., more storminess with warmer temperatures.

Moving over to the United States, Zhang *et al.* (2000) used 10 long-term records of storm surges derived from hourly tide gauge measurements to calculate annual values of the number, duration, and integrated intensity of storms in eastern North America. Their analysis did not reveal any trends in storm activity during the twentieth century, which

they say is suggestive of “a lack of response of storminess to minor global warming along the U.S. Atlantic coast during the last 100 yr.”

Similar results were found by Boose *et al.* (2001). After scouring historical records to reconstruct hurricane damage regimes for an area composed of the six New England states plus adjoining New York City and Long Island for the period 1620-1997, they could discern “no clear century-scale trend in the number of major hurricanes.” For the most recent and reliable 200-year portion of the record, however, the cooler nineteenth century had five of the highest-damage category 3 storms, while the warmer twentieth century had only one such storm. Hence, as the earth experienced the warming associated with its recovery from the cold temperatures of the Little Ice Age, it would appear this part of the planet (New England, USA) experienced a decline in the intensity of severe hurricanes.

Going back further in time, Noren *et al.* (2002) extracted sediment cores from 13 small lakes distributed across a 20,000-km<sup>2</sup> region of Vermont and eastern New York, finding that “the frequency of storm-related floods in the northeastern United States has varied in regular cycles during the past 13,000 years (13 kyr), with a characteristic period of about 3 kyr.” The most recent upswing in storminess did not begin with what the supposedly unprecedented warming of the twentieth century, but “at about 600 yr BP [Before Present], coincident with the beginning of the Little Ice Age.” According to the authors, the increase in storminess was likely a product of natural changes in the Arctic Oscillation.

Moving to southern North America, land-falling hurricanes whose eyes crossed the coast between Cape Sable, Florida and Brownsville, Texas between 1896 and 1995 were the subject of investigation by Bove *et al.* (1998). The authors note that the first half of the twentieth century saw considerably more hurricanes than the last half: 11.8 per decade vs. 9.4 per decade. The same holds true for intense hurricanes of category 3 on the Saffir-Simpson storm scale: 4.8 vs. 3.6. The numbers of all hurricanes and the numbers of intense hurricanes have both been trending downward since 1966, with the decade starting in 1986 exhibiting the fewest intense hurricanes of the century.

Liu and Fearn (1993) also studied major storms along the U.S. Gulf Coast, but over a much longer time period: the past 3,500 years. Using sediment cores taken from the center of Lake Shelby in Alabama they determined that “major hurricanes of

category 4 or 5 intensity directly struck the Alabama coast ... with an average recurrence interval of ~600 years,” the last of which super-storms occurred around 700 years ago. They further note that “climate modeling results based on scenarios of greenhouse warming predict a 40%—50% increase in hurricane intensities in response to warmer tropical oceans.” If one of these severe storms (which is now about a century overdue) were to hit the Alabama coast again, some commentators would probably cite its occurrence as vindication of the IPCC’s doomsday predictions. In reality, it would be the result of natural (not man-made) causes.

Muller and Stone (2001) examined historical data relating to tropical storm and hurricane strikes along the southeast U.S. coast from South Padre Island, Texas to Cape Hatteras, North Carolina for the 100-year period 1901-2000. Their analysis revealed that the temporal variability of tropical storm and hurricane strikes was “great and significant,” with most coastal sites experiencing “pronounced clusters of strikes separated by tens of years with very few strikes.” With respect to the claim of a tendency for increased storminess during warmer El Niño years, the data didn’t cooperate. For tropical storms and hurricanes together, the authors found an average of 1.7 storms per El Niño season, 2.6 per neutral season, and 3.3 per La Niña season. For hurricanes only, the average rate of occurrence ranged from 0.5 per El Niño season to 1.7 per La Niña season.

In the interior of the United States, Changnon and Changnon (2000) examined hail-day and thunder-day occurrences over the 100-year period 1896-1995 in terms of 20-year averages obtained from records of 66 first-order weather stations distributed across the country. They found that the frequency of thunder-days peaked in the second of the five 20-year intervals, while hail-day frequency peaked in the third or middle interval. Thereafter, both parameters declined to their lowest values of the century in the final 20-year period. Hail-day occurrence, in fact, decreased to only 65 percent of what it was at mid-century, accompanied by a drop in national hail insurance losses over the same period.

After completing this large regional study, S.A. Changnon (2001) turned his attention to an urban and a more rural site in Chicago in an attempt to determine if there might be an urban heat island influence on thunderstorm activity. Over the 40-year period investigated (1959-1998), he found the urban station experienced an average of 4.5 (12 percent) more thunderstorm days per year than the more rural

station; statistical tests revealed this difference to be significant at the 99 percent level in all four seasons of the year. This suggests that the actual decreases in hail- and thunder-days Changnon and Changnon found for the interior of the United States over the last half of the twentieth century may well have been even greater than what they reported in 2000.

Also in the interior of North America, Schwartz and Schmidlin (2002) compiled a blizzard database for the years 1959-2000 for the conterminous United States. A total of 438 blizzards were identified in the 41-year record, yielding an average of 10.7 blizzards per year. Year-to-year variability was significant, with the number of annual blizzards ranging from a low of 1 in the winter of 1980/81 to a high of 27 during the winter of 1996/97. Linear regression analysis revealed a statistically significant increase in the annual number of blizzards during the 41-year period; but the total area affected by blizzards each winter remained relatively constant and showed no trend. If these observations are both correct, then average blizzard size is much smaller now than it was four decades ago. As the authors note, however, “it may also be that the NWS is recording smaller, weaker blizzards in recent years that went unrecorded earlier in the period, as occurred also in the official record of tornadoes in the United States.”

The results of this study thus suggest that—with respect to U.S. blizzards—frequency may have increased, but if it did, intensity likely decreased. On the other hand, the study’s authors suggest that the reported increase in blizzard frequency may well be due to an observational bias that developed over the years, for which there is a known analogue in the historical observation of tornados. For example, Gulev *et al.* (2001) analyzed trends in Northern Hemispheric winter cyclones over essentially the same time period (1958-1999) and found a statistically significant decline of 1.2 cyclones per year using NCEP/NCAR reanalysis pressure data.

Further evidence that the blizzard frequency data are observationally biased can be deduced from the study of Hayden (1999), who investigated storm frequencies over North America between 25° and 55°N latitude and 60° and 125°W longitude from 1885 to 1996. Over this 112-year period, Hayden reports that large regional changes in storm occurrences were observed; but when integrated over the entire geographic area, no net change in storminess was evident.

To the north, Mason and Jordan (2002) studied numerous depositional environments along the

tectonically stable, unglaciated eastern Chuckchi Sea coast that stretches across northwest Alaska, deriving a 6,000-year record of sea-level change while simultaneously learning some interesting things about the correlation between storminess and climate in that part of the world. With respect to storminess, they learned that “in the Chukchi Sea, storm frequency is correlated with colder rather than warmer climatic conditions.” Consequently, they say that their data “do not therefore support predictions of more frequent or intense coastal storms associated with atmospheric warming for this region.”

Hudak and Young (2002) examined the number of fall (June-November) storms in the southern Beaufort Sea region based on criteria of surface wind speed for the relatively short period of 1970-1995. Although there was considerable year-to-year variability in the number of storms, there was no discernible trend over the 26-year period in this region of the globe, where climate models predict the effects of CO<sub>2</sub>-induced global warming would be most evident.

In conclusion, as the earth has warmed over the past 150 years during its recovery from the global chill of the Little Ice Age there has been no significant increase in either the frequency or intensity of stormy weather in Europe and North America. In fact, most studies suggest just the opposite has probably occurred.

Additional information on this topic, including reviews of storms not discussed here, can be found at [http://www.co2science.org/subject/s/subject\\_s.php](http://www.co2science.org/subject/s/subject_s.php) under the heading Storms.

## 6.7. Snow

The IPCC claims “snow cover has decreased in most regions, especially in spring,” and “decreases in snowpack have been documented in several regions worldwide based upon annual time series of mountain snow water equivalent and snow death. (IPCC, 2007-I, p. 43). Later in the report, the authors claim “observations show a global-scale decline of snow and ice over many years, especially since 1980 and increasing during the past decade, despite growth in some places and little change in others” (p. 376). Has global warming really caused there to be less snow? We addressed this question regarding polar regions in Chapters 3 and 4 of this report. In this section, we focus (as the IPCC does) on studies conducted in North America.

Brown (2000) employed data from Canada and the United States to reconstruct monthly snow cover properties over mid-latitude (40-60°N) regions of North America back to the early 1900s, finding evidence of what he described as “a general twentieth century increase in North American snow cover extent, with significant increases in winter (December-February) snow water equivalent averaging 3.9% per decade.” This finding is consistent with climate model simulations that indicate increased precipitation in response to global warming, but it covers too little time to tell us much about the *cause* of increased snow cover.

Moore *et al.* (2002) studied a longer period of time in their analysis of a 103-meter ice core retrieved from a high elevation site on Mount Logan—Canada’s highest mountain—which is located in the heavily glaciated Saint Elias region of the Yukon. From this deep core, as well as from some shallow coring and snow-pit sampling, they derived a snow accumulation record that extended over three centuries (from 1693 to 2000), which indicated that heavier snow accumulation at their study site was generally associated with warmer tropospheric temperatures over northwestern North America.

Over the first half of their record, there is no significant trend in the snow accumulation data. From 1850 onward, however, there is a positive trend that is significant at the 95 percent confidence level, which indicates that recovery from the cold conditions of the Little Ice Age began in the mid-1800s, well before there was a large increase in the air’s CO<sub>2</sub> concentration. This finding is further strengthened by the temperature reconstruction of Esper *et al.* (2002), which places the start of modern warming at about the same time as that suggested by Moore *et al.*’s snow data, contradicting the temperature record of Mann *et al.* (1998, 1999), which puts the beginning of the modern warming trend at about 1910.

Cowles *et al.* (2002) analyzed snow water equivalent (SWE) data obtained from four different measuring systems—snow courses, snow telemetry, aerial markers, and airborne gamma radiation—at more than 2,000 sites in the 11 westernmost states of the conterminous USA over the period 1910-1998, finding that the long-term SWE trend of the region was negative, indicative of declining winter precipitation. In addition, they report that their results “reinforce more tenuous conclusions made by previous authors,” citing Changnon *et al.* (1993) and McCabe and Legates (1995), who studied snow course data from 1951-1985 and 1948-1987, respectively, at 275 and 311 sites, and who also found a decreasing trend in SWE at most sites in the Pacific Northwest.

Schwartz and Schmidlin (2002) examined past issues of *Storm Data*—a publication of the U.S. National Weather Service (NWS)—to compile a blizzard database for the years 1959-2000 for the conterminous United States. This effort resulted in a total of 438 blizzards being identified in the 41-year record, yielding an average of 10.7 blizzards per year; linear regression analysis revealed a statistically significant increase in the annual number of blizzards during the 41-year period. However, the total *area*

affected by blizzards each winter remained relatively constant. If these observations are both correct, average blizzard size must have decreased over the four-decade period. On the other hand, as the researchers note, “it may also be that the NWS is recording smaller, weaker blizzards in recent years that went unrecorded earlier in the period, as occurred also in the official record of tornadoes in the United States.”

In a study of winter weather variability, Woodhouse (2003) generated a tree-ring based reconstruction of SWE for the Gunnison River basin of western Colorado that spans the period 1569-1999. This work revealed, in her words, that “the twentieth century is notable for several periods that lack extreme years.” She reports that “the twentieth century is notable for several periods that contain few or no extreme years, for both low and high SWE extremes.”

Lawson (2003) examined meteorological records for information pertaining to the occurrence and severity of blizzards within the Prairie Ecozone of western Canada. Over the period 1953-1997, no significant trends were found in central and eastern locations. However, there was a significant *downward* trend in blizzard frequency in the western prairies; Lawson remarks that “this trend is consistent with results found by others that indicate a decrease in cyclone frequency over western Canada.” He also notes that the blizzards that do occur there “exhibit no trend in the severity of their individual weather elements.” These findings, in his words, “serve to illustrate that the changes in extreme weather events anticipated under Climate Change may not always be for the worse.”

Berger *et al.* (2003) collected a 50-year record (1949/1950 to 1998/1999) of snowfall occurrences using data from a dense network of cooperative station observations covering northwest and central Missouri provided by the Missouri Climate Center. The study looked at long-term trends and interannual variability in snowfall occurrence as related to sea surface temperature variations in the Pacific Ocean basin associated with the El Niño and Southern Oscillation (ENSO) and the North Pacific Oscillation (NPO). These trends and variations were then related to four synoptic-scale flow regimes that produce these snowfalls in the Midwest. The authors found no significant long-term trend in overall snowfall occurrence and a decrease in the number of extreme events ( $\geq 10$  in,  $> 25$  cm) was noted. Two years later, Lupo *et al.* (2005) assembled a similar 54-year

database (1948/1949 to 2002/2003) of snowfall occurrences for southwest Missouri and found “no variability or trends with respect to longer-term climatic variability and/or climate change.”

Bartlett *et al.* (2005) set out to determine what changes might have occurred in the mean onset date of snow and its yearly duration in North America over the period 1950-2002, based on data for the contiguous United States that come from the 1,062 stations of the U.S. Historical Climatology Network, data for Canada that come from the 3,785 stations of the Canadian Daily Climate Dataset, and data for Alaska that come from the 543 stations of the National Weather Service cooperative network in that state. As a result of their efforts, the three researchers found that “for the period 1961-1990 the mean snow onset date in North America [was] 15 December, with mean snow cover duration of 81 days.” They report there were “no significant trends in either onset or duration from 1950 to 2002.” However, interannual variations of as much as 18 and 15 days in onset and duration, respectively, were present in the data; for both parameters they report that “no net trend was observed.”

We find it significant that from 1950 to 2002, during which time the air’s CO<sub>2</sub> concentration rose by 20 percent (from approximately 311 to 373 ppm), there was no net change in either the mean onset or duration of snow cover for the entire continent of North America. To provide some context for this 62-ppm increase in atmospheric CO<sub>2</sub> concentration, we note that it is essentially identical to the mean difference between the highs and lows of the three interglacials and glacials reported by Siegenthaler *et al.* (2005) for the period prior to 430,000 years ago. Surely, one would expect that such a change should have had some effect on North American snow cover—unless, of course, atmospheric CO<sub>2</sub> enrichment has very little or no impact on climate.

Julander and Bricco (2006) reported that snowpack data were being consistently used as indicators of global warming, and that individuals doing so should quantify, as best they could, all other influences embedded in their data. That meeting this requirement is no trivial undertaking is indicated by their statement that “snow data may be impacted by site physical changes, vegetation changes, weather modification, pollution, sensor changes, changes in transportation or sampling date, comparisons of snow course to SNOTEL data, changes in measurement personnel or recreational and other factors,” including sensors that “do not come back to zero at the end of

the snow season.” In an analysis of 134 sites (some having pertinent data stretching back to at least 1912), they thus selected 15 long-term Utah snow courses representing complete elevational and geographic coverage of the dominant snowpacks within the state and adjusted them for the major known site conditions affecting the data, after which the adjusted data for the period 1990-2005 were “compared to earlier portions of the historic record to determine if there were statistically significant differences in snowpack characteristics, particularly those that could indicate the impacts of global warming.”

Of the 15 sites studied in greatest detail, the two researchers found that seven of them exhibited increased snowpack in recent years, while eight exhibited decreased snow accumulation. They also report that “six of the seven sites with increases have significant vegetative or physical conditions leading us to believe that the impacts associated with this analysis are overstated.” The ultimate conclusion of Julander and Bricco, therefore, was that “any signature of global warming currently present in the snowpack data of Utah is not yet at a level of statistical significance ... and will likely be very difficult to isolate from other causes of snowpack decline.”

Changnon and Changnon (2006) analyzed the spatial and temporal distributions of damaging snowstorms and their economic losses by means of property-casualty insurance data pertaining to “highly damaging storm events, classed as catastrophes by the insurance industry, during the 1949-2000 period.” This work indicated, as they describe it, that “the incidence of storms peaked in the 1976-1985 period,” but that snowstorm incidence “exhibited no up or down trend during 1949-2000.” The two researchers concluded their paper by stating that “the temporal frequency of damaging snowstorms during 1949-2000 in the United States does not display any increase over time, indicating that either no climate change effect on cyclonic activity has begun, or if it has begun, altered conditions have not influenced the incidence of snowstorms.”

Evidence supporting Changnon and Changnon’s conclusion can be found in the work of Paul Kocin of The Weather Channel and Louis Uccellini of the National Weather Service (Kocin and Uccellini, 2004; Squires and Lawrimore, 2006). The authors created a scale to classify snowstorms, called the Northeast Snowfall Impact Scale (NESIS), that characterizes and ranks high-impact Northeast snowstorms. These storms typically cover large areas with snowfall

accumulations of 10 inches or more. NESIS uses population information in addition to meteorological measurements to help communicate the social and economic impact of snowstorms. Storms are put into five categories with 1 being the smallest (“notable”) and 5 being the largest (“extreme”).

Using the NESIS scale, the National Oceanic and Atmospheric Administration’s National Climatic Data Center created a list of 36 “high-impact snowstorms that affected the Northeast urban corridor,” with the earliest storm occurring in 1956 and the most recent on March 1-3, 2009 (NOAA, 2009). Since population has increased in the Northeast over time, more recent storms rank higher on the NESIS scale even if they are no more severe than storms of the past. Nevertheless, fully half (6) of the highest rated (most severe) snowstorms on this record occurred before 1970, as did 14 of all 36 storms in the record. The three most severe storms occurred in 1993, 1996, and 2003, but the next three worst happened in 1960, 1961, and 1964.

Similarly, the National Weather Service tracks the “biggest snowstorms on record” for several cities, with tables showing the dates of the storms and number of inches of snowfall for each posted on its Web site (NWS, 2009). The table for Washington DC shows 15 snowstorms, with five storms having occurred since 1970, four between 1930 and 1970, and six prior to 1930. The biggest snowstorm ever to hit Washington DC arrived in January 1772, when 36 inches fell in the Washington-Baltimore area. It has been called the Washington-Jefferson snowstorm because it was recorded in both of their diaries. It is unlikely that human activity could have contributed to the severity of that storm, or to any other storm prior to the start of significant anthropogenic greenhouse gas emissions in the 1940s.

The research summarized in this section reveals that there has been no trend toward less snowfall or snow accumulation, or toward more snowstorms, in North America during the second half of the twentieth century. This record contradicts either the claim that warmer temperatures will lead to more snowfall and winter storms, or the claim that North America experienced warmer winter temperatures during the past half-century. In either case, the IPCC’s claims in this regard must be erroneous.

Additional information on this topic, including reviews on snow not discussed here, can be found at [http://www.co2science.org/subject/s/subject\\_s.php](http://www.co2science.org/subject/s/subject_s.php) under the heading Snow.

## 6.8. Storm Surges

One of the many catastrophes said to be caused by global warming is the heaving of the world's seas beyond their normal bounds in more frequent and increasingly violent storm surges. The following section summarizes the findings of a number of pertinent papers.

De Lange and Gibb (2000) analyzed trends in sea-level data obtained from several tide gauges

located within Tauranga Harbor, New Zealand, over the period 1960-1998. In studying seasonal, interannual, and decadal distributions of storm surge data, they discovered a considerable decline in the annual number of storm surge events in the latter half of the nearly four-decade-long record. A similar trend was noted in the magnitude of storm surges. In addition, maximum water levels, including tides, also declined over the past two decades.

Decadal variations in the data were linked to the Inter-decadal Pacific Oscillation (IPO) and the El Niño-Southern Oscillation (ENSO), with La Niña events producing more storm surge days than El Niño events. In addition, wavelet analyses of annual storm surge frequency data indicated that before 1978 the frequency "was enhanced by the IPO, and subsequently it has been attenuated."

Pirazzoli (2000) analyzed tide-gauge and meteorological (wind and atmospheric pressure) data for the slightly longer period of 1951-1997 along the northern portion of the Atlantic coast of France. This effort revealed that the number of atmospheric depressions (storms) and strong surge winds in this region "are becoming less frequent" and that "ongoing trends of climate variability show a decrease in the frequency and hence the gravity of coastal flooding." Pirazzoli suggests these findings should be "reassuring," especially for those concerned about coastal flooding.

Raicich (2003) analyzed 62 years of sea-level data for the period 1 July 1939 to 30 June 2001 at Trieste, in the Northern Adriatic, in an attempt to determine historical trends of positive and negative surge anomalies. This work led to the discovery that weak and moderate positive surges did not exhibit any definite trends, while strong positive surges clearly became less frequent over the period of study, even in the face of a gradually rising sea level, "presumably," in Raicich's words, "as a consequence of a general weakening of the atmospheric activity," which was likewise found by Pirazzoli to be the case for Brittany.

Based on data for the somewhat longer period of 1901-1990, Wroblewski (2001) determined there was a linear increase in mean annual sea level at the southern Baltic seaport of Kolobrzeg of  $12 \pm 2$  cm per century. Over this same period, however, there was no trend in annual sea-level maxima. Two high values stood out above the rest in the 1980s, but two similar spikes occurred in the 1940s; there were half-a-dozen comparable high values in the first two decades of the record. In light of the slow upward trend in mean sea

level, therefore, it is extremely surprising that annual maximum sea levels due to storm surges did not likewise rise over the past century. One can only conclude these events must have become less intense over the same time interval.

Utilizing a full century of data, Zhang *et al.* (2000) analyzed 10 very long records of storm surges derived from hourly tide gauge measurements made along the east coast of the United States, in order to calculate indexes of count, duration and integrated intensity of surge-producing storms that provide objective, quantitative, and comprehensive measures of historical storm activities in this region. The end result of their comprehensive undertaking was a demonstrable lack of “any discernible long-term secular trend in storm activity during the twentieth century,” which finding, in their words, “suggests a lack of response of storminess to minor global warming along the U.S. Atlantic coast during the last 100 years.”

Looking considerably further back in time, Woodworth and Blackman (2002) analyzed four discontinuous sets of high-water data from the UK’s Liverpool waterfront that span the period 1768-1999, looking for changes in annual maximum high water (tide plus surge), surge at annual maximum high water (surge component of annual maximum high water), and annual maximum surge-at-high-water. They could detect no significant trends in the first two parameters over the period of study; but they found that the annual maximum surge-at-high-water declined at a rate of  $0.11 \pm 0.04$  meters per century. This finding suggests the winds responsible for producing high storm surges were much stronger and/or more common during the early part of the record (Little Ice Age) than during the latter part (Current Warm Period).

Last, in what is the longest look back in time of the papers treating this subject, Nott and Hayne (2001) produced a 5,000-year record of tropical cyclone frequency and intensity along a 1,500-km stretch of coastline in northeastern Australia located between latitudes 13 and 24°S by (1) geologically dating and topographically surveying landform features left by surges produced by historic hurricanes and (2) running numerical models to estimate storm surge and wave heights necessary to reach the landform locations. This work revealed that several “super-cyclones” with central pressures less than 920 hPa and wind speeds in excess of 182 kilometers per hour had occurred over the past 5,000 years at intervals of roughly 200 to 300 years in all parts of

the region of study. The two researchers also report that the Great Barrier Reef “experienced at least five such storms over the past 200 years, with the area now occupied by Cairns experiencing two super-cyclones between 1800 and 1870.” The twentieth century, however, was totally devoid of such storms, “with only one such event (1899) since European settlement in the mid-nineteenth century.”

It seems safe to conclude that storm surges around the world have not responded to rising temperatures during the twentieth century. In the majority of cases investigated, they have decreased.

## 6.9. Temperature Variability

One more measure of climatic change is temperature variability. Has the earth experienced more record highs or lows of temperature during the Current Warm Period?

Oppo *et al.* (1998) studied sediments from Ocean Drilling Project site 980 on the Feni Drift (55.5°N, 14.7°W) in the North Atlantic. Working with a core pertaining to the period from 500,000 to 340,000 years ago, they analyzed  $\delta^{18}\text{O}$  and  $\delta^{13}\text{C}$  obtained from benthic foraminifera and  $\delta^{18}\text{O}$  obtained from planktonic foraminifera to develop histories of deep water circulation and sea surface temperature (SST), respectively. In doing so, they discovered a number of persistent climatic oscillations with periods of 6,000, 2,600, 1,800 and 1,400 years that traversed the entire length of the sediment core record, extending through glacial and interglacial epochs alike. These SST variations, which were found to be in phase with deep-ocean circulation changes, were on the order of 3°C during cold glacial maxima but only 0.5 to 1°C during warm interglacials.

Similar results were obtained by McManus *et al.* (1999), who also examined a half-million-year-old deep-sea sediment core from the eastern North Atlantic. Significant SST oscillations were again noted throughout the record, and they too were of much greater amplitude during glacial periods (4 to 6°C) than during interglacials (1 to 2°C). Likewise, in another study of a half-million-year-long sediment core from the same region, Helmke *et al.* (2002) found that the most stable of all climates held sway during what they called “peak interglaciations” or periods of greatest warmth. In this regard, we note that the temperatures of all four of the interglacials that preceded the one in which we currently live were warmer than the present one, and by an average temperature in excess of 2°C, as determined by Petit *et al.* (1999). Hence, even if the earth were to continue its recent (and possibly ongoing) recovery from the global chill of the Little Ice Age, that warming likely would lead to a state of reduced temperature variability, as evidenced by real-world data pertaining to the past half-million years.

Shifting our focus to the past millennium, Cook *et al.* (2002) report the results of a tree-ring study of long-lived silver pines on the West Coast of New Zealand’s South Island. The chronology they derived provides a reliable history of Austral summer temperatures from AD 1200 to 1957, after which measured temperatures were used to extend the history to 1999. Cook *et al.* say their reconstruction indicates “there have been several periods of above and below average temperature that have not been experienced in the 20th century.” This finding indicates that New Zealand temperatures grew less variable over the twentieth century.

Manrique and Fernandez-Cancio (2000) employed a network of approximately 1,000 samples of tree-ring series representative of a significant part of Spain to reconstruct thousand-year chronologies of temperature and precipitation, after which they used this database to identify anomalies in these parameters that varied from their means by more than four standard deviations. In doing so, they found that the greatest concentration of extreme climatic excursions, which they describe as “the outstanding oscillations of the Little Ice Age,” occurred between AD 1400 and 1600, during a period when extreme low temperatures reached their maximum frequency.

In yet another part of the world, many long tree-ring series obtained from widely spaced Himalayan cedar trees were used by Yadav *et al.* (2004) to develop a temperature history of the western Himalayas for the period AD 1226-2000. “Since the 16th century,” to use their words, “the reconstructed temperature shows higher variability as compared to the earlier part of the series (AD 1226-1500), reflecting unstable climate during the Little Ice Age (LIA).” With respect to this greater variability of climate during colder conditions, they note that similar results have been obtained from juniper tree-ring chronologies from central Tibet (Braeuning, 2001), and that “historical records on the frequency of droughts, dust storms and floods in China also show that the climate during the LIA was highly unstable (Zhang and Crowley, 1989).” Likewise, in a study of the winter half-year temperatures of a large part of China, Ge *et al.* (2003) identified greater temperature anomalies during the 1600s than in the 1980s and 1990s.

Focusing on just the past century, Rebetz (2001) analyzed day-to-day variability in two temperature series from Switzerland over the period 1901-1999, during which time the two sites experienced temperatures increases of 1.2 and 1.5°C. Their work revealed that warmer temperatures led to a reduction in temperature variability at both locations. As they describe it, “warmer temperatures are accompanied by a general reduction of variability, both in daily temperature range and in the monthly day-to-day variability.” We see that even on this much finer time scale, it is cooling, not warming, that brings an increase in temperature variability.

In a study based on daily maximum (max), minimum (min), and mean air temperatures (T) from 1,062 stations of the U.S. Historical Climatology Network, Robeson (2002) computed the slopes of the relationships defined by plots of daily air temperature

standard deviation vs. daily mean air temperature for each month of the year for the period 1948-1997. This protocol revealed, in Robeson's words, that "for most of the contiguous USA, the slope of the relationship between the monthly mean and monthly standard deviation of daily Tmax and Tmin—the variance response—is either negative or near-zero," which means, he describes it, that "for most of the contiguous USA, a warming climate should produce either reduced air-temperature variability or no change in air-temperature variability." He also reports that the negative relationships are "fairly strong, with typical reductions in standard deviation ranging from 0.2 to 0.5°C for every 1°C increase in mean temperature."

In Canada, according to Shabbar and Bonsal (2003), "extreme temperature events, especially those during winter, can have many adverse environmental and economic impacts." They chose to examine trends and variability in the frequency, duration, and intensity of winter (January-March) cold and warm spells during the second half of the twentieth century. From 1950-1998, they found that western Canada experienced decreases in the frequency, duration, and intensity of winter cold spells. In the east, however, distinct increases in the frequency and duration of winter cold spells occurred. With respect to winter warm spells, significant increases in both their frequency and duration were observed across most of Canada, with the exception of the extreme northeastern part of the country, where warm spells appear to be becoming shorter and less frequent. In the mean, therefore, there appear to be close-to-compensating trends in the frequency and intensity of winter cold spells in different parts of Canada, while winter warm spells appear to be increasing somewhat. As a result, Canada appears to have experienced a slight amelioration of extreme winter weather over the past half-century.

In another study that suffers from the difficulty of having but a few short decades of data to analyze, Iskenderian and Rosen (2000) studied two mid-tropospheric temperature datasets spanning the past 40 years, calculating day-to-day variability within each month, season, and year. Averaged over the entire Northern Hemisphere, they found that mid-tropospheric temperature variability exhibited a slight upward trend since the late 1950s in one of the datasets; but, as they note, "this trend is significant in the spring season only." They also admit that "the robustness of this springtime trend is in doubt," because the trend obtained from the other dataset was

negative. For the conterminous United States, however, the two datasets both showed "mostly small positive trends in most seasons." But, again, none of these trends was statistically significant. Therefore, Iskenderian and Rosen acknowledge they "cannot state with confidence that there has been a change in synoptic-scale temperature variance in the mid-troposphere over the United States since 1958."

In an attempt to determine the role that might have been played by the planet's mean temperature in influencing temperature variability over the latter half of the twentieth century, Higgins *et al.* (2002) examined the influence of two important sources of Northern Hemispheric climate variability—the El Niño/Southern Oscillation (ENSO) and the Arctic Oscillation—on winter (Jan-Mar) daily temperature extremes over the conterminous United States from 1950 to 1999. With respect to the Arctic Oscillation, there was basically no difference in the number of extreme temperature days between its positive and negative phases. With respect to the ENSO phenomenon, however, Higgins *et al.* found that during El Niño years, the total number of extreme temperature days was found to decrease by around 10 percent, while during La Niña years they increased by around 5 percent. With respect to winter temperatures across the conterminous United States, therefore, the contention that warmer global temperatures—such as are typically experienced during El Niño years—would produce more extreme weather conditions is found to be false.

Over the same time period, Zhai and Pan (2003) derived trends in the frequencies of warm days and nights, cool days and nights, and hot days and frost days for the whole of China, based on daily surface air temperature data obtained from approximately 200 weather observation stations scattered across the country. Over the period of record, and especially throughout the 1980s and 1990s, there were increases in the numbers of warm days and nights, while there were decreases in the numbers of cool days and nights, consistent with an overall increase in mean daily temperature. At the extreme hot end of the temperature spectrum, however, the authors report that "the number of days with daily maximum temperature above 35°C showed a slightly decreasing trend for China as a whole," while at the extreme cold end of the spectrum, the number of frost days with daily minimum temperature below 0°C declined at the remarkable rate of 2.4 days per decade.

In considering this entire body of research, it is evident that air temperature variability almost always decreases when mean air temperature rises.

Additional information on this topic, including reviews of newer publications as they become available, can be found at <http://www.co2science.org/subject/e/extremetemp.php>.

## 6.10. Wildfires

As stated by the IPCC, “an intensification and expansion of wildfires is likely globally, as temperatures increase and dry spells become more frequent and more persistent” (IPCC, 2007-II). Below, we test this claim by reviewing the results of studies conducted in various parts of the world, ending with a recent satellite study that evaluated the globe as a whole.

Carcaillet *et al.* (2001) developed high-resolution charcoal records from laminated sediment cores extracted from three small kettle lakes located within the mixed-boreal and coniferous-boreal forest region of eastern Canada, after which they determined whether vegetation change or climate change was the primary determinant of changes in fire frequency, comparing their fire history with hydro-climatic reconstructions derived from  $\delta^{18}\text{O}$  and lake-level data. Throughout the Climatic Optimum of the mid-Holocene, between about 7,000 and 3,000 years ago, when it was significantly warmer than it is today, they report that “fire intervals were double those in the last 2000 years,” meaning fires were only half as frequent throughout the earlier warmer period as they were during the subsequent cooler period. They also determined that “vegetation does not control the long-term fire regime in the boreal forest,” but that “climate appears to be the main process triggering fire.” In addition, they report that “dendroecological

studies show that both frequency and size of fire decreased during the 20th century in both west (e.g. Van Wagner, 1978; Johnson *et al.*, 1990; Larsen, 1997; Weir *et al.*, 2000) and east Canadian coniferous forests (e.g. Cwynar, 1997; Foster, 1983; Bergeron, 1991; Bergeron *et al.*, 2001), possibly due to a drop in drought frequency and an increase in long-term annual precipitation (Bergeron and Archambault, 1993).” These several findings thus led them to conclude that a “future warmer climate is likely to be less favorable for fire ignition and spread in the east Canadian boreal forest than over the last 2 millennia.”

In another Canadian study that sheds important new light on this subject, four forest scientists investigated “regional fire activity as measured by the decadal proportion of area burned and the frequency of fire years vs. non-fire years in the Waswanipi area of northeastern Canada [49.5-50.5°N, 75-76.5°W], and the long-term relationship with large-scale climate variations ... using dendroecological sampling along with forest inventories, aerial photographs, and ecoforest maps.” The results of their investigation revealed that instead of the interval of time between wildfires shortening as time progressed and the climate warmed, there was “a major lengthening of the fire cycle.” In addition, the four researchers note that “in the context of the past 300 years, many regional fire regimes of the Canadian boreal forest, as reconstructed from dendroecological analysis, experienced a decrease in fire frequency after 1850 [or the “end of the Little Ice Age,” as they describe it] (Bergeron and Archambault, 1993; Larsen, 1996) and a further decrease after 1940 (Bergeron *et al.*, 2001, 2004a,b, 2006).”

In further study of this subject, Lauzon *et al.* (2007) investigated the fire history of a 6,480-km<sup>2</sup> area located in the Baie-Des-Chaleurs region of Gaspesie at the southeastern edge of Quebec, “using Quebec Ministry of Natural Resource archival data and aerial photographs combined with dendrochronological data.” Results indicated that coincident with the 150-year warming that led to the demise of the Little Ice Age and the establishment of the Current Warm Period, there was “an increase in the fire cycle from the pre-1850 period (89 years) to the post-1850 period (176 years),” and that “both maximum and mean values of the Fire Weather Index decreased statistically between 1920 and 2003,” during which period “extreme values dropped from the very high to high categories, while mean values changed from moderate to low categories.” In this particular part of the world, therefore, twentieth

century global warming has led to a significant decrease in the frequency of forest fires, as weather conditions conducive to their occurrence have gradually become less prevalent and extreme.

Pitkanen *et al.* (2003) constructed a Holocene fire history of dry heath forests in eastern Finland on the basis of charcoal layer data obtained from two small mire basins and fire scars on living and dead pine trees. This work revealed a “decrease in fires during climatic warming in the Atlantic chronozone (about 9000-6000 cal. yr. BP),” prompting them to conclude that “the very low fire frequency during the Atlantic chronozone despite climatic warming with higher summer temperatures, is contrary to assumptions about possible implications of the present climatic warming due to greenhouse gases.”

Thereafter, the researchers observed an increase in fire frequency at the transition between the Atlantic and Subboreal chronozones around 6,000 cal. yr. BP, noting that “the climatic change that triggered the increase in fire frequency was cooling and a shift to a more continental climate.” In addition, they report that the data of Bergeron and Archambault (1993) and Carcaillet *et al.* (2001) from Canada suggest much the same thing; i.e., fewer boreal forest fires during periods of greater warmth. Consequently, “as regards the concern that fire frequency will increase in [the] near future owing to global warming,” the researchers say their data “suggest that fires from ‘natural’ causes (lightning) are not likely to increase significantly in eastern Finland and in geographically and climatically related areas.”

Back in Canada, Girardin *et al.* (2006) introduced their study of the subject by citing a number of predictions that “human-induced climate change could lead to an increase in forest fire activity in Ontario, owing to the increased frequency and severity of drought years, increased climatic variability and incidence of extreme climatic events, and increased spring and fall temperatures,” noting that “climate change therefore could cause longer fire seasons (Wotton and Flannigan, 1993), with greater fire activity and greater incidence of extreme fire activity years (Colombo *et al.*, 1998; Parker *et al.*, 2000).” To see if any of these predictions might have recently come to pass, they reconstructed a history of area burned within the province of Ontario for the period AD 1781-1982 from 25 tree-ring width chronologies obtained from various sites throughout the province. An increase in area burned within Ontario is known to have occurred from 1970 through 1981 (Podur *et al.*, 2002).

The three researchers report that “while in recent decades area burned has increased, it remained below the level recorded prior to 1850 and particularly below levels recorded in the 1910s and 1920s,” noting further that “the most recent increase in area burned in the province of Ontario (circa 1970-1981) [Podur *et al.*, 2002] was preceded by the period of lowest fire activity ever estimated for the past 200 years (1940s-1960s).”

Schoennagel *et al.* (2007) investigated “climatic mechanisms influencing subalpine forest fire occurrence in western Colorado, which provide a key to the intuitive link between drought and large, high-severity fires that are keystone disturbance processes in many high-elevation forests in the western United States,” focusing on three major climatic oscillations: the El Niño Southern Oscillation (ENSO), the Pacific Decadal Oscillation (PDO), and the Atlantic Multidecadal Oscillation (AMO).

Results of this analysis revealed that “fires occurred during short-term periods of significant drought and extreme cool (negative) phases of ENSO and PDO and during positive departures from [the] mean AMO index,” while “at longer time scales, fires exhibited 20-year periods of synchrony with the cool phase of the PDO, and 80-year periods of synchrony with extreme warm (positive) phases of the AMO.” In addition, they say that “years of combined positive AMO and negative ENSO and PDO phases represent ‘triple whammies’ that significantly increased the occurrence of drought-induced fires.” On the other hand, they write that “drought and wildfire are associated with warm phases of ENSO and PDO in the Pacific Northwest and northern Rockies while the opposite occurs in the Southwest and southern Rockies,” citing the findings of Westerling and Swetnam (2003), McCabe *et al.* (2004), and Schoennagel *et al.* (2005). Schoennagel *et al.* conclude that “there remains considerable uncertainty regarding the effects of CO<sub>2</sub>-induced warming at regional scales.” Nevertheless, they report “there is mounting evidence that the recent shift to the positive phase of the AMO will promote higher fire frequencies” in the region of their study, i.e., high-elevation western U.S. forests. The body of their work clearly suggests that such a consequence should not be viewed as a response to CO<sub>2</sub>-induced global warming.

A contrary example, where warming does appear to enhance fire occurrence, is provided by Pierce *et al.* (2004), who dated fire-related sediment deposits in alluvial fans in central Idaho, USA, in a research

program designed to reconstruct Holocene fire history in xeric ponderosa pine forests and to look for links to past climate change. This endeavor focused on tributary alluvial fans of the South Fork Payette (SFP) River area, where fans receive sediment from small but steep basins in weathered batholith granitic rocks that are conducive to post-fire erosion. They obtained 133 AMS <sup>14</sup>C-derived dates from 33 stratigraphic sites in 32 different alluvial fans. In addition, they compared their findings with those of Meyer *et al.* (1995), who had earlier reconstructed a similar fire history for nearby Yellowstone National Park in Wyoming, USA.

Pierce *et al.*'s work revealed, in their words, that “intervals of stand-replacing fires and large debris-flow events are largely coincident in SFP ponderosa pine forests and Yellowstone, most notably during the ‘Medieval Climatic Anomaly’ (MCA), ~1,050-650 cal. yr BP.” What is more, they note that “in the western USA, the MCA included widespread, severe multidecadal droughts (Stine, 1998; Woodhouse and Overpeck, 1998), with increased fire activity across diverse northwestern conifer forests (Meyer *et al.*, 1995; Rollins *et al.*, 2002).”

Following the Medieval Warm Period and its frequent large-event fires was the Little Ice Age, when, as Pierce *et al.* describe it, “colder conditions maintained high canopy moisture, inhibiting stand-replacing fires in both Yellowstone lodgepole pine forests and SFP ponderosa pine forests (Meyer *et al.*, 1995; Rollins *et al.*, 2002; Whitlock *et al.*, 2003).” Subsequently, however, they report that “over the twentieth century, fire size and severity have increased in most ponderosa pine forests,” which they suggest may be largely due to “the rapidity and magnitude of twentieth-century global climate change.”

With respect to their central thesis, which appears to be well supported by both the SFP and Yellowstone data, we agree with Pierce *et al.* that both the size and severity of large-event stand-replacing fires tend to increase with increasing temperature in the part of the world and for the specific forests they studied. We note that the Yellowstone data also depict a sharp drop in large-event fire frequency and severity during the earlier Dark Ages Cold Period, which followed on the heels of the preceding peak in such fires that was concomitant with the still earlier Roman Warm Period.

Also working in the United States, and coming to much the same general conclusion, were Westerling

*et al.* (2006), who compiled a comprehensive database of large wildfires in western United States forests since 1970 and compared it to hydro-climatic and land-surface data. Their findings are succinctly summarized by Running (2006) in an accompanying Perspective, wherein he writes that “since 1986, longer warmer summers have resulted in a fourfold increase of major wildfires and a sixfold increase in the area of forest burned, compared to the period from 1970 to 1986,” noting also that “the length of the active wildfire season in the western United States has increased by 78 days, and that the average burn duration of large fires has increased from 7.5 to 37.1 days.” In addition, he notes that “four critical factors—earlier snowmelt [by one to four weeks], higher summer temperatures [by about 0.9°C], longer fire season, and expanded vulnerable area of high-elevation forests—are combining to produce the observed increase in wildfire activity.”

So what is the case for the world as a whole—i.e., what is the net result of the often-opposite wildfire responses to warming that are typical of different parts of the planet?

This question was recently explored by Riano *et al.* (2007), who conducted “an analysis of the spatial and temporal patterns of global burned area with the Daily Tile US National Oceanic and Atmospheric Administration-Advanced Very High-Resolution Radiometer Pathfinder 8 km Land dataset between 1981 and 2000.” For several areas of the world, this effort revealed there were indeed significant upward trends in land area burned. Some parts of Eurasia and western North America, for example, had annual upward trends as high as 24.2 pixels per year, where a pixel represents an area of 64 km<sup>2</sup>. These increases in burned area, however, were offset by equivalent decreases in burned area in tropical southeast Asia and Central America. Consequently, in the words of Riano *et al.*, “there was no significant global annual upward or downward trend in burned area.” In fact, they say “there was also no significant upward or downward global trend in the burned area for any individual month.” In addition, they say that “latitude was not determinative, as divergent fire patterns were encountered for various land cover areas at the same latitude.”

Although one can readily identify specific parts of the planet that have experienced both significant increases and decreases in land area burned over the last two or three decades of the twentieth century, as we have done in the materials reviewed above, for the globe as a whole there was no relationship between

global warming and total area burned over this latter period, during which time it is claimed the world warmed at a rate and to a degree that were both unprecedented over the past millennium.

Additional information on this topic, including reviews of newer publications as they become available, can be found at <http://www.co2science.org/subject/f/firegw.php>.

### 7. Biological Effects of Carbon Dioxide Enrichment

- 7.1. Plant Productivity Responses
- 7.2. Water Use Efficiency
- 7.3. Amelioration of Environmental Stresses
- 7.4. Acclimation
- 7.5. Competition
- 7.6. Respiration
- 7.7. Carbon Sequestration
- 7.8. Other Benefits
- 7.9. Greening of the Earth

### Introduction

The Contribution of Group 1 to the Fourth Assessment Report of the Intergovernmental Panel on Climate Change (IPCC) hardly mentions the beneficial effects of earth's rising atmospheric carbon dioxide (CO<sub>2</sub>) concentration on the biosphere. In a chapter titled "Changes in Atmospheric Constituents and in Radiative Forcing" the authors say the following (IPCC, 2007-I, p. 186):

Increased CO<sub>2</sub> concentrations can also "fertilize" plants by stimulating photosynthesis, which models suggest has contributed to increased vegetation cover and leaf area over the 20<sup>th</sup> century (Cramer *et al.*, 2001). Increases in the Normalized Difference Vegetation Index, a remote sensing product indicative of leaf area, biomass and potential photosynthesis, have been observed (Zhou *et al.*, 2001), although other causes including climate change itself are also likely to have contributed. Increased vegetative cover and leaf area would decrease surface albedo, which would act to oppose the increase in albedo due to deforestation. The RF due to this process has not been evaluated and there is a very low scientific understanding of these effects.

Later in that report, in a chapter titled "Couplings Between Changes in the Climate System and

Biogeochemistry," a single paragraph is devoted to the "effects of elevated carbon dioxide" on plants. The paragraph concludes, "it is not yet clear how strong the CO<sub>2</sub> fertilization effect actually is" (p. 527).

Since CO<sub>2</sub> fertilization could affect crop yields and how efficiently plants use mineral nutrients and water, one would expect the subject to be addressed in the Contribution of Group 2, on "Impacts, Adaption and Vulnerability," and indeed it is, in a chapter titled "Food, Fibre and Forest Products" (IPCC, 2007-II). But that chapter belittles and largely ignores research on the benefits of enhanced CO<sub>2</sub> while exaggerating the possible negative effects of rapidly rising temperatures and extreme weather events predicted by computer models. The subject is not even mentioned in Chapter 8 of that report, on "Human Health," although even a modest effect on crops would have some effect on human health. (See Chapter 9 of the present report for our own, more complete, discussion of the health effects of climate change.)

The IPCC's failure to report the beneficial effects of rising CO<sub>2</sub> concentrations is surprising when literally thousands of peer-reviewed journal articles exist on the subject. It is also a major defect of the IPCC report and one reason why it is not a reliable summary of the science of climate change. In this

chapter, we seek to provide the balance that eluded the IPCC.

The chapter begins with a survey of the scientific literature on the productivity responses of plants to higher CO<sub>2</sub> concentrations, and then reviews research on the effect of enhanced CO<sub>2</sub> on plant water-use efficiency, responsiveness to environmental stress, acclimation, competition among species (e.g., crops versus weeds), respiration, and other effects. We end with a survey of literature showing the general “greening of the Earth” that has occurred during the Current Warm Period.

## 7.1. Plant Productivity Responses

Perhaps the best-known consequence of the rise in atmospheric CO<sub>2</sub> is the stimulation of plant productivity. This growth enhancement occurs because carbon dioxide is the primary raw material utilized by plants to produce the organic matter out of which they construct their tissues. Consequently, the

more CO<sub>2</sub> there is in the air, the better plants grow. Over the past decade, the Center for the Study of Carbon Dioxide and Global Change, has archived thousands of results from hundreds of peer-reviewed research studies conducted by hundreds of researchers demonstrating this fact. The archive is available free of charge at <http://www.co2science.org/data/plantgrowth/plantgrowth.php>.

The Center’s Web site lists the photosynthetic and dry weight responses of plants growing in CO<sub>2</sub>-enriched air, arranged by scientific or common plant name. It also provides the full peer-reviewed journal references and experimental conditions in which each study was conducted for each record. We have summarized those results in two tables appearing in Appendix 2 and Appendix 3 to the current report. The first table, Table 7.1.1, indicates the mean biomass response of nearly 1,000 plants to a 300-ppm increase in atmospheric CO<sub>2</sub> concentration. The second table, Table 7.1.2, indicates the photosynthetic response to the same CO<sub>2</sub> enrichment for a largely similar list of plants.

In the rest of this section of Chapter 7, we provide a review of research on a representative sample of herbaceous and woody plants, chosen with an eye toward their importance to agriculture and the forestry and papermaking industries, followed by several aquatic plants.

### 7.1.1. Herbaceous Plants

A 300 ppm increase in the air’s CO<sub>2</sub> content typically raises the productivity of most herbaceous plants by about one-third (Cure and Acock, 1986; Mortensen, 1987). This positive response occurs in plants that utilize all three of the major biochemical pathways (C<sub>3</sub>, C<sub>4</sub>, and crassulacean acid metabolism (CAM)) of photosynthesis (Poorter, 1993). Thus, with more CO<sub>2</sub> in the air, the productivity of nearly all crops rises, as they produce more branches and tillers, more and thicker leaves, more extensive root systems, and more flowers and fruit (Idso, 1989).

On average, a 300 ppm increase in atmospheric CO<sub>2</sub> enrichment leads to yield increases of 15 percent for CAM crops, 49 percent for C<sub>3</sub> cereals, 20 percent for C<sub>4</sub> cereals, 24 percent for fruits and melons, 44 percent for legumes, 48 percent for roots and tubers, and 37 percent for vegetables (Idso and Idso, 2000). It should come as no surprise, therefore, that the father of modern research in this area—Sylvan H. Wittwer—has said “it should be considered good fortune that we are

living in a world of gradually increasing levels of atmospheric CO<sub>2</sub>,” and “the rising level of atmospheric CO<sub>2</sub> is a universally free premium, gaining in magnitude with time, on which we can all reckon for the future.”

### 7.1.1.1. Alfalfa

Morgan *et al.* (2001) grew the C<sub>3</sub> legume alfalfa (*Medicago sativa* L.) for 20 days post-defoliation in growth chambers maintained at atmospheric CO<sub>2</sub> concentrations of 355 and 700 ppm and low or high levels of soil nitrogen to see how these factors affected plant regrowth. They determined that the plants in the elevated CO<sub>2</sub> treatment attained total dry weights over the 20-day regrowth period that were 62 percent greater than those reached by the plants grown in ambient air, irrespective of soil nitrogen concentration.

De Luis *et al.* (1999) grew alfalfa plants in controlled environment chambers in air of 400 and 700 ppm CO<sub>2</sub> for two weeks before imposing a two-week water treatment on them, wherein the soil in which half of the plants grew was maintained at a moisture content approaching field capacity while the soil in which the other half grew was maintained at a moisture content that was only 30 percent of field capacity. Under these conditions, the CO<sub>2</sub>-enriched water-stressed plants displayed an average water-use

efficiency that was 2.6 and 4.1 times greater than that of the water-stressed and well-watered plants, respectively, growing in ambient 400-ppm-CO<sub>2</sub> air. In addition, under ambient CO<sub>2</sub> conditions, the water stress treatment increased the mean plant root:shoot ratio by 108 percent, while in the elevated CO<sub>2</sub> treatment it increased it by 269 percent. As a result, the nodule biomass on the roots of the CO<sub>2</sub>-enriched water-stressed plants was 40 and 100 percent greater than the nodule biomass on the roots of the well-watered and water-stressed plants, respectively, growing in ambient air. Hence, the CO<sub>2</sub>-enriched water-stressed plants acquired 31 and 97 percent more total plant nitrogen than the well-watered and water-stressed plants, respectively, growing in ambient air. The CO<sub>2</sub>-enriched water-stressed plants attained 2.6 and 2.3 times more total biomass than the water-stressed and well-watered plants, respectively, grown at 400 ppm CO<sub>2</sub>.

Luscher *et al.* (2000) grew effectively and ineffectively nodulating (good nitrogen-fixing vs. poor nitrogen-fixing) alfalfa plants in large free-air CO<sub>2</sub> enrichment (FACE) plots for multiple growing seasons at atmospheric CO<sub>2</sub> concentrations of 350 and 600 ppm, while half of the plants in each treatment received a high supply of soil nitrogen and the other half received only minimal amounts of this essential nutrient. The extra CO<sub>2</sub> increased the yield of effectively nodulating plants by about 50 percent, regardless of soil nitrogen supply; caused a 25 percent yield reduction in ineffectively nodulating plants subjected to low soil nitrogen; and produced an intermediate yield stimulation of 11 percent for the same plants under conditions of high soil nitrogen, which suggests that the ability to symbiotically fix nitrogen is an important factor in eliciting strong positive growth responses to elevated CO<sub>2</sub> under conditions of low soil nitrogen supply.

Sgherri *et al.* (1998) grew alfalfa in open-top chambers at ambient (340 ppm) and enriched (600 ppm) CO<sub>2</sub> concentrations for 25 five days, after which water was withheld for five additional days so they could investigate the interactive effects of elevated CO<sub>2</sub> and water stress on plant water status, leaf soluble protein and carbohydrate content, and chloroplast thylakoid membrane composition. They found that the plants grown in elevated CO<sub>2</sub> exhibited the best water status during the moisture deficit part of the study, as indicated by leaf water potentials that were approximately 30 percent higher (less negative) than those observed in plants grown in ambient CO<sub>2</sub>. This beneficial adjustment was achieved by partial

closure of leaf stomata and by greater production of nonstructural carbohydrates (a CO<sub>2</sub>-induced enhancement of 50 percent was observed), both of which phenomena can lead to decreases in transpirational water loss, the former by guard cells physically regulating stomatal apertures to directly control the exodus of water from leaves, and the latter by nonstructural carbohydrates influencing the amount of water available for transpiration. This latter phenomenon occurs because many nonstructural carbohydrates are osmotically active solutes that chemically associate with water through the formation of hydrogen bonds, thereby effectively reducing the amount of unbound water available for bulk flow during transpiration. Under water-stressed conditions, however, the CO<sub>2</sub>-induced difference in total leaf nonstructural carbohydrates disappeared. This may have resulted from an increased mobilization of nonstructural carbohydrates to roots in the elevated CO<sub>2</sub> treatment, which would decrease the osmotic potential in that part of the plant, thereby causing an increased influx of soil moisture into the roots. If this did indeed occur, it would also contribute to a better overall water status of CO<sub>2</sub>-enriched plants during drought conditions.

The plants grown at elevated CO<sub>2</sub> also maintained greater leaf chlorophyll contents and lipid to protein ratios, especially under conditions of water stress. Leaf chlorophyll content, for example, decreased by a mere 6 percent at 600 ppm CO<sub>2</sub>, while it plummeted by approximately 30 percent at 340 ppm, when water was withheld. Moreover, leaf lipid contents in plants grown with atmospheric CO<sub>2</sub> enrichment were about 22 and 83 percent higher than those measured in plants grown at ambient CO<sub>2</sub> during periods of ample and insufficient soil moisture supply, respectively. Furthermore, at elevated CO<sub>2</sub> the average amounts of unsaturation for two of the most important lipids involved in thylakoid membrane composition were approximately 20 and 37 percent greater than what was measured in plants grown at 340 ppm during times of adequate and inadequate soil moisture, respectively. The greater lipid contents observed at elevated CO<sub>2</sub>, and their increased amounts of unsaturation, may allow thylakoid membranes to maintain a more fluid and stable environment, which is critical during periods of water stress in enabling plants to continue photosynthetic carbon uptake.

### 7.1.1.2. Cotton

As the CO<sub>2</sub> content of the air increases, cotton (*Gossypium hirsutum* L.) plants typically display enhanced rates of photosynthetic carbon uptake, as noted by Reddy *et al.* (1999), who reported that twice-ambient atmospheric CO<sub>2</sub> concentrations boosted photosynthetic rates of cotton by 137 to 190 percent at growth temperatures ranging from 2°C below ambient to 7°C above ambient.

Elevated CO<sub>2</sub> also enhances total plant biomass and harvestable yield. Reddy *et al.* (1998), for example, reported that plant biomass at 700 ppm CO<sub>2</sub> was enhanced by 31 to 78 percent at growth temperatures ranging from 20 to 40°C, while boll production was increased by 40 percent. Similarly, Tischler *et al.* (2000) found that a doubling of the atmospheric CO<sub>2</sub> concentration increased seedling biomass by at least 56 percent.

These results indicate that elevated CO<sub>2</sub> concentrations tend to ameliorate the negative effects of heat stress on productivity and growth in cotton. In addition, Booker (2000) discovered that elevated CO<sub>2</sub> reduced the deleterious effects of elevated ozone on leaf biomass and starch production.

Atmospheric CO<sub>2</sub> enrichment also can induce changes in cotton leaf chemistry that tend to increase carbon sequestration in plant biolitter and soils. Booker *et al.* (2000), for example, observed that biolitter produced from cotton plants grown at 720 ppm CO<sub>2</sub> decomposed at rates that were 10 to 14

percent slower than those displayed by ambiently grown plants; a after three years of exposure to air containing 550 ppm CO<sub>2</sub>, Leavitt *et al.* (1994) reported that 10 percent of the organic carbon present in soils beneath CO<sub>2</sub>-enriched FACE plots resulted from the extra CO<sub>2</sub> supplied to them.

In summary, as the CO<sub>2</sub> content of the air increases, cotton plants will display greater rates of photosynthesis and biomass production, which should lead to greater boll production in this important fiber crop, even under conditions of elevated air temperature and ozone concentration. In addition, carbon sequestration in fields planted to cotton should also increase with future increases in the air's CO<sub>2</sub> content.

### 7.1.1.3. Maize

Maroco *et al.* (1999) grew corn (*Zea mays* L.), or maize as it is often called, for 30 days in plexiglass chambers maintained at either ambient or triple-ambient concentrations of atmospheric CO<sub>2</sub> to determine the effects of elevated CO<sub>2</sub> on the growth of this important agricultural C<sub>4</sub> species. This exercise revealed that elevated CO<sub>2</sub> (1,100 ppm) increased maize photosynthetic rates by about 15 percent relative to those measured in plants grown at 350 ppm CO<sub>2</sub>, in spite of the fact that both rubisco and PEP-carboxylase were down-regulated. This increase in carbon fixation likely contributed to the 20 percent greater biomass accumulation observed in the CO<sub>2</sub>-enriched plants. In addition, leaves of CO<sub>2</sub>-enriched plants contained approximately 10 percent fewer stomates per unit leaf area than leaves of control plants, and atmospheric CO<sub>2</sub> enrichment reduced stomatal conductance by as much as 71 percent in elevated-CO<sub>2</sub>-grown plants. As a result of these several different phenomena, the higher atmospheric CO<sub>2</sub> concentration greatly increased the intrinsic water-use efficiency of the CO<sub>2</sub>-enriched plants.

In a study designed to examine the effects of elevated CO<sub>2</sub> under real-world field conditions, Leakey *et al.* (2004) grew maize out-of-doors at the SoyFACE facility in the heart of the United States Corn Belt, while exposing different sections of the field to atmospheric CO<sub>2</sub> concentrations of either 354 or 549 ppm. The crop was grown, in the words of the researchers, using cultural practices deemed "typical for this region of Illinois," during a year that turned out to have experienced summer rainfall that was "very close to the 50-year average for this site, indicating that the year was not atypical or a drought year." Then, on five different days during the growing season (11 and 22 July, 9 and 21 August, and 5 September), they measured diurnal patterns of photosynthesis, stomatal conductance, and microclimatic conditions.

Contrary to what many people had long assumed would be the case for a C<sub>4</sub> crop such as corn growing under even the best of natural conditions, Leakey *et al.* found that "growth at elevated CO<sub>2</sub> significantly increased leaf photosynthetic CO<sub>2</sub> uptake rate by up to 41 percent." The greatest whole-day increase was 21 percent (11 July) followed by 11 percent (22 July), during a period of low rainfall. Thereafter, however, during a period of greater rainfall, there were no significant differences between the photosynthetic rates of the plants in the two CO<sub>2</sub> treatments, so that

over the entire growing season, the CO<sub>2</sub>-induced increase in leaf photosynthetic rate averaged 10 percent.

Additionally, on all but the first day of measurements, stomatal conductance was significantly lower (-23 percent on average) under elevated CO<sub>2</sub> compared to ambient CO<sub>2</sub>, which led to reduced transpiration rates in the CO<sub>2</sub>-enriched plants on those days as well. Since “low soil water availability and high evaporative demand can both generate water stress and inhibit leaf net CO<sub>2</sub> assimilation in C<sub>4</sub> plants,” they state that the lower stomatal conductance and transpiration rate they observed under elevated CO<sub>2</sub> “may have counteracted the development of water stress under elevated CO<sub>2</sub> and prevented the inhibition of leaf net CO<sub>2</sub> assimilation observed under ambient CO<sub>2</sub>.”

The implication of their research, in the words of Leakey *et al.*, was that “contrary to expectations, this US Corn Belt summer climate appeared to cause sufficient water stress under ambient CO<sub>2</sub> to allow the ameliorating effects of elevated CO<sub>2</sub> to significantly enhance leaf net CO<sub>2</sub> assimilation.” They concluded that “this response of *Z. mays* to elevated CO<sub>2</sub> indicates the potential for greater future crop biomass and harvestable yield across the US Corn Belt.”

Also germane to this subject and supportive of the above conclusion are the effects of elevated CO<sub>2</sub> on weeds associated with corn. Conway and Toenniessen (2003), for example, speak of maize in Africa being attacked by the parasitic weed *Striga hermonthica*, which sucks vital nutrients from its roots, as well as from the roots of many other C<sub>4</sub> crops of the semi-arid tropics, including sorghum, sugar cane, and millet, plus the C<sub>3</sub> crop rice, particularly throughout much of Africa, where *Striga* is one of the region’s most economically important parasitic weeds. Research shows how atmospheric CO<sub>2</sub> enrichment greatly reduces the damage done by this devastating weed (Watling and Press, 1997; Watling and Press, 2000).

Baczek-Kwinta and Koscielniak (2003) studied another phenomenon that is impacted by atmospheric CO<sub>2</sub> enrichment and that can affect the productivity of maize. Noting the tropical origin of maize and that the crop “is extremely sensitive to chill (temperatures 0-15°C),” they report that it is nevertheless often grown in cooler temperate zones. In such circumstances, however, maize can experience a variety of maladies associated with exposure to periods of low air temperature. To see if elevated CO<sub>2</sub> either exacerbates or ameliorates this problem, they grew two hybrid genotypes—KOC 9431 (chill-resistant) and

K103xK85 (chill-sensitive)—from seed in air of either ambient (350 ppm) or elevated (700 ppm) CO<sub>2</sub> concentration (AC or EC, respectively), after which they exposed the plants to air of 7°C for eleven days, whereupon they let them recover for one day in ambient air of 20°C, all the while measuring several physiological and biochemical parameters pertaining to the plants’ third fully expanded leaves.

The two researchers’ protocol revealed that “EC inhibited chill-induced depression of net photosynthetic rate (PN), especially in leaves of chill-resistant genotype KOC 9431,” which phenomenon “was distinct not only during chilling, but also during the recovery of plants at 20°C.” In fact, they found that “seedlings subjected to EC showed 4-fold higher PN when compared to AC plants.” They also determined that “EC diminished the rate of superoxide radical formation in leaves in comparison to the AC control.” In addition, they found that leaf membrane injury “was significantly lower in samples of plants subjected to EC than AC.” Last, they report that enrichment of the air with CO<sub>2</sub> successfully inhibited the decrease in the maximal quantum efficiency of photosystem 2, both after chilling and during the one-day recovery period. And in light of all of these positive effects of elevated CO<sub>2</sub>, they concluded that “the increase in atmospheric CO<sub>2</sub> concentration seems to be one of the protective factors for maize grown in cold temperate regions.”

But what about the effects of climate change, both past and possibly future, on corn production? For nine areas of contrasting environment within the Pampas region of Argentina, Magrin *et al.* (2005) evaluated changes in climate over the twentieth century along with changes in the yields of the region’s chief crops. Then, after determining upward low-frequency trends in yield due to technological improvements in crop genetics and management techniques, plus the aerial fertilization effect of the historical increase in the air’s CO<sub>2</sub> concentration, annual yield anomalies and concomitant climatic anomalies were calculated and used to develop relations describing the effects of changes in precipitation, temperature and solar radiation on crop yields, so that the effects of long-term changes in these climatic parameters on Argentina agriculture could be determined.

Noting that “technological improvements account for most of the observed changes in crop yields during the second part of the twentieth century,” which totaled 110 percent for maize, Magrin *et al.* report that due to changes in climate between the

periods 1950-70 and 1970-99, maize yields increased by 18 percent.

Much the same has been found to be true in Alberta, Canada, where Shen *et al.* (2005) derived and analyzed long-term (1901-2002) temporal trends in the agroclimate of the region. They report, for example, that “an earlier last spring frost, a later first fall frost, and a longer frost-free period are obvious all over the province.” They also found that May-August precipitation in Alberta increased 14 percent from 1901 to 2002, and that annual precipitation exhibited a similar increasing trend, with most of the increase coming in the form of low-intensity events. In addition, the researchers note that “the area with sufficient corn heat units for corn production, calculated according to the 1973-2002 normal, has extended to the north by about 200-300 km, when compared with the 1913-32 normal, and by about 50-100 km, when compared with the 1943-72 normal.”

In light of these findings, Shen *et al.* conclude that “the changes of the agroclimatic parameters imply that Alberta agriculture has benefited from the last century’s climate change,” emphasizing that “the potential exists to grow crops and raise livestock in more regions of Alberta than was possible in the past.” They also note that the increase in the length of the frost-free period “can greatly reduce the frost risks to crops and bring economic benefits to Alberta agricultural producers,” and that the northward extension of the corn heat unit boundary that is sufficient for corn production “implies that Alberta farmers now have a larger variety of crops to choose from than were available previously.” Hence, they say “there is no hesitation for us to conclude that the warming climate and increased precipitation benefit agriculture in Alberta.”

With respect to the future, Bootsma *et al.* (2005) derived relationships between agroclimatic indices and average yields of major grain crops, including corn, from field trials conducted in eastern Canada, after which they used them to estimate potential impacts of projected climate change scenarios on anticipated average yields for the period 2040 to 2069. Based on a range of available heat units projected by multiple General Circulation Model (GCM) experiments, they determined that average yields achievable in field trials could increase by 40 to 115 percent for corn, “not including the direct effect of increased atmospheric CO<sub>2</sub> concentrations.” Adding expected CO<sub>2</sub> increases to the mix, along with gains in yield anticipated to be achieved through

breeding and improved technology, these numbers rose to 114 to 186 percent.

In light of their findings, Bootsma *et al.* predict there will be a “switch to high-energy and high-protein-content crops (corn and soybeans) that are better adapted to the warmer climate.”

In summary, as the air’s CO<sub>2</sub> content continues to rise, and even if the climate of the world changes in the ways suggested by GCM and IPCC calculations, maize plants will likely display greater rates of photosynthesis and biomass production, as well as reduced transpirational water losses and increased water-use efficiencies, and more areas of the world will likely become suitable for growing this important crop.

#### 7.1.1.4. Peanut

Stanciel *et al.* (2000) grew peanuts (*Arachis hypogaea* L.) hydroponically for 110 days in controlled environment chambers maintained at atmospheric CO<sub>2</sub> concentrations of 400, 800 and 1200 ppm, finding that the net photosynthetic rates of plants grown at 800 ppm CO<sub>2</sub> were 29 percent greater than those of plants grown at 400 ppm CO<sub>2</sub>, but that plants grown at 1200 ppm CO<sub>2</sub> displayed photosynthetic rates that were 24 percent lower than those exhibited by plants grown in 400-ppm CO<sub>2</sub> air. Nevertheless, the number of pods, pod weight and seed dry weight per unit area were all greater at 1200 ppm than at 400 ppm CO<sub>2</sub>. Also, harvest index, which is the ratio of seed dry weight to pod dry weight, was 19 and 31 percent greater at 800 and 1200 ppm CO<sub>2</sub>, respectively, than it was at 400 ppm CO<sub>2</sub>. In addition, as the atmospheric CO<sub>2</sub> concentration increased, stomatal conductance decreased, becoming 44 and 50 percent lower at 800 and 1200 ppm than it was at 400 ppm CO<sub>2</sub>. Thus, atmospheric CO<sub>2</sub> enrichment also reduced transpirational water loss, leading to a significant increase in plant water use efficiency.

Prasad *et al.* (2003) grew Virginia Runner (Georgia Green) peanuts from seed to maturity in sunlit growth chambers maintained at atmospheric CO<sub>2</sub> concentrations of 350 and 700 ppm and daytime-maximum/nighttime-minimum air temperatures of 32/22, 36/26, 40/30 and 44/34°C, while they assessed various aspects of vegetative and reproductive growth. In doing so, they found that leaf photosynthetic rates were unaffected by air temperature over the range investigated, but they rose by 27 percent in response to the experimental doubling of the air's CO<sub>2</sub> content. Vegetative biomass, on the other hand, increased by 51 percent and 54 percent in the ambient and CO<sub>2</sub>-enriched air, respectively, as air temperature rose from 32/22 to 40/30°C. A further air temperature increase to 44/34°C, however, caused moderate to slight decreases in vegetative biomass in both the ambient

and CO<sub>2</sub>-enriched air, so that the final biomass increase over the entire temperature range investigated was 27 percent in ambient air and 53 percent in CO<sub>2</sub>-enriched air. When going from the lowest temperature ambient CO<sub>2</sub> treatment to the highest temperature elevated CO<sub>2</sub> treatment, however, there was a whopping 106 percent increase in vegetative biomass.

By contrast, seed yields in both the ambient and CO<sub>2</sub>-enriched air dropped dramatically with each of the three temperature increases studied, declining at the highest temperature regime to but a small percentage of what they were at the lowest temperature regime. Nevertheless, Prasad *et al.* report that "seed yields at 36.4/26.4°C under elevated CO<sub>2</sub> were similar to those obtained at 32/22°C under ambient CO<sub>2</sub>," the latter pair of which temperatures they describe as "present-day seasonal temperatures."

It would appear that a warming of 4.4°C above present-day seasonal temperatures for peanut production would have essentially no effect on peanut seed yields, as long as the atmosphere's CO<sub>2</sub> concentration rose concurrently, by something on the order of 350 ppm. It is also important to note, according to Prasad *et al.*, that "maximum/minimum air temperatures of 32/22°C and higher are common in many peanut-producing countries across the globe." In fact, they note that "the Anantapur district in Andhra Pradesh, which is one of the largest peanut-producing regions in India, experiences season-long temperatures considerably greater than 32/22°C from planting to maturity."

In light of these real-world observations, i.e., that some of the best peanut-producing regions in the world currently experience air temperatures considerably greater than what Prasad *et al.* suggest is optimum for peanuts (something less than 32/22°C), it would appear that real-world declines in peanut seed yields in response to a degree or two of warming, even in air of ambient CO<sub>2</sub> concentration, must be very slight or even non-existent, for how else could the places that commonly experience these considerably higher temperatures remain some of the best peanut-producing areas in the world? This in turn suggests that for more realistic values of CO<sub>2</sub>-induced global warming, i.e., temperature increases on the order of 0.4°C for a doubling of the air's CO<sub>2</sub> content (Idso, 1998), there would likely be a significant increase in real-world peanut production.

In another pertinent study, Vu (2005) grew peanut plants from seed to maturity in greenhouses maintained at atmospheric CO<sub>2</sub> concentrations of 360

and 720 ppm and at air temperatures that were 1.5 and 6.0°C above outdoor air temperatures, while he measured a number of parameters related to the plants' photosynthetic performance. His work revealed that although Rubisco protein content and activity were down-regulated by elevated CO<sub>2</sub>, the Rubisco photosynthetic efficiency (the ratio of midday light-saturated carbon exchange rate to Rubisco initial or total activity) of the elevated-CO<sub>2</sub> plants "was 1.3- to 1.9-fold greater than that of the ambient-CO<sub>2</sub> plants at both growth temperatures." He also determined that "leaf soluble sugars and starch of plants grown at elevated CO<sub>2</sub> were 1.3- and 2-fold higher, respectively, than those of plants grown at ambient CO<sub>2</sub>." In addition, he discovered that the leaf transpiration of the elevated-CO<sub>2</sub> plants relative to that of the ambient-CO<sub>2</sub> plants was 12 percent less at near-ambient temperatures and 17 percent less in the higher temperature regime, while the water use efficiency of the elevated-CO<sub>2</sub> plants relative to the ambient-CO<sub>2</sub> plants was 56 percent greater at near-ambient temperatures and 41 percent greater in the higher temperature environment.

In commenting on his findings, Vu notes that because less Rubisco protein was required by the elevated-CO<sub>2</sub> plants, the subsequent redistribution of excess leaf nitrogen "would increase the efficiency of nitrogen use for peanut under elevated CO<sub>2</sub>," just as the optimization of inorganic carbon acquisition and greater accumulation of the primary photosynthetic products in the CO<sub>2</sub>-enriched plants "would be beneficial for peanut growth at elevated CO<sub>2</sub>." Indeed, in the absence of other stresses, Vu's conclusion was that "peanut photosynthesis would perform well under rising atmospheric CO<sub>2</sub> and temperature predicted for this century."

In a somewhat different type of study, Alexandrov and Hoogenboom (2000) studied how year-to-year changes in temperature, precipitation and solar radiation had influenced the yields of peanuts over a 30-year period in the southeastern United States, after which they used the results to predict future crop yields based on climate-change output from various global circulation models (GCMs) of the atmosphere. At ambient CO<sub>2</sub> concentrations, the GCM scenarios suggested a decrease in peanut yields by the year 2020, due in part to predicted changes in temperature and precipitation. However, when the yield-enhancing effects of a doubling of the atmospheric CO<sub>2</sub> concentration were included, a totally different result was obtained: a yield *increase*.

Although we have little faith in GCM scenarios, it is interesting to note that their climate change predictions often result in positive outcomes for agricultural productivity when the direct effects of elevated CO<sub>2</sub> on plant growth and development are included in the analyses. These results support the research reported later in this chapter describing the stress-ameliorating effects of atmospheric CO<sub>2</sub> enrichment on plant growth and development under unfavorable growing conditions characterized by high air temperatures and inadequate soil moisture.

In conclusion, it would appear that even if the climate changes that are typically predicted to result from anticipated increases in the air's CO<sub>2</sub> content were to materialize, the concurrent rise in the air's CO<sub>2</sub> concentration should more than compensate for any deleterious effects those changes in climate might otherwise have had on the growth and yield of peanuts.

Additional information on this topic, including reviews of newer publications as they become available, can be found at <http://www.co2science.org/subject/a/peanut.php>.

#### 7.1.1.5. Potato

In the study of Sicher and Bunce (1999), exposure to twice-ambient atmospheric CO<sub>2</sub> concentrations enhanced rates of net photosynthesis in potato plants (*Solanum tuberosum* L.) by 49 percent; while in the study of Schapendonk *et al.* (2000), a doubling of the air's CO<sub>2</sub> content led to an 80 percent increase in net photosynthesis. In a study that additionally considered the role of the air's vapor pressure deficit (VPD), Bunce (2003) found that exposure to twice-ambient atmospheric CO<sub>2</sub> concentrations boosted net photosynthesis by 36 percent at a VPD of 0.5 kPa (moist air) but by 70 percent at a VPD of 3.5 kPa (dry air). Yet another complexity was investigated by Olivo *et al.* (2002), who assessed the effect of a doubling of the air's CO<sub>2</sub> content on the net photosynthetic rates of high-altitude (*Solanum curtilobum*) and low-altitude (*S. tuberosum*) and found the rate of the former to be enhanced by 56 percent and that of the latter by 53 percent. In addition, although they did not directly report photosynthetic rates, Louche-Tessandier *et al.* (1999) noted that photosynthetic acclimation was reduced in CO<sub>2</sub>-enriched plants that were inoculated with a fungal symbiont, which consequently allowed them to produce greater amounts of biomass than non-inoculated control plants grown in ambient air.

Because elevated CO<sub>2</sub> concentrations stimulate photosynthesis in potatoes, it is to be expected they would also increase potato biomass production. Miglietta *et al.* (1998), for example, reported that potatoes grown at 660 ppm CO<sub>2</sub> produced 40 percent more tuber biomass than control plants grown in ambient air. Such reports are common, in fact, with twice-ambient atmospheric CO<sub>2</sub> concentrations having been reported to produce yield increases of 25 percent (Lawson *et al.*, 2001), 36 percent (Chen and Setter, 2003), 37 percent (Schapendonk *et al.*, 2000), 40 percent (Olivo *et al.*, 2002), 44 percent (Sicher and Bunce, 1999), 85 percent (Olivo *et al.*, 2002) and 100 percent (Ludewig *et al.*, 1998).

A few studies have been conducted at even higher atmospheric CO<sub>2</sub> concentrations. Kauder *et al.* (2000), for example, grew plants for up to seven weeks in controlled environments receiving an extra 600 ppm CO<sub>2</sub>, obtaining final tuber yields that were 30 percent greater than those of ambiently grown plants. Also, in a study of potato microcuttings grown for four weeks in environmental chambers maintained at ambient air and air enriched with an extra 1200 ppm CO<sub>2</sub>, Pruski *et al.* (2002) found that the average

number of nodes per stem was increased by 64 percent, the average stem dry weight by 92 percent, and the average shoot length by 131 percent.

Atmospheric CO<sub>2</sub> enrichment also leads to reductions in transpirational water loss by potato plants. Magliulo *et al.* (2003), for example, grew potatoes in the field within FACE rings maintained at either ambient (370 ppm) or enriched (550 ppm) atmospheric CO<sub>2</sub> concentrations for two consecutive years, finding that the CO<sub>2</sub>-enriched plants used 12 percent less water than the ambient-treatment plants, while they produced 47 percent more tuber biomass. Hence, the CO<sub>2</sub>-enriched plants experienced a 68 percent increase in water use efficiency, or the amount of biomass produced per unit of water used in producing it. Likewise, Olivo *et al.* (2002) found that a doubling of the air's CO<sub>2</sub> content increased the instantaneous water-use efficiencies of high-altitude and low-altitude potato species by 90 percent and 80 percent, respectively.

In the final phenomenon considered here, we review the findings of three studies that evaluated the ability of atmospheric CO<sub>2</sub> enrichment to mitigate the deleterious effects of ozone pollution on potato growth. Fangmeier and Bender (2002) determined the mean tuber yield of potato as a function of atmospheric CO<sub>2</sub> concentration for conditions of ambient and high atmospheric O<sub>3</sub> concentrations, as derived from a trans-European set of experiments. At the mean ambient CO<sub>2</sub> concentration of 380 ppm, the high O<sub>3</sub> stress reduced mean tuber yield by approximately 9 percent. At CO<sub>2</sub> concentrations of 540 and 680 ppm, however, the high O<sub>3</sub> stress had no significant effect on tuber yield.

Much the same results were obtained by Wolf and van Oijen (2002, 2003), who used the validated potato model LPOTCO to project future European tuber yields. Under two climate change scenarios that incorporated the effects of increased greenhouse gases on climate (i.e., increased air temperature and reduced precipitation), the model generated increases in irrigated tuber production ranging from 2,000 to 4,000 kg of dry matter per hectare across Europe, with significant reductions in the negative effects of O<sub>3</sub> pollution.

### 7.1.1.6. Rice

DeCosta *et al.* (2003a) grew two crops of rice (*Oryza sativa* L.) at the Rice Research and Development Institute of Sri Lanka from January to March (the maha season) and from May to August (the yala season) in open-top chambers in air of either ambient or ambient plus 200 ppm CO<sub>2</sub>, determining that leaf net photosynthetic rates were significantly higher in the CO<sub>2</sub>-enriched chambers than in the ambient-air chambers: 51-75 percent greater in the maha season and 22-33 percent greater in the yala season. Likewise, in the study of Gesch *et al.* (2002), where one-month-old plants were maintained at either 350 ppm CO<sub>2</sub> or switched to a concentration of 700 ppm for 10 additional days, the plants switched to CO<sub>2</sub>-enriched air immediately displayed large increases in their photosynthetic rates that at the end of the experiment were still 31 percent greater than those exhibited by unswitched control plants.

With respect to the opposite of photosynthesis, Baker *et al.* (2000) reported that rates of carbon loss via dark respiration in rice plants decreased with increasing nocturnal CO<sub>2</sub> concentrations. As a result, it is not surprising that in the study of Weerakoon *et al.* (2000), rice plants exposed to an extra 300 ppm of atmospheric CO<sub>2</sub> exhibited a 35 percent increase in mean season-long radiation-use efficiency, defined as the amount of biomass produced per unit of solar radiation intercepted. In light of these several observations, therefore, one would logically expect rice plants to routinely produce more biomass at elevated levels of atmospheric CO<sub>2</sub>.

In conjunction with the study of DeCosta *et al.* (2003a), DeCosta *et al.* (2003b) found that CO<sub>2</sub>-enriched rice plants produced more leaves per hill, more tillers per hill, more total plant biomass, greater root dry weight, and more panicles per plant and had harvest indices that were increased by 4 percent and 2 percent, respectively, in the maha and yala seasons, which suite of benefits led to grain yield increases of 24 percent and 39 percent in those two periods. In another study, Kim *et al.* (2003) grew rice crops from the seedling stage to maturity at atmospheric CO<sub>2</sub> concentrations of ambient and ambient plus 200 ppm using FACE technology and three levels of applied nitrogen—low (LN, 4 g N m<sup>-2</sup>), medium (MN, 8 and 9 g N m<sup>-2</sup>), and high (HN, 15 g N m<sup>-2</sup>)—for three cropping seasons (1998-2000). They found that “the yield response to elevated CO<sub>2</sub> in crops supplied with MN (+14.6 percent) or HN (+15.2 percent) was about twice that of crops supplied with LN (+7.4 percent),” confirming the importance of N availability to the response of rice to atmospheric CO<sub>2</sub> enrichment that had previously been determined by Kim *et al.* (2001) and Kobaysahi *et al.* (2001).

Various environmental stresses can significantly alter the effect of elevated CO<sub>2</sub> on rice. In the study of Tako *et al.* (2001), rice plants grown at twice-ambient CO<sub>2</sub> concentrations and ambient temperatures displayed no significant increases in biomass production; but when air temperatures were raised by 2°C, the CO<sub>2</sub>-enriched plants produced 22 percent more biomass than the plants grown in non-CO<sub>2</sub>-enriched air. By contrast, Ziska *et al.* (1997) reported that CO<sub>2</sub>-enriched rice plants grown at elevated air temperatures displayed no significant increases in biomass; but when the plants were grown at ambient air temperatures, the additional 300 ppm of CO<sub>2</sub> boosted their rate of biomass production by 40 percent. In light of these observations, rice growers should select cultivars that are most responsive to elevated CO<sub>2</sub> concentrations at the air temperatures likely to prevail in their locality in order to maximize their yield production in a future high-CO<sub>2</sub> world.

Water stress can also severely reduce rice production. As an example, Widodo *et al.* (2003) grew rice plants in eight outdoor, sunlit, controlled-environment chambers at daytime atmospheric CO<sub>2</sub> concentrations of 350 and 700 ppm for an entire season. In one set of chambers, the plants were continuously flooded. In another set, drought stress was imposed during panicle initiation. In another, it was imposed during anthesis; and in the last set, drought stress was imposed at both stages. The

resultant drought-induced effects, according to the scientists, “were more severe for plants grown at ambient than at elevated CO<sub>2</sub>.” They report, for example, that “plants grown under elevated CO<sub>2</sub> were able to maintain midday leaf photosynthesis, and to some extent other photosynthetic-related parameters, longer into the drought period than plants grown at ambient CO<sub>2</sub>.”

Recovery from the drought-induced water stress was also more rapid in the elevated CO<sub>2</sub> treatment. At panicle initiation, for example, Widodo *et al.* observed that “as water was added back following a drought induction, it took more than 24 days for the ambient CO<sub>2</sub> [water]-stressed plants to recuperate in midday leaf CER, compared with only 6-8 days for the elevated CO<sub>2</sub> [water]-stressed plants.” Similarly, they report that “for the drought imposed during anthesis, midday leaf CER of the elevated CO<sub>2</sub> [water]-stressed plants were fully recovered after 16 days of re-watering, whereas those of the ambient CO<sub>2</sub> [water]-stressed plants were still 21 percent lagging behind their unstressed controls at that date.” Hence, they concluded that “rice grown under future rising atmospheric CO<sub>2</sub> should be better able to tolerate drought situations.”

In a somewhat different type of study, Watling and Press (2000) found that rice plants growing in ambient air and infected with a root hemiparasitic angiosperm obtained final biomass values that were only 35 percent of those obtained by uninfected plants. In air of 700 ppm CO<sub>2</sub>, however, the infected plants obtained biomass values that were 73 percent of those obtained by uninfected plants. Thus, atmospheric CO<sub>2</sub> enrichment significantly reduced the negative impact of this parasite on biomass production in rice.

In summary, as the CO<sub>2</sub> concentration of the air continues to rise, rice plants will likely experience greater photosynthetic rates, produce more biomass, be less affected by root parasites, and better deal with environmental stresses, all of which effects should lead to greater grain yields.

Additional information on this topic, including reviews of newer publications as they become available, can be found at <http://www.co2science.org/subject/a/agriculture/rice.php>.

### 7.1.1.7. Sorghum

Many laboratory and field experiments have demonstrated a significant positive impact of elevated levels of atmospheric CO<sub>2</sub> on total biomass and grain production in the C<sub>4</sub> crop sorghum (*Sorghum bicolor* (L.) Moench).

Ottman *et al.* (2001) grew sorghum plants in a FACE experiment conducted near Phoenix, Arizona, USA, where plants were fumigated with air containing either 360 or 560 ppm CO<sub>2</sub> and where they were further subjected to irrigation regimes resulting in both adequate and inadequate levels of soil moisture. Averaged over the two years of their study, the extra CO<sub>2</sub> increased grain yield by only 4 percent in the plots receiving adequate levels of soil moisture but by 16 percent in the dry soil moisture plots.

Prior *et al.* (2005) grew sorghum in two different years in 7-meter-wide x 76-meter-long x 2-m-deep bins filled with a silt loam soil, upon which they constructed a number of clear-plastic-wall open-top chambers they maintained at ambient CO<sub>2</sub> concentrations and ambient concentrations plus 300 ppm. In the first of the two years, the extra CO<sub>2</sub> increased sorghum residue production by 14 percent, while in the second year it increased crop residue production by 24 percent and grain production by 22 percent. For a CO<sub>2</sub> increase of 200 ppm comparable to that employed in the study of Ottman *et al.*, these figures translate to crop residue increases of 9 percent and 16 percent and a grain increase of 15 percent.

In a review of primary research papers describing results obtained from large-scale FACE experiments conducted over the prior 15 years, Ainsworth and Long (2005) determined that, in the mean, sorghum grain yield was increased by approximately 7 percent in response to a 200-ppm increase in the atmosphere's CO<sub>2</sub> concentration.

An experiment with a bit more complexity was carried out several years earlier by Watling and Press (1997), who grew sorghum with and without infection by the parasitic C<sub>3</sub> weeds *Striga hermonthica* and *S. asiatica*. The study lasted for about two months and was conducted in controlled environment cabinets fumigated with air of either 350 or 700 ppm CO<sub>2</sub>. In the absence of parasite infection, the extra 350 ppm of CO<sub>2</sub> boosted plant biomass production by 35 percent, which adjusted downward to make it compatible with

the 200-ppm increase employed in most FACE studies corresponds to an increase of just under 21 percent. When infected with *S. asiatica*, the biomass stimulation provided by the extra CO<sub>2</sub> was about the same; but when infected with *S. hermonthica*, it was almost 80 percent, which corresponds to a similarly downward adjusted biomass increase of 45 percent.

In light of these several observations, it would appear that although the CO<sub>2</sub>-induced increase in total biomass and grain yield of sorghum is rather modest, ranging from 4 to 16 percent under well-watered conditions, it can be on the high end of this range when the plants are stressed by a shortage of water (16 percent has been observed) and by parasitic infection (45 percent has been observed). Consequently, elevated levels of atmospheric CO<sub>2</sub> seem to help sorghum most when help is most needed.

Additional information on this topic, including reviews on sorghum not discussed here, can be found at [http://www.co2science.org/subject/a/subject\\_a.php](http://www.co2science.org/subject/a/subject_a.php) under the main heading Agriculture, sub heading Sorghum.

### 7.1.1.8. Soybean

Wittwer (1995) reports that the common soybean (*Glycine max* L.) “provides about two-thirds of the world’s protein concentrate for livestock feeding, and is a valuable ingredient in formulated feeds for poultry and fish.” Bernacchi *et al.* (2005) characterize the soybean as “the world’s most important seed legume.” Consequently, it is important to determine how soybeans will likely respond to rising atmospheric CO<sub>2</sub> concentrations with and without concomitant increases in air temperature and under both well-watered and water-stressed conditions.

Rogers *et al.* (2004) grew soybeans from emergence to grain maturity in ambient and CO<sub>2</sub>-enriched air (372 and 552 ppm CO<sub>2</sub>, respectively) at the SoyFACE facility of the University of Illinois at Urbana-Champaign, Illinois, USA, while CO<sub>2</sub> uptake and transpiration measurements were made from pre-dawn to post-sunset on seven days representative of different developmental stages of the crop. Across the growing season, they found that the mean daily integral of leaf net photosynthesis rose by 24.6 percent in the elevated CO<sub>2</sub> treatment, while mid-day stomatal conductance dropped by 21.9 percent, in response to the 48 percent increase in atmospheric CO<sub>2</sub> employed in their study. With respect to photosynthesis, they additionally report “there was no evidence of any loss of stimulation toward the end of the growing season,” noting that the largest stimulation actually occurred during late seed filling. Nevertheless, they say that the photosynthetic stimulation they observed was only “about half the 44.5 percent theoretical maximum increase calculated from Rubisco kinetics.” Thus, there is an opportunity for soybeans to perhaps become even more responsive to atmospheric CO<sub>2</sub> enrichment than they are currently, which potential could well be realized via future developments in the field of genetic engineering.

Bunce (2005) grew soybeans in the field in open-top chambers maintained at atmospheric CO<sub>2</sub> concentrations of ambient and ambient +350 ppm at the Beltsville Agricultural Research Center in Maryland, USA, where net CO<sub>2</sub> exchange rate measurements were performed on a total of 16 days between 18 July and 11 September of 2000 and 2003, during flowering to early pod-filling. Over the course of this study, daytime net photosynthesis per unit leaf area was 48 percent greater in the plants growing in the CO<sub>2</sub>-enriched air, while nighttime respiration per unit leaf area was not affected by elevated CO<sub>2</sub>.

However, because the elevated CO<sub>2</sub> increased leaf dry mass per unit area by an average of 23 percent, respiration per unit mass was significantly lower for the leaves of the soybeans growing in the CO<sub>2</sub>-enriched air, producing a sure recipe for accelerated growth and higher soybean seed yields.

Working in Australia, Japan, and the United States, Ziska *et al.* (2001b) observed a recurrent diurnal pattern of atmospheric CO<sub>2</sub> concentration, whereby maximum values of 440-540 ppm occurred during a three-hour pre-dawn period that was followed by a decrease to values of 350-400 ppm by mid-morning, after which there was a slow but steady increase in the late afternoon and early evening that brought the air's CO<sub>2</sub> concentration back to its pre-dawn maximum value. In an attempt to see if the pre-dawn CO<sub>2</sub> spikes they observed affected plant growth, they grew soybeans for one month in controlled-environment chambers under three different sets of conditions: a constant 24-hour exposure to 370 ppm CO<sub>2</sub>, a constant 370 ppm CO<sub>2</sub> exposure during the day followed by a constant 500 ppm CO<sub>2</sub> exposure at night, and a CO<sub>2</sub> exposure of 500 ppm from 2200 to 0900 followed by a decrease to 370 ppm by 1000, which was maintained until 2200, somewhat mimicking the CO<sub>2</sub> cycle they observed in nature. This program revealed that the 24-hour exposure to 370 ppm CO<sub>2</sub> and the 370-ppm-day/500-ppm-night treatments produced essentially the same results in terms of biomass production after 29 days. However, the CO<sub>2</sub> treatment that mimicked the observed atmospheric CO<sub>2</sub> pattern resulted in a plant biomass increase of 20 percent.

In a study that evaluated a whole range of atmospheric CO<sub>2</sub> concentrations, from far below ambient levels to high above them, Allen *et al.* (1998) grew soybeans for an entire season in growth chambers maintained at atmospheric CO<sub>2</sub> concentrations of 160, 220, 280, 330, 660, and 990 ppm. In doing so, they observed a consistent increase in total nonstructural carbohydrates in all vegetative components including roots, stems, petioles, and especially the leaves, as CO<sub>2</sub> concentrations rose. There was, however, no overall significant effect of treatment CO<sub>2</sub> concentration on nonstructural carbohydrate accumulation in soybean reproductive components, including podwalls and seeds, which observations indicate that the higher yields reported in the literature for soybeans exposed to elevated CO<sub>2</sub> most likely result from increases in the number of pods produced per plant, and not from the production of larger individual pods or seeds.

The increasing amounts of total nonstructural carbohydrates that were produced with each additional increment of CO<sub>2</sub> provided the raw materials to support greater biomass production at each CO<sub>2</sub> level. Although final biomass and yield data were not reported in this paper, the authors did present biomass data obtained at 66 days into the experiment. Relative to above-ground biomass measured at 330 ppm CO<sub>2</sub>, the plants that were grown in sub-ambient CO<sub>2</sub> concentrations of 280, 220, and 160 ppm exhibited 12, 33, and 60 percent *less* biomass, respectively, while plants grown in atmospheric CO<sub>2</sub> concentrations of 660 and 990 ppm displayed 46 and 66 percent more biomass.

In a study of two contrasting soybean cultivars, Ziska and Bunce (2000) grew *Ripley*, which is semi-dwarf and determinate in growth, and *Spencer*, which is standard-size and indeterminate in growth, for two growing seasons in open-top chambers maintained at atmospheric CO<sub>2</sub> concentrations of ambient and ambient plus 300 ppm. Averaged over both years, the elevated CO<sub>2</sub> treatment increased photosynthetic rates in the Ripley and Spencer varieties by 76 and 60 percent, respectively. However, Spencer showed a greater CO<sub>2</sub>-induced increase in vegetative biomass than Ripley (132 vs. 65 percent). Likewise, elevated CO<sub>2</sub> enhanced seed yield in Spencer by 60 percent but by only 35 percent in Ripley, suggesting that cultivar selection for favorable yield responses to atmospheric CO<sub>2</sub> enrichment could have a big impact on future farm productivity.

In another study of contrasting types of soybeans, Nakamura *et al.* (1999) grew nodulated and non-nodulated plants in pots within controlled-environmental cabinets maintained at atmospheric CO<sub>2</sub> concentrations of 360 and 700 ppm in combination with low and high soil nitrogen supply for three weeks. They found that at low nitrogen, elevated CO<sub>2</sub> increased total plant dry mass by approximately 40 and 80 percent in nodulated soybeans grown at low and high nitrogen supply, respectively, while non-nodulated plants exhibited no CO<sub>2</sub>-induced growth response at low nitrogen but an approximate 60 percent growth enhancement at high nitrogen supply. Hence, it would appear that as the air's CO<sub>2</sub> content continues to rise, non-nodulated soybeans will display increases in biomass only if they are grown in nitrogen-rich soils. Nodulated soybeans, however, should display increased growth in both nitrogen-rich and nitrogen-poor soils, with their responses being about twice as large in high as in low soil nitrogen conditions.

In yet another study of soybeans with different genetic characteristics, Ziska *et al.* (2001a) grew one modern and eight ancestral soybean genotypes in glasshouses maintained at atmospheric CO<sub>2</sub> concentrations of 400 and 710 ppm, finding that the elevated CO<sub>2</sub> increased photosynthetic rates in all cultivars by an average of 75 percent. This photosynthetic enhancement led to CO<sub>2</sub>-induced increases in seed yield that averaged 40 percent, except for one of the ancestral varieties that exhibited an 80 percent increase in seed yield.

To get a glimpse of what might happen if future temperatures also continue to rise, Ziska (1998) grew soybeans for 21 days in controlled environments having atmospheric CO<sub>2</sub> concentrations of approximately 360 (ambient) or 720 ppm and soil temperatures of 25° (ambient) or 30°C. He found that elevated CO<sub>2</sub> significantly increased whole plant net photosynthesis at both temperatures, with the greatest effect occurring at 30°C. As time progressed, however, this photosynthetic stimulation dropped from 50 percent at 13 days into the experiment to 30 percent at its conclusion eight days later; in spite of this partial acclimation, which was far from complete, atmospheric CO<sub>2</sub> enrichment significantly enhanced total plant dry weight at final harvest by 36 and 42 percent at 25° and 30°C, respectively.

Studying the complicating effects of water stress were Serraj *et al.* (1999), who grew soybeans from seed in pots within a glasshouse until they were four weeks old, after which half of the plants were subjected to an atmospheric CO<sub>2</sub> concentration of 360 ppm, while the other half were exposed to an elevated concentration of 700 ppm. In addition, half of the plants at each CO<sub>2</sub> concentration were well-watered and half of them were allowed to experience water stress for a period of 18 days. This protocol revealed that short-term (18-day) exposure of soybeans to elevated CO<sub>2</sub> significantly decreased daily and cumulative transpirational water losses compared to plants grown at 360 ppm CO<sub>2</sub>, regardless of water treatment. In fact, elevated CO<sub>2</sub> reduced total water loss by 25 and 10 percent in well-watered and water-stressed plants, respectively. Also, drought stress significantly reduced rates of net photosynthesis among plants of both CO<sub>2</sub> treatments. However, plants grown in elevated CO<sub>2</sub> consistently exhibited higher photosynthetic rates than plants grown at ambient CO<sub>2</sub>, regardless of soil water status.

At final harvest, the elevated CO<sub>2</sub> treatment had little effect on the total dry weight of plants grown at optimal soil moisture, but it increased the total dry

weight of water-stressed plants by about 33 percent. Also, while root dry weight declined for plants grown under conditions of water stress and ambient CO<sub>2</sub> concentration, no such decline was exhibited by plants subjected to atmospheric CO<sub>2</sub> enrichment and water stress.

Studying *both* water and high-temperature stress were Ferris *et al.* (1999), who grew soybeans in glasshouses maintained at atmospheric CO<sub>2</sub> concentrations of 360 and 700 ppm for 52 days, before having various environmental stresses imposed on them for eight days during early seed filling. For the eight-day stress period, some plants were subjected to air temperatures that were 15°C higher than those to which the control plants were exposed, while some were subjected to a water stress treatment in which their soil moisture contents were maintained at 40 percent of that experienced by the control plants. Averaged across all stress treatments and harvests, this protocol revealed that the high CO<sub>2</sub> treatment increased total plant biomass by 41 percent. Both high-temperature and water-deficit treatments, singly or in combination, reduced overall biomass by approximately the same degree, regardless of CO<sub>2</sub> treatment. Thus, even when the greatest biomass reductions of 17 percent occurred in the CO<sub>2</sub>-enriched and ambiently grown plants, in response to the combined stresses of high temperature and low soil moisture, plants grown in elevated CO<sub>2</sub> still exhibited an average biomass that was 24 percent greater than that displayed by plants grown in ambient CO<sub>2</sub>.

Averaged across all stress treatments and harvests, elevated CO<sub>2</sub> increased seed yield by 32 percent. In addition, it tended to ameliorate the negative effects of environmental stresses. CO<sub>2</sub>-enriched plants that were water stressed, for example, had an average seed yield that was 34 percent greater than that displayed by water-stressed controls grown at ambient CO<sub>2</sub>, while CO<sub>2</sub>-enriched plants exposed to high temperatures produced 38 percent more seed than their respectively stressed counterparts. In fact, the greatest relative impact of elevated CO<sub>2</sub> on seed yield occurred in response to the combined stresses of high temperature and low soil moisture, with CO<sub>2</sub>-enriched plants exhibiting a seed yield that was 50 percent larger than that of similarly stressed plants grown in ambient CO<sub>2</sub>.

In a predictive application of this type of knowledge, but based on a different means of obtaining it, Alexandrov and Hoogenboom (2000) studied how temperature, precipitation, and solar radiation influenced soybean yields over a 30-year

period in the southeastern United States, after which they used the results they obtained to predict future crop yields based on climate output from various global circulation models of the atmosphere. At ambient CO<sub>2</sub> concentrations, the model-derived scenarios pointed to a decrease in soybean yields by the year 2020, due in part to predicted changes in temperature and precipitation. However, when the yield-enhancing effects of a doubling of the air's CO<sub>2</sub> concentration were included in the simulations, a completely different projection was obtained: a yield *increase*.

Shifting to the subject of soybean seed *quality*, Caldwell *et al.* (2005) write that “the beneficial effects of isoflavone-rich foods have been the subject of numerous studies (Birt *et al.*, 2001; Messina, 1999),” and that “foods derived from soybeans are generally considered to provide both specific and general health benefits,” presumably via these substances. Hence, it is only natural they would wonder how the isoflavone content of soybean seeds may be affected by the ongoing rise in the air's CO<sub>2</sub> content, and that they would conduct a set of experiments to find the answer.

The scientists grew well-watered and fertilized soybean plants from seed to maturity in pots within two controlled-environment chambers, one maintained at an atmospheric CO<sub>2</sub> concentration of 400 ppm and one at 700 ppm. The chambers were initially kept at a constant air temperature of 25°C. At the onset of seed fill, however, air temperature was reduced to 18°C until seed development was complete, in order to simulate average outdoor temperatures at this stage of plant development. In a second experiment, this protocol was repeated, except the temperature during seed fill was maintained at 23°C, with and without drought (a third treatment), while in a third experiment, seed-fill temperature was maintained at 28°C, with or without drought.

In the first experiment, where air temperature during seed fill was 18°C, the elevated CO<sub>2</sub> treatment increased the total isoflavone content of the soybean seeds by 8 percent. In the second experiment, where air temperature during seed fill was 23°C, the extra CO<sub>2</sub> increased total seed isoflavone content by 104 percent, while in the third experiment, where air temperature during seed fill was 28°C, the CO<sub>2</sub>-induced isoflavone increase was 101 percent. Finally, when drought-stress was added as a third environmental variable, the extra CO<sub>2</sub> boosted total seed isoflavone content by 186 percent when seed-fill air temperature was 23°C, while at a seed-fill

temperature of 28°C, it increased isoflavone content by 38 percent.

Under all environmental circumstances studied, enriching the air with an extra 300 ppm of CO<sub>2</sub> increased the total isoflavone content of soybean seeds. In addition, the percent increases measured under the stress situations investigated were always greater than the percent increase measured under optimal growing conditions.

Also writing on the subject of soybean seed quality, Thomas *et al.* (2003) say “the unique chemical composition of soybean has made it one of the most valuable agronomic crops worldwide,” noting that “oil and protein comprise ~20 and 40%, respectively, of the dry weight of soybean seed.” Consequently, they explored the effects of elevated CO<sub>2</sub> plus temperature on soybeans that were grown to maturity in sunlit controlled-environment chambers with sinusoidally varying day/night max/min temperatures of 28/18°, 32/22°, 36/26°, 40/30°, and 44/34°C and atmospheric CO<sub>2</sub> concentrations of 350 and 700 ppm. This work revealed that the effect of temperature on seed composition and gene expression was “pronounced,” but that “there was no effect of CO<sub>2</sub>.” In this regard, however, they note that “Heagle *et al.* (1998) observed a positive significant effect of CO<sub>2</sub> enrichment on soybean seed oil and oleic acid concentration,” the latter of which parameters their own study found to rise with increasing temperature all the way from 28/18° to 44/34°C. In addition, they determined that “32/22°C is optimum for producing the highest oil concentration in soybean seed,” that “the degree of fatty acid saturation in soybean oil was significantly increased by increasing temperature,” and that crude protein concentration increased with temperature to 40/30°C.

In commenting on these observations, Thomas *et al.* note that “the intrinsic value of soybean seed is in its supply of essential fatty acids and amino acids in the oil and protein, respectively.” Hence, we conclude that the temperature-driven changes they identified in these parameters, as well as the CO<sub>2</sub> effect observed by Heagle *et al.*, bode well for the future production of this important crop and its value to society in a CO<sub>2</sub>-enriched and warming world. Thomas *et al.* note, however, that “temperatures during the soybean-growing season in the southern USA are at, or slightly higher than, 32/22°C,” and that warming could negatively impact the soybean oil industry in this region. For the world as a whole, however, warming would be a positive development for soybean production; while in the southern United States, shifts

in planting zones could readily accommodate changing weather patterns associated with this phenomenon.

In conclusion, as the air's CO<sub>2</sub> content continues to rise, soybeans will likely respond by displaying significant increases in growth and yield, with possible improvements in seed quality; these beneficial effects will likely persist even if temperatures rise or soil moisture levels decline, regardless of their cause.

### 7.1.1.9. Strawberry

In the open-top chamber study of Bunce (2001), strawberry plants (*Fragaria x ananassa*) exposed to air containing an extra 300 and 600 ppm CO<sub>2</sub>

displayed photosynthetic rates that were 77 and 106 percent greater, respectively, than rates displayed by plants grown in ambient air containing 350 ppm CO<sub>2</sub>. Similarly, Bushway and Pritts (2002) reported that strawberry plants grown at atmospheric CO<sub>2</sub> concentrations between 700 and 1,000 ppm exhibited photosynthetic rates that were consistently more than 50 percent greater than rates displayed by control plants.

Because elevated CO<sub>2</sub> stimulates rates of photosynthesis in strawberry plants, it is expected that it would also increase biomass production in this important agricultural species. After growing plants in air containing an additional 170 ppm CO<sub>2</sub> above ambient concentrations, Deng and Woodward (1998) reported that total fresh fruit weights were 42 and 17 percent greater than weights displayed by control plants receiving high and low soil nitrogen inputs, respectively. In addition, Bushway and Pritts (2002) reported that a two- to three-fold increase in the air's CO<sub>2</sub> content boosted strawberry fruit yield by 62 percent.

As the air's CO<sub>2</sub> content continues to rise, strawberry plants will likely exhibit enhanced rates of photosynthesis and biomass production, which should lead to greater fruit yields.

#### 7.1.1.10. Sunflower

As the CO<sub>2</sub> content of the air increases, sunflower plants (*Helianthus annuus* L.) will likely display enhanced rates of photosynthetic carbon uptake. In

the study of Sims *et al.* (1999), exposure to twice-ambient atmospheric CO<sub>2</sub> concentrations enhanced rates of net photosynthesis in individual upper-canopy sunflower leaves by approximately 50 percent. Similarly, Luo *et al.* (2000) reported that sunflowers grown at 750 ppm CO<sub>2</sub> displayed canopy carbon uptake rates that were fully 53 percent greater than those exhibited by plants grown at 400 ppm CO<sub>2</sub>.

The study of Zerihun *et al.* (2000) reported that twice-ambient CO<sub>2</sub> concentrations increased whole plant biomass in sunflowers by 44, 13, and 115 percent when the plants were simultaneously exposed to low, medium, and high levels of soil nitrogen, respectively.

Additional information on this topic, including reviews of newer publications as they become available, can be found at <http://www.co2science.org/subject/a/agriculturesun.php>.

#### 7.1.1.11. Tomato

In the study of Ziska *et al.* (2001), tomato plants (*Lycopersicon esculentum* Mill.) grown at a nocturnal atmospheric CO<sub>2</sub> concentration of 500 ppm displayed total plant biomass values that were 10 percent greater than those exhibited by control plants growing in air containing 370 ppm CO<sub>2</sub>. This result was likely the consequence of the elevated CO<sub>2</sub> reducing the rate of nocturnal respiration in the plants, which would have allowed them to utilize the retained carbon to produce more biomass.

This CO<sub>2</sub>-induced benefit, as well as a host of other positive effects of atmospheric CO<sub>2</sub> enrichment, are also manifest under unfavorable growing conditions. Jwa and Walling (2001), for example,

reported that fungal infection reduced plant biomass in tomatoes growing in normal air by about 30 percent. However, in fungal-infected plants grown at twice-ambient atmospheric CO<sub>2</sub> concentrations, the elevated CO<sub>2</sub> completely ameliorated the growth-reducing effects of the pathogen.

In another stressful situation, Maggio *et al.* (2002) reported that a 500-ppm increase in the air's CO<sub>2</sub> concentration increased the average value of the root-zone salinity threshold in tomato plants by about 60 percent. In addition, they reported that the water-use efficiency of the CO<sub>2</sub>-enriched plants was about twice that of the ambiently grown plants.

As the CO<sub>2</sub> content of the air increases, tomato plants will likely display greater rates of photosynthesis and biomass production, which should consequently lead to greater fruit yields, even under stressful conditions of fungal infection and high soil salinity.

### 7.1.1.12. Wheat

In one study, Dijkstra *et al.* (1999) grew winter wheat (*Triticum aestivum* L.) in open-top chambers and field-tracking sun-lit climatized enclosures maintained at atmospheric CO<sub>2</sub> concentrations of ambient and ambient plus 350 ppm CO<sub>2</sub> for two years, determining that the elevated CO<sub>2</sub> increased both final grain yield and total above-ground biomass by 19 percent. In another study, Masle (2000) grew two varieties of wheat for close to a month in

greenhouses maintained at atmospheric CO<sub>2</sub> concentrations of 350 and 900 ppm, finding that the CO<sub>2</sub>-enriched plants exhibited biomass increases of 52 to 93 percent, depending upon variety and vernalization treatment.

Based on a plethora of experimental observations of this nature, many scientists have developed yield prediction models for wheat. Using the output of several such models, Alexandrov and Hoogenboom (2000) estimated the impact of typically predicted climate changes on wheat production in Bulgaria in the twenty-first century, finding that a doubling of the air's CO<sub>2</sub> concentration would likely enhance wheat yields there between 12 and 49 percent in spite of a predicted 2.9° to 4.1°C increase in air temperature. Likewise, Eitzinger *et al.* (2001) employed the WOFOST crop model to estimate wheat production in northeastern Austria in the year 2080. For a doubled atmospheric CO<sub>2</sub> concentration with concomitant climate changes derived from five different general circulation models of the atmosphere, they obtained simulated yield increases of 30 to 55 percent, even in the face of predicted changes in both temperature and precipitation.

Southworth *et al.* (2002) used the CERES-Wheat growth model to calculate winter wheat production during the period 2050-2059 for 10 representative farm locations in Indiana, Illinois, Ohio, Michigan, and Wisconsin, USA, for six future climate scenarios. They report that some of the southern portions of this group of states would have exhibited climate-induced yield decreases had the aerial fertilization effect of the CO<sub>2</sub> increase that drove the predicted changes in climate not been included in the model. When they did include the increase in the air's CO<sub>2</sub> concentration (to a value of 555 ppm), however, they note that "wheat yields increased 60 to 100% above current yields across the central and northern areas of the study region," while in the southern areas "small increases and small decreases were found." The few minor decreases, however, were associated with the more extreme Hadley Center greenhouse run that presumed a 1 percent increase in greenhouse gases per year and a doubled climate variability; hence, they would have to be considered highly unlikely.

In discussing their findings, Southworth *et al.* note that other modeling studies have obtained similar results for other areas. They report, for example, that Brown and Rosenberg (1999) found winter wheat yields across other parts of the United States to increase "under all climate change scenarios modeled (1, 2.5, and 5°C temperature increases)," and that

Cuculeanu *et al.* (1999) found modeled yields of winter wheat in southern Romania to increase by 15 to 21 percent across five sites. Also, they note that Harrison and Butterfield (1996) “found increased yields of winter wheat across Europe under all the climate change scenarios they modeled.”

Van Ittersum *et al.* (2003) performed a number of simulation experiments with the Agricultural Production Systems Simulator (APSIM)-Nwheat model in which they explored the implications of possible increases in atmospheric CO<sub>2</sub> concentration and near-surface air temperature for wheat production and deep drainage at three sites in Western Australia differing in precipitation, soil characteristics, nitrogenous fertilizer application rates, and wheat cultivars. They first assessed the impact of the ongoing rise in the air’s CO<sub>2</sub> content, finding that wheat grain yield increased linearly at a rate of 10-16 percent for each 100-ppm increase in atmospheric CO<sub>2</sub> concentration, with only a slight concomitant increase in deep drainage (a big win, small loss outcome). For a likely future CO<sub>2</sub> increase of 200 ppm, increases in grain yield varied between 3 and 17 percent for low nitrogen fertilizer application rates and between 21 and 34 percent for high rates of nitrogen application, with the greatest relative yield response being found for the driest site studied.

When potential warming was factored into the picture, the results proved even better. The positive effects of the CO<sub>2</sub> increase on wheat grain yield were enhanced an extra 3-8 percent when temperatures were increased by 3°C in the model simulations. These yield increases were determined to result in an increased financial return to the typical Western Australian wheat farmer of 15-35 percent. In addition, the imposition of the simultaneous temperature increase led to a significant decline in deep drainage, producing a truly win-win situation that enhanced the average farmer’s net income by an additional 10-20 percent. Consequently, it was determined that the CO<sub>2</sub>-induced increase in temperature predicted by the IPCC could well increase the net profitability of Western Australian wheat farmers by anywhere from 25-55 percent, while at the same time mitigating what van Ittersum *et al.* refer to as “one of Australia’s most severe land degradation problems.”

In a wide variety of circumstances, atmospheric CO<sub>2</sub> enrichment significantly increases the biomass production and yield of wheat plants, thereby benefiting both wheat producers and consumers alike.

### 7.1.2. Woody Plants

The growth response of woody plants to atmospheric CO<sub>2</sub> enrichment has also been extensively studied. Ceulemans and Mousseau (1994), for example, tabulated the results of 95 separate experimental investigations related to this topic. The review of Poorter (1993) includes 41 additional sets of pertinent results, and the two reviews of Wullschleger et al. (1995, 1997) contain 40 other sets of applicable data. When averaged together, these 176 individual woody plant experiments reveal a mean growth enhancement on the order of 50 percent for an approximate doubling of the air's CO<sub>2</sub> content, which is about one-and-a-half times as much as the response of non-woody herbaceous plants.

It is possible, however, that this larger result is still an underestimate of the capacity of trees and shrubs to respond to atmospheric CO<sub>2</sub> enrichment; for the mean duration of the 176 woody plant experiments described above was only five months, which may not have been sufficient for the long-term equilibrium effects of the CO<sub>2</sub> enrichment of the air to be manifest. In the world's longest such experiment, for example, Kimball *et al.* (2007) observed a 70 percent sustained increase in biomass production over the entire last decade of a 17-year study in response to a 75 percent increase in the air's CO<sub>2</sub> content employed throughout the experiment. Likewise, studies of Eldarica pine trees conducted at the same location have revealed a similarly increasing growth response over the same length of time (Idso and Kimball, 1994).

In the subsections that follow, we highlight the results of studies that have examined the growth response of several woody plants to atmospheric CO<sub>2</sub> enrichment. We end the section with discussions of the effect of CO<sub>2</sub> enhancement on wood density and forest productivity and carbon sequestration. For more information on this topic, see [http://www.co2science.org/data/plant\\_growth/plantgrowth.php](http://www.co2science.org/data/plant_growth/plantgrowth.php).

#### 7.1.2.1. Aspen-Poplar

Several studies have documented the effects of elevated levels of atmospheric CO<sub>2</sub> on photosynthesis in various aspen clones (*Populus tremuloides*). In the short-term study of Kruger *et al.* (1998), aspen seedlings grown for 70 days at atmospheric CO<sub>2</sub> concentrations of 650 ppm exhibited photosynthetic rates that were approximately 10 percent greater than those displayed by seedlings maintained at ambient CO<sub>2</sub> concentrations. In the longer five-month study of Kubiske *et al.* (1998), atmospheric CO<sub>2</sub> enrichment significantly increased photosynthetic rates in four aspen genotypes, regardless of soil nitrogen status.

In an even longer 2.5-year study, Wang and Curtis (2001) also observed significant CO<sub>2</sub>-induced photosynthetic increases in two male and two female aspen clones; when six aspen genotypes were grown in open-top chambers for 2.5 years at atmospheric CO<sub>2</sub> concentrations of 350 and 700 ppm, Curtis *et al.* (2000) reported that the elevated CO<sub>2</sub> concentrations increased rates of net photosynthesis by 128 and 31 percent at high and low soil nitrogen contents, respectively. In addition, in a study that looked only at air temperature effects that was conducted at ambient CO<sub>2</sub> concentrations, King *et al.* (1999) determined that increasing the air temperature from 13° to 29°C enhanced photosynthetic rates in four different aspen clones by an average of 35 percent.

In a FACE study, where O<sub>3</sub>-sensitive and O<sub>3</sub>-tolerant clones were grown for six months in field plots receiving 360 and 560 ppm CO<sub>2</sub> in combination with ambient and enriched (1.5 times ambient) O<sub>3</sub> levels, Noormets *et al.* (2001) reported that CO<sub>2</sub>-induced increases in photosynthetic rates were at least maintained, and sometimes even increased, when clones were simultaneously exposed to elevated O<sub>3</sub>. After an entire year of treatment exposure, in fact, Karnosky *et al.* (1999) noted that the powerful ameliorating effect of elevated CO<sub>2</sub> on ozone-induced damage was still operating strongly in this system. O<sub>3</sub>-induced foliar damages in O<sub>3</sub>-sensitive and O<sub>3</sub>-tolerant clones were reduced from 55 and 17 percent, respectively, at ambient CO<sub>2</sub>, to 38 and 3 percent, respectively, at elevated CO<sub>2</sub>.

With respect to biomass production, Pregitzer *et al.* (2000) reported that 2.5 years of exposure to twice-ambient concentrations of atmospheric CO<sub>2</sub> increased fine-root biomass in six aspen genotypes by an average of 65 and 17 percent on nitrogen-rich and nitrogen-poor soils, respectively. Using this same experimental system, Zak *et al.* (2000) determined that elevated CO<sub>2</sub> enhanced total seedling biomass by 38 percent at high soil nitrogen and by 16 percent at low soil nitrogen. Similar results were reported in the two-year open-top chamber study of Mikan *et al.* (2000), who observed 50 and 25 percent CO<sub>2</sub>-induced increases in total seedling biomass at high and low soil nitrogen levels, respectively.

As the air's CO<sub>2</sub> content continues to increase, aspen seedlings will likely display enhanced rates of photosynthesis and biomass production, regardless of genotype, gender, O<sub>3</sub>-sensitivity, and soil nitrogen status. Consequently, greater amounts of carbon will likely be sequestered in the tissues of this most abundant of North American tree species and in the soils in which they are rooted in the years and decades ahead.

### 7.1.2.2. Beech

Egli and Korner (1997) rooted eight beech saplings (genus *Fagus*) directly into calcareous or acidic soils in open-top chambers and exposed them to atmospheric CO<sub>2</sub> concentrations of either 370 or 570 ppm. Over the first year of their study, the saplings growing on calcareous soil in CO<sub>2</sub>-enriched air

exhibited a 9 percent increase in stem diameter; they speculated that this initial small difference may “cumulate to higher ‘final’ tree biomass through compounding interest.” At the end of three years of differential CO<sub>2</sub> exposure, the trees in the CO<sub>2</sub>-enriched chambers were experiencing net ecosystem carbon exchange rates that were 58 percent greater than the rates of the trees in the ambient CO<sub>2</sub> chambers, regardless of soil type; the stem dry mass of the CO<sub>2</sub>-enriched trees was increased by about 13 percent over that observed in the ambient-air chambers (Maurer *et al.*, 1999).

In a similar but much shorter experiment, Dyckmans *et al.* (2000) grew three-year-old seedlings of beech for six weeks in controlled environment chambers maintained at atmospheric CO<sub>2</sub> concentrations of 350 and 700 ppm, finding that the doubling of the air’s CO<sub>2</sub> content increased seedling carbon uptake by 63 percent. They also noted that the majority of the assimilated carbon was allocated to the early development of leaves, which would be expected to subsequently lead to greater absolute amounts of photosynthetic carbon fixation.

In the two-year study of Grams *et al.* (1999), beech seedlings grown at ambient CO<sub>2</sub> concentrations displayed large reductions in photosynthetic rates when simultaneously exposed to twice-ambient levels of ozone. However, at twice-ambient CO<sub>2</sub> concentrations, twice-ambient ozone concentrations had no negative effects on the trees’ photosynthetic rates. Thus, atmospheric CO<sub>2</sub> enrichment completely ameliorated the negative effects of ozone on photosynthesis in this species.

Similarly, Polle *et al.* (1997) reported that beech seedlings grown at 700 ppm CO<sub>2</sub> for two years displayed significantly reduced activities of catalase and superoxide dismutase, which are antioxidative enzymes responsible for detoxifying highly reactive oxygenated compounds within cells. Their data imply that CO<sub>2</sub>-enriched atmospheres are conducive to less oxidative stress and, therefore, less production of harmful oxygenated compounds than typically occurs in ambient air. Consequently, the seedlings growing in the CO<sub>2</sub>-enriched air were likely able to remobilize a portion of some of their valuable raw materials away from the production of detoxifying enzymes and reinvest them into other processes required for facilitating optimal plant development and growth.

With respect to this concept of resource optimization, Duquesnay *et al.* (1998) studied the relative amounts of <sup>12</sup>C and <sup>13</sup>C in tree rings of beech growing for the past century in northeastern France

and determined that the intrinsic water-use efficiency of the trees had increased by approximately 33 percent over that time period, no doubt in response to the concomitant rise in the air’s CO<sub>2</sub> concentration over the past 100 years.

In conclusion, as the CO<sub>2</sub> content of the air increases, beech trees will likely display enhanced rates of photosynthesis and decreased damage resulting from oxidative stress. Together, these phenomena should allow greater optimization of raw materials within beech, allowing them to produce greater amounts of biomass ever more efficiently as the atmospheric CO<sub>2</sub> concentration increases.

7.1.2.3. Birch

In the relatively short-term study of Wayne *et al.* (1998), yellow birch seedlings (*Betula pendula*) grown for two months at atmospheric CO<sub>2</sub> concentrations of 800 ppm exhibited photosynthetic rates that were about 50 percent greater than those displayed by control seedlings fumigated with air containing 400 ppm CO<sub>2</sub>. Similarly, in the three-month study of Tjoelker *et al.* (1998a), paper birch seedlings grown at 580 ppm CO<sub>2</sub> displayed photosynthetic rates that were approximately 30 percent greater than those exhibited by seedlings exposed to 370 ppm CO<sub>2</sub>. Likewise, Kellomaki and Wang (2001) reported that birch seedlings exposed to an atmospheric CO<sub>2</sub> concentration of 700 ppm for five months displayed photosynthetic rates that were about 25 percent greater than seedlings grown at 350 ppm CO<sub>2</sub>. Finally, in the much longer four-year study conducted by Wang *et al.* (1998), silver birch seedlings grown in open-top chambers receiving twice-ambient concentrations of atmospheric CO<sub>2</sub> displayed photosynthetic rates that were fully 110 percent greater than rates displayed by their ambiently grown counterparts. Thus, short-term photosynthetic enhancements resulting from atmospheric CO<sub>2</sub> enrichment appear to persist for several years or longer.

Because elevated CO<sub>2</sub> enhances photosynthetic rates in birch trees, it likely will also lead to increased biomass production in these important deciduous trees, as it has in several experiments. In the three-month study of Tjoelker *et al.* (1998b), for example, a 57 percent increase in the air's CO<sub>2</sub> content increased the biomass of paper birch seedlings by 50 percent. When similar seedlings were grown at 700 ppm CO<sub>2</sub> for four months, Catovsky and Bazzaz (1999) reported that elevated CO<sub>2</sub> increased total seedling biomass by 27 and 130 percent under wet and dry soil moisture regimes, respectively. In the interesting study of Godbold *et al.* (1997), paper birch seedlings grown at 700 ppm for six months not only increased their total biomass, but also increased the number of root tips per plant by more than 50 percent. In the longer two-year study of Berntson and Bazzaz (1998), twice-ambient levels of CO<sub>2</sub> increased the biomass of a mixed yellow and white birch mesocosm by 31 percent; and in another two-year study, Wayne *et al.* (1998) reported that yellow birch seedlings grown at 800 ppm CO<sub>2</sub> produced 60 and 227 percent more biomass than seedlings grown at 400 ppm CO<sub>2</sub> at ambient and elevated air temperatures, respectively.

Finally, after exposing silver birch seedlings to twice-ambient CO<sub>2</sub> concentrations for four years, Wang *et al.* (1998) noted that CO<sub>2</sub>-enriched seedlings produced 60 percent more biomass than ambiently grown seedlings. Hence, atmospheric CO<sub>2</sub> enrichment clearly enhances birch biomass in both short- and medium-term experiments.

In some studies, elevated CO<sub>2</sub> also reduced stomatal conductances in birch trees, thereby boosting their water-use efficiencies. Tjoelker *et al.* (1998a), for example, reported that paper birch seedlings grown at 580 ppm CO<sub>2</sub> for three months experienced 10-25 percent reductions in stomatal conductance, which contributed to 40-80 percent increases in water-use efficiency. Similar CO<sub>2</sub>-induced reductions in stomatal conductance (21 percent) were reported in silver birch seedlings grown for four years at 700 ppm CO<sub>2</sub> by Rey and Jarvis (1998).

The results of these several studies suggest that the ongoing rise in the air's CO<sub>2</sub> content will likely increase rates of photosynthesis and biomass production in birch trees, as well as improve their water use efficiencies, irrespective of any concomitant changes in air temperature and/or soil moisture status that might occur. Consequently, rates of carbon sequestration by this abundant temperate forest species should also increase in the years and decades ahead.

#### 7.1.2.4. Citrus Trees

How does atmospheric CO<sub>2</sub> enrichment affect the growth and development of citrus trees and the fruit they produce?

In the study of Keutgen and Chen (2001), cuttings of *Citrus madurensis* grown for three months at 600 ppm CO<sub>2</sub> displayed rates of photosynthesis that were more than 300 percent greater than those measured on control cuttings grown at 300 ppm CO<sub>2</sub>. In addition, elevated CO<sub>2</sub> concentrations have been shown to increase photosynthetic rates in mango (Schaffer *et al.*, 1997), mangosteen (Schaffer *et al.*, 1999), and sweet orange (Jifon *et al.*, 2002). In the study of Jifon *et al.*, it was further reported that twice-ambient CO<sub>2</sub> concentrations increased photosynthetic rates in mycorrhizal- and non-mycorrhizal-treated sour orange seedlings by 118 and 18 percent, respectively.

Such CO<sub>2</sub>-induced increases in photosynthesis should lead to enhanced biomass production; and so they do. Idso and Kimball (2001), for example, have documented how a 75 percent increase in the air's CO<sub>2</sub> content has boosted the long-term production of above-ground wood and fruit biomass in sour orange trees by 80 percent in a study that has been ongoing since November 1987. Furthermore, Idso *et al.* (2002) have additionally demonstrated that the 300-ppm increase in the air's CO<sub>2</sub> content has increased the fresh weight of individual oranges by an average of 4

percent and the vitamin C content of their juice by an average of 5 percent.

In summary, these peer-reviewed studies suggest that as the air's CO<sub>2</sub> content slowly but steadily rises, citrus trees will respond by increasing their rates of photosynthesis and biomass production. In addition, they may also increase the vitamin C content of their fruit, which may help to prevent an array of human health problems brought about by insufficient intake of vitamin C.

Additional information on this topic, including reviews of newer publications as they become available, can be found at <http://www.co2science.org/subject/t/treescitrus.php>.

#### 7.1.2.5. Eucalyptus

In the eight-month study of Roden *et al.* (1999), *Eucalyptus pauciflora* seedlings growing at 700 ppm CO<sub>2</sub> displayed seasonal rates of net photosynthesis

that were approximately 30 percent greater than those exhibited by their ambiently grown counterparts. In another eight-month study, Palanisamy (1999) reported that well-watered *Eucalyptus cladocalyx* seedlings exposed to 800 ppm CO<sub>2</sub> exhibited photosynthetic rates that were 120 percent higher than those observed in control plants growing at 380 ppm CO<sub>2</sub>. Moreover, after a one-month period of water stress, photosynthetic rates of CO<sub>2</sub>-enriched seedlings were still 12 percent greater than rates displayed by ambiently grown water-stressed seedlings.

Because elevated CO<sub>2</sub> enhances photosynthetic rates in eucalyptus species, this phenomenon should lead to increased biomass production in these rapidly growing trees. And so it does. In the eight-month experiment of Gleadow *et al.* (1998), for example, *Eucalyptus cladocalyx* seedlings growing at 800 ppm CO<sub>2</sub> displayed 134 and 98 percent more biomass than seedlings growing at 400 ppm CO<sub>2</sub> at low and high soil nitrogen concentrations, respectively. Similarly, *Eucalyptus pauciflora* seedlings growing at twice-ambient CO<sub>2</sub> concentrations for eight months produced 53 percent more biomass than control seedlings (Roden *et al.*, 1999).

In summary, as the CO<sub>2</sub> content of the air increases, eucalyptus seedlings will likely display enhanced rates of photosynthesis and biomass production, regardless of soil moisture and nutrient status. Consequently, greater amounts of carbon will likely be sequestered by this rapidly growing tree species.

Additional information on this topic, including reviews of newer publications as they become available, can be found at <http://www.co2science.org/subject/t/treeseuc.php>.

### 7.1.2.6. Fruit-Bearing

Several studies have recently documented the effects of elevated atmospheric CO<sub>2</sub> concentrations on photosynthesis in various fruiting trees. In an eight-day experiment, Pan *et al.* (1998) found that twice-ambient CO<sub>2</sub> concentrations increased rates of net photosynthesis in one-year-old apple seedlings by 90 percent. In a longer three-month study, Keutgen and Chen (2001) noted that cuttings of *Citrus madurensis* exposed to 600 ppm CO<sub>2</sub> displayed rates of photosynthesis that were more than 300 percent greater than rates observed in control cuttings exposed to 300 ppm CO<sub>2</sub>. Likewise, in the review paper of Schaffer *et al.* (1997), it was noted that atmospheric CO<sub>2</sub> enrichment had previously been shown to enhance rates of net photosynthesis in various tropical and sub-tropical fruit trees, including avocado, banana, citrus, mango, and mangosteen. Finally in the two-year study of Centritto *et al.* (1999a), cherry seedlings grown at 700 ppm CO<sub>2</sub> exhibited photosynthetic rates that were 44 percent greater than those displayed by seedlings grown in ambient air, independent of a concomitant soil moisture treatment.

Because elevated CO<sub>2</sub> enhances the photosynthetic rates of fruiting trees, it should also lead to increased biomass production in them. In the two-year study of Centritto *et al.* (1999b), for example, well-watered and water-stressed seedlings growing at twice-ambient CO<sub>2</sub> concentrations displayed basal trunk areas that were 47 and 51 percent larger than their respective ambient controls. Similarly, in a study spanning more than 13 years, Idso and Kimball (2001) demonstrated that the above-ground wood biomass of mature sour orange trees growing in air enriched with an additional 300 ppm of CO<sub>2</sub> was 80 percent greater than that attained by control trees growing in ambient air.

As the CO<sub>2</sub> content of the air increases, fruit trees will likely display enhanced rates of photosynthesis and biomass production, regardless of soil moisture conditions. Consequently, greater amounts of carbon will likely be sequestered in the woody trunks and branches of such species. Moreover, fruit yields may increase as well. In the study of Idso and Kimball, for example, fruit yields were stimulated to essentially the same degree as above-ground wood biomass; i.e., by 80 percent in response to a 75 percent increase in the air's CO<sub>2</sub> content.

### 7.1.2.7. Nitrogen-Fixing Trees

In the six-week study of Schortemeyer *et al.* (1999), seedlings of Australian blackwood (*Acacia melanoxylon*) grown at twice-ambient atmospheric CO<sub>2</sub> concentrations displayed photosynthetic rates that were 22 percent greater than those of ambiently grown seedlings. In addition, the CO<sub>2</sub>-enriched seedlings exhibited biomass values that were twice as large as those displayed by control seedlings grown in air of 350 ppm CO<sub>2</sub>. Likewise, Polley *et al.* (1999) reported that a doubling of the atmospheric CO<sub>2</sub> concentration for three months increased honey mesquite (*Prosopis glandulosa*) seedling root and shoot biomass by 37 and 46 percent, respectively.

Several studies have investigated the effects of elevated CO<sub>2</sub> on black locust (*Robinia pseudoacacia*) seedlings. Uselman *et al.* (2000), grew seedlings for

three months at 700 ppm CO<sub>2</sub> and reported that this treatment increased the root exudation of organic carbon compounds by 20 percent, while Uselman *et al.* (1999) reported no CO<sub>2</sub>-induced increases in the root exudation of organic nitrogen compounds. Nonetheless, elevated CO<sub>2</sub> enhanced total seedling biomass by 14 percent (Uselman *et al.*, 2000).

In the study of Olesniewicz and Thomas (1999), black locust seedlings grown at twice-ambient CO<sub>2</sub> concentrations for two months exhibited a 69 percent increase in their average rate of nitrogen-fixation when they were not inoculated with an arbuscular mycorrhizal fungal species. It was further determined that the amount of seedling nitrogen derived from nitrogen-fixation increased in CO<sub>2</sub>-enriched plants by 212 and 90 percent in non-inoculated and inoculated seedlings, respectively. Elevated CO<sub>2</sub> enhanced total plant biomass by 180 and 51 percent in non-inoculated and inoculated seedlings, respectively.

As the CO<sub>2</sub> content of the air increases, nitrogen-fixing trees respond by exhibiting enhanced rates of photosynthesis and biomass production, as well as enhanced rates of nitrogen fixation.

#### 7.1.2.8. Oak

How do oak (genus *Quercus*) trees respond to atmospheric CO<sub>2</sub> enrichment? In the two-month study of Anderson and Tomlinson (1998), northern red oak seedlings exposed to 700 ppm CO<sub>2</sub> displayed photosynthetic rates that were 34 and 69 percent greater than those displayed by control plants growing under well-watered and water-stressed conditions, respectively. Similarly, in the four-month study of Li *et al.* (2000), *Quercus myrtifolia* seedlings growing at twice-ambient CO<sub>2</sub> concentrations exhibited rates of photosynthesis at the onset of senescence that were 97 percent greater than those displayed by ambiently growing seedlings.

In the year-long study of Staudt *et al.* (2001), *Quercus ilex* seedlings grown at 700 ppm CO<sub>2</sub> displayed trunk and branch biomasses that were 90 percent greater than those measured on seedlings growing at 350 ppm CO<sub>2</sub>. Also, in the eight-month inter-generational study performed by Polle *et al.* (2001), seedlings produced from acorns collected from ambient and CO<sub>2</sub>-enriched mother trees and germinated in air of either ambient or twice-ambient atmospheric CO<sub>2</sub> concentration displayed whole-plant biomass values that were 158 and 246 percent greater, respectively, than those exhibited by their respective control seedlings growing in ambient air.

In another study, Schulte *et al.* (1998) grew oak seedlings for 15 weeks at twice-ambient CO<sub>2</sub> concentrations, finding that elevated CO<sub>2</sub> enhanced seedling biomass by 92 and 128 percent under well-watered and water-stressed conditions, respectively. In a similar study conducted by Tomlinson and Anderson (1998), water-stressed seedlings growing at 700 ppm CO<sub>2</sub> displayed biomass values that were similar to those exhibited by well-watered plants growing in ambient air. Thus, atmospheric CO<sub>2</sub> enrichment continues to benefit oak trees even under water-stressed conditions.

Additional studies have demonstrated that oak seedlings also respond positively to atmospheric CO<sub>2</sub> enrichment when they are faced with other environmental stresses and resource limitations. When pedunculate oak seedlings were subjected to two different soil nutrient regimes, for example,

Maillard *et al.* (2001) reported that a doubling of the atmospheric CO<sub>2</sub> concentration enhanced seedling biomass by 140 and 30 percent under high and low soil nitrogen conditions, respectively. And in the study of Usami *et al.* (2001), saplings of *Quercus myrsinaefolia* that were grown at 700 ppm CO<sub>2</sub> displayed biomass increases that were 110 and 140 percent greater than their ambiently grown counterparts when they were simultaneously subjected to air temperatures that were 3° and 5°C greater than ambient temperature, respectively. Thus, elevated CO<sub>2</sub> concentrations tend to ameliorate some of the negative effects caused by growth-reducing stresses in oaks. In fact, when Schwanz and Polle (1998) reported that elevated CO<sub>2</sub> exposure caused reductions in the amounts of several foliar antioxidative enzymes in mature oak trees, they suggested that this phenomenon was the result of atmospheric CO<sub>2</sub> enrichment causing the trees to experience less oxidative stress and, therefore, they had less need for antioxidative enzymes.

In some studies, elevated CO<sub>2</sub> has been shown to reduce stomatal conductances in oak trees, thus contributing to greater tree water-use efficiencies. Tognetti *et al.* (1998a), for example, reported that oak seedlings growing near a natural CO<sub>2</sub>-emitting spring exhibited less water loss and more favorable turgor pressures than trees growing further away from the spring. The resulting improvement in water-use efficiency was so significant that Tognetti *et al.* (1998b) stated, “such marked increases in water-use efficiency under elevated CO<sub>2</sub> might be of great importance in Mediterranean environments in the perspective of global climate change.”

In summary, it is clear that as the CO<sub>2</sub> content of the air increases, oak seedlings will likely display enhanced rates of photosynthesis and biomass production, regardless of air temperature, soil moisture, and soil nutrient status. Consequently, greater amounts of carbon will likely be removed from the atmosphere by the trees of this abundant genus and stored in their tissues and the soils in which they are rooted.

- 7.1.2.9. Pine
- 7.1.2.9.1. Loblolly
- Tissue *et al.* (1997) grew seedlings of loblolly pine trees (*Pinus taeda* L.) for a period of four years in open-top chambers maintained at atmospheric CO<sub>2</sub> concentrations of either 350 or 650 ppm in a study of the long-term effects of elevated CO<sub>2</sub> on the growth of this abundant pine species. This experiment indicated there was a mean biomass accumulation in the seedlings grown in CO<sub>2</sub>-enriched air that was 90 percent greater than that attained by the seedlings grown in ambient air.
- Johnson *et al.* (1998) reviewed 11 of their previously published papers, describing the results of a series of greenhouse and open-top chamber studies of the growth responses of loblolly pine seedlings to a range of atmospheric CO<sub>2</sub> and soil nitrogen concentrations. This work indicated that when soil nitrogen levels were so low as to be extremely deficient, or so high as to be toxic, growth responses to atmospheric CO<sub>2</sub> enrichment were negligible. For moderate soil nitrogen deficiencies, however, a doubling of the air's CO<sub>2</sub> content sometimes boosted growth by as much as 1,000 percent. Consequently, since the nitrogen status of most of earth's ecosystems falls somewhere between extreme deficiency and toxicity, these results suggest that loblolly pine trees may experience large increases in growth as the air's CO<sub>2</sub> content continues to climb.
- Naidu and DeLucia (1999) described the results of working one full year in 30-meter-diameter circular FACE plots maintained at atmospheric CO<sub>2</sub> concentrations of either 350 or 560 ppm in an originally 13-year-old loblolly pine plantation in North Carolina, USA, where they determined the effects of the elevated CO<sub>2</sub> treatment on the productivity of the trees, which were growing in soil that was characteristically low in nitrogen and phosphorus. After the first year of atmospheric CO<sub>2</sub> enrichment in this Duke Forest Face Study, the growth rate of the CO<sub>2</sub>-enriched trees was about 24 percent greater than that of the trees exposed to ambient CO<sub>2</sub>, in spite of the likelihood of soil nutrient limitations and a severe summer drought (rainfall in August 1997 was about 90 percent below the 50-year average).

After four years of work at the Duke Forest Face Site, Finzi *et al.* (2002) reported that the extra 200 or so ppm of CO<sub>2</sub> had increased the average yearly dry matter production of the CO<sub>2</sub>-enriched trees by 32 percent, while at the eight-year point of the experiment Moore *et al.* (2006) reported there had been a sustained increase in trunk basal area increment that varied between 13 and 27 percent with variations in weather and the timing of growth. What is more, they say “there was no evidence of a decline in the relative enhancement of tree growth by elevated CO<sub>2</sub> as might be expected if soil nutrients were becoming progressively more limiting,” which many people had expected would occur in light of the site’s low soil nitrogen and phosphorus content. In addition, at the six-year point of the study Pritchard *et al.* (2008) determined that the extra CO<sub>2</sub> had increased the average standing crop of fine roots by 23 percent.

Gavazzi *et al.* (2000) grew one-year-old loblolly pine seedlings for about four months in pots placed within growth chambers maintained at atmospheric CO<sub>2</sub> concentrations of either 360 or 660 ppm and adequate or inadequate levels of soil moisture, while the pots were seeded with a variety of C<sub>3</sub> and C<sub>4</sub> weeds. In the course of this experiment, they found that total seedling biomass was always greater under well-watered as opposed to water-stressed conditions, and that elevated CO<sub>2</sub> increased total seedling biomass by 22 percent in both water treatments. In the elevated CO<sub>2</sub> and water-stressed treatment, however, they also found that seedling root-to-shoot ratios were about 80 percent greater than they were in the elevated CO<sub>2</sub> and well-watered treatment, due to a 63 percent increase in root biomass. In the case of the weeds, total biomass was also always greater under well-watered compared to water-stressed conditions. However, the elevated CO<sub>2</sub> did *not* increase weed biomass; in fact, it reduced it by approximately 22 percent. Consequently, in assessing the effects of elevated CO<sub>2</sub> on competition between loblolly pine seedlings and weeds, the seedlings were definitely the winners, with the researchers concluding that the CO<sub>2</sub>-induced increase in root-to-shoot ratio under water-stressed conditions may “contribute to an improved ability of loblolly pine to compete against weeds on dry sites.”

Working with data obtained from stands of loblolly pine plantations at 94 locations scattered throughout the southeastern United States, Westfall and Amateis (2003) employed mean height measurements made at three-year intervals over a

period of 15 years to calculate a site index related to mean growth rate for each of the five three-year periods, which index would be expected to increase monotonically if growth rates were being enhanced above “normal” by some monotonically increasing growth-promoting factor. This protocol indicated, in their words, that “mean site index over the 94 plots consistently increased at each remeasurement period,” which would suggest, as they phrase it, that “loblolly pine plantations are realizing greater than expected growth rates,” and, we would add, that the growth rate increases are growing larger and larger with each succeeding three-year period.

As for what might be causing the monotonically increasing growth rates of loblolly pine trees over the entire southeastern region of the United States, the two researchers say that in addition to rising atmospheric CO<sub>2</sub> concentrations, “two other likely factors that could affect growth are temperature and precipitation.” However, they report that a review of annual precipitation amounts and mean ground surface temperatures showed no trends in these factors over the period of their study. They also suggest that if increased nitrogen deposition were the cause, “such a factor would have to be acting on a regional scale to produce growth increases over the range of study plots.” Hence, they are partial to the aerial fertilization effect of atmospheric CO<sub>2</sub> enrichment as the explanation. What is more, they note that “similar results were reported by Boyer (2001) for natural stands of longleaf pine, where increases in dominant stand height are occurring over generations on the same site.”

The studies reported here indicate that as the CO<sub>2</sub> content of the air continues to rise, loblolly pine trees will likely experience significant increases in biomass production, even on nutrient-poor soils, during times of drought, and in competition with weeds.

#### 7.1.2.9.2. Ponderosa

Walker *et al.* (1998b) grew seedlings of Ponderosa pine (*Pinus ponderosa* Dougl. ex P. Laws & C. Laws) for an entire year in controlled environment chambers with atmospheric CO<sub>2</sub> concentrations of either 350 (ambient), 525, or 700 ppm. In addition, low or high levels of nitrogen and phosphorus were supplied to determine the main and interactive effects of atmospheric CO<sub>2</sub> enrichment and soil nutrition on seedling growth and fungal colonization of the seedlings' roots. After 12 months, they found that phosphorus supply had little impact on overall

seedling growth, while high nitrogen increased nearly every parameter measured, including root, shoot, and total biomass, as did atmospheric CO<sub>2</sub> enrichment. Averaged over all nitrogen and phosphate treatments, total root dry weights at 525 and 700 ppm CO<sub>2</sub> were 92 and 49 percent greater, respectively, than those observed at ambient CO<sub>2</sub>, while shoot dry weights were 83 and 26 percent greater. Consequently, seedlings grown at 525 and 700 ppm CO<sub>2</sub> had total dry weights that were 86 and 35 percent greater, respectively, than those measured at ambient CO<sub>2</sub>. In addition, elevated CO<sub>2</sub> increased the total number of ectomycorrhizal fungi on roots by 170 percent at 525 ppm CO<sub>2</sub> and 85 percent at 700 ppm CO<sub>2</sub> relative to the number observed at ambient CO<sub>2</sub>.

Walker *et al.* (1998a) grew Ponderosa pine seedlings for two growing seasons out-of-doors in open-top chambers having atmospheric CO<sub>2</sub> concentrations of 350, 525, and 700 ppm on soils of low, medium, and high nitrogen content to determine the interactive effects of these variables on juvenile tree growth. The elevated CO<sub>2</sub> concentrations had little effect on most growth parameters after the first growing season, with the one exception of below-ground biomass, which increased with both CO<sub>2</sub> and soil nitrogen. After two growing seasons, however, elevated CO<sub>2</sub> significantly increased all growth parameters, including tree height, stem diameter, shoot weight, stem volume, and root volume, with the greatest responses typically occurring at the highest CO<sub>2</sub> concentration in the highest soil nitrogen treatment. Root volume at 700 ppm CO<sub>2</sub> and high soil nitrogen, for example, exceeded that of all other treatments by at least 45 percent, as did shoot volume by 42 percent. Similarly, at high CO<sub>2</sub> and soil nitrogen coarse root and shoot weights exceeded those at ambient CO<sub>2</sub> and high nitrogen by 80 and 88 percent, respectively.

Johnson *et al.* (1998) reviewed 11 of their previously published papers (including the two discussed above) in which they describe the results of a series of greenhouse and open-top chamber studies of the growth responses of Ponderosa pine seedlings to a range of atmospheric CO<sub>2</sub> and soil nitrogen concentrations. These studies indicated that when soil nitrogen levels were so low as to be extremely deficient, or so high as to be toxic, growth responses to atmospheric CO<sub>2</sub> enrichment were negligible. For moderate soil nitrogen deficiencies, however, a doubling of the air's CO<sub>2</sub> content sometimes boosted growth by as much as 1,000 percent. In addition, atmospheric CO<sub>2</sub> enrichment mitigated the negative

growth response of ponderosa pine to extremely high soil nitrogen in two separate studies.

Maherali and DeLucia (2000) grew Ponderosa pine seedlings for six months in controlled environment chambers maintained at atmospheric CO<sub>2</sub> concentrations ranging from 350 to 1,100 ppm, while they were subjected to either low (15/25°C night/day) or high (20/30°C night/day) temperatures. This study revealed that although elevated CO<sub>2</sub> had no significant effect on stomatal conductance, seedlings grown in the high temperature treatment exhibited a 15 percent increase in this parameter relative to seedlings grown in the low temperature treatment. Similarly, specific hydraulic conductivity, which is a measure of the amount of water moving through a plant relative to its leaf or needle area, also increased in the seedlings exposed to the high temperature treatment. In addition, biomass production rose by 42 percent in the low temperature treatment and 62 percent in the high temperature treatment when the atmospheric CO<sub>2</sub> concentration was raised from 350 to 1,100 ppm.

Tingey *et al.* (2005) studied the effects of atmospheric CO<sub>2</sub> enrichment (to approximately 350 ppm above ambient) on the fine-root architecture of Ponderosa pine seedlings growing in open-top chambers via minirhizotron tubes over a period of four years. This experiment showed that “elevated CO<sub>2</sub> increased both fine root extensity (degree of soil exploration) and intensity (extent that roots use explored areas) but had no effect on mycorrhizae,” the latter of which observations was presumed to be due to the fact that soil nitrogen was not limiting to growth in this study. More specifically, they report that “extensity increased 1.5- to 2-fold in elevated CO<sub>2</sub> while intensity increased only 20 percent or less,” noting that similar extensity results had been obtained over shorter periods of four months to two years by Arnone (1997), Berntson and Bazzaz (1998), DeLucia *et al.* (1997) and Runion *et al.* (1997), while similar intensity results had been obtained by Berntson (1994).

Last, Soule and Knapp (2006) studied Ponderosa pine trees growing naturally at eight sites within the Pacific Northwest of the United States, in order to see how they may have responded to the increase in the atmosphere’s CO<sub>2</sub> concentration that occurred after 1950. In selecting these sites, they chose locations that “fit several criteria designed to limit potential confounding influences associated with anthropogenic disturbance.” They also say they selected locations with “a variety of climatic and

topoedaphic conditions, ranging from extremely water-limiting environments ... to areas where soil moisture should be a limiting factor for growth only during extreme drought years,” additionally noting that all sites were located in areas “where ozone concentrations and nitrogen deposition are typically low.”

At each of the eight sites that met all of these criteria, Soule and Knapp obtained core samples from about 40 mature trees that included “the potentially oldest trees on each site,” so that their results would indicate, as they put it, “the response of mature, naturally occurring ponderosa pine trees that germinated before anthropogenically elevated CO<sub>2</sub> levels, but where growth, particularly post-1950, has occurred under increasing and substantially higher atmospheric CO<sub>2</sub> concentrations.” Utilizing meteorological evaluations of the Palmer Drought Severity Index, they thus compared ponderosa pine radial growth rates during matched wet and dry years pre- and post-1950.

So what did they find? Overall, the two researchers report finding a post-1950 radial growth enhancement that was “more pronounced during drought years compared with wet years, and the greatest response occurred at the most stressed site.” As for the magnitude of the response, they determined that “the relative change in growth [was] upward at seven of our [eight] sites, ranging from 11 to 133%.”

With respect to the meaning and significance of their observations, Soule and Knapp say their results “showing that radial growth has increased in the post-1950s period ... while climatic conditions have generally been unchanged, suggest that nonclimatic driving forces are operative.” In addition, they say that “these radial growth responses are generally consistent with what has been shown in long-term open-top chamber (Idso and Kimball, 2001) and FACE studies (Ainsworth and Long, 2005).” Hence, they say their findings suggest that “elevated levels of atmospheric CO<sub>2</sub> are acting as a driving force for increased radial growth of ponderosa pine, but that the overall influence of this effect may be enhanced, reduced or obviated by site-specific conditions.”

Summarizing their findings Soule and Knapp recount how they had “hypothesized that ponderosa pine ... would respond to gradual increases in atmospheric CO<sub>2</sub> over the past 50 years, and that these effects would be most apparent during drought stress and on environmentally harsh sites,” and they state in their very next sentence that their results “support these hypotheses.” Hence, they conclude

their paper by stating it is likely that “an atmospheric CO<sub>2</sub>-driven growth-enhancement effect exists for ponderosa pine growing under specific natural conditions within the [USA’s] interior Pacific Northwest.”

### 7.1.2.9.3. Scots

Rouhier and Read (1998) grew seedlings of Scots pine (*Pinus sylvestris* L.) for four months in growth cabinets maintained at atmospheric CO<sub>2</sub> concentrations of either 350 or 700 ppm. In addition, one-third of the seedlings were inoculated with one species of mycorrhizal fungi, one-third were inoculated with another species, and one-third were not inoculated at all, in order to determine the effects of elevated CO<sub>2</sub> on mycorrhizal fungi and their interactive effects on seedling growth. These procedures resulted in the doubled atmospheric CO<sub>2</sub> content increasing seedling dry mass by an average of 45 percent regardless of fungal inoculation. In addition, the extra CO<sub>2</sub> increased the number of hyphal tips associated with seedling roots by about 62 percent for both fungal species. Hyphal growth was also accelerated by elevated CO<sub>2</sub>; after 55 days of treatment, the mycorrhizal network produced by one of the fungal symbionts occupied 444 percent more area than its counterpart exposed to ambient CO<sub>2</sub>.

These results suggest that as the air’s CO<sub>2</sub> content continues to rise, fungal symbionts of Scots pine will likely receive greater allocations of carbon from their host. This carbon can be used to increase their mycorrhizal networks, which would enable the fungi to explore greater volumes of soil in search of minerals and nutrients to benefit the growth of its host. In addition, by receiving greater allocations of carbon, fungal symbionts may keep photosynthetic down regulation from occurring, as they provide an additional sink for leaf-produced carbohydrates.

Janssens *et al.* (1998) grew three-year-old Scots pine seedlings in open-top chambers kept at ambient and 700 ppm atmospheric CO<sub>2</sub> concentrations for six months while they studied the effects of elevated CO<sub>2</sub> on root growth and respiration. In doing so, they learned that the elevated CO<sub>2</sub> treatment significantly increased total root length by 122 percent and dry mass by 135 percent relative to the roots of seedlings grown in ambient-CO<sub>2</sub> air. In addition, although starch accumulation in the CO<sub>2</sub>-enriched roots was nearly 90 percent greater than that observed in the roots produced in the ambient-CO<sub>2</sub> treatment, the carbon-to-nitrogen ratio of the CO<sub>2</sub>-enriched roots was significantly *lower* than that of the control-plant roots, indicative of the fact that they contained an even greater relative abundance of nitrogen. The most important implication of this study, therefore, was that Scots pine seedlings will likely be able to find the nitrogen they need to sustain large growth responses to atmospheric CO<sub>2</sub> enrichment with the huge root systems they typically produce in CO<sub>2</sub>-enriched air.

Kainulainen *et al.* (1998) constructed open-top chambers around Scots pine trees that were about 20 years old and fumigated them with combinations of ambient or CO<sub>2</sub>-enriched air (645 ppm) and ambient or twice-ambient (20 to 40 ppb) ozone-enriched air for three growing seasons to study the interactive effects of these gases on starch and secondary metabolite production. In doing so, they determined that elevated CO<sub>2</sub> and O<sub>3</sub> (ozone) had no significant impact on starch production in Scots pine, even after two years of treatment exposure. However, near the end of the third year, the elevated CO<sub>2</sub> alone significantly enhanced starch production in current-year needles, although neither extra CO<sub>2</sub>, extra O<sub>3</sub>, nor combinations thereof had any significant effects on the concentrations of secondary metabolites they investigated.

Kellomaki and Wang (1998) constructed closed-top chambers around 30-year-old Scots pine trees, which they fumigated with air containing either 350 or 700 ppm CO<sub>2</sub> at ambient and elevated (ambient plus 4°C) air temperatures for one full year, after which they assessed tree water-use by measuring cumulative sap flow for 32 additional days. This protocol revealed that the CO<sub>2</sub>-enriched air reduced cumulative sap flow by 14 percent at ambient air temperatures, but that sap flow was unaffected by atmospheric CO<sub>2</sub> concentration in the trees growing at the elevated air temperatures. These findings suggest that cumulative water-use by Scots pine trees in a

CO<sub>2</sub>-enriched world of the future will likely be less than or equal to—but no more than—what it is today.

Seven years later, Wang *et al.* (2005) published a report of a study in which they measured sap flow, crown structure, and microclimatic parameters in order to calculate the transpiration rates of individual 30-year-old Scots pine trees that were maintained for a period of *three* years in ambient air and air enriched with an extra 350 ppm of CO<sub>2</sub> and/or warmed by 2° to 6°C in closed-top chambers constructed within a naturally seeded stand of the trees. As they describe it, the results of this experiment indicated that “(i) elevated CO<sub>2</sub> significantly enhanced whole-tree transpiration rate during the first measuring year [by 14%] due to a large increase in whole-tree foliage area, 1998, but reduced it in the subsequent years of 1999 and 2000 [by 13% and 16%, respectively] as a consequence of a greater decrease in crown conductance which off-set the increase in foliage area per tree; (ii) trees growing in elevated temperature always had higher sap flow rates throughout three measuring years [by 54%, 45% and 57%, respectively]; and (iii) the response of sap flow to the combination of elevated temperature and CO<sub>2</sub> was similar to that of elevated temperature alone, indicating a dominant role for temperature and a lack of interaction between elevated CO<sub>2</sub> and temperature.” These observations suggest that as the air’s CO<sub>2</sub> content continues to rise, we probably can expect to see a decrease in evaporative water loss rates from naturally occurring stands of Scots pine trees ... unless there is a large concurrent increase in air temperature.

Also working with closed-top chambers that were constructed around 20-year-old Scots pines and fumigated with air containing 350 and 700 ppm CO<sub>2</sub> at ambient and elevated (ambient plus 4°C) air temperatures for a period of three years were Peltola *et al.* (2002), who studied the effects of elevated CO<sub>2</sub> and air temperature on stem growth in this coniferous species when it was growing on a soil low in nitrogen. After three years of treatment, they found that cumulative stem diameter growth in the CO<sub>2</sub>-enriched trees growing at ambient air temperatures was 57 percent greater than that displayed by control trees growing at ambient CO<sub>2</sub> and ambient air temperatures, while the trees exposed to elevated CO<sub>2</sub> *and* elevated air temperature exhibited cumulative stem-diameter growth that was 67 percent greater than that displayed by trees exposed to ambient-CO<sub>2</sub> air and ambient air temperatures. Consequently, as the air’s CO<sub>2</sub> content continues to rise, Scots pine trees

will likely respond by increasing stem-diameter growth, even if growing on soils low in nitrogen, and even if air temperatures rise by as much as 4°C.

In a somewhat different type of study, Kainulainen *et al.* (2003) collected needle litter beneath 22-year-old Scots pines that had been growing for the prior three years in open-top chambers that had been maintained at atmospheric CO<sub>2</sub> concentrations of 350 and 600 ppm in combination with ambient and elevated (approximately 1.4 x ambient) ozone concentrations to determine the impacts of these variables on the subsequent decomposition of senesced needles. This they did by enclosing the needles in litterbags and placing the bags within a native litter layer in a Scots pine forest, where decomposition rates were assessed by measuring accumulated litterbag mass loss over a period of 19 months. Interestingly, the three researchers found that exposure to elevated CO<sub>2</sub> during growth did *not* affect subsequent rates of needle decomposition, nor did elevated O<sub>3</sub> exposure affect decomposition, nor did exposure to elevated concentrations of the two gases together affect it.

Finally, Bergh *et al.* (2003) used a boreal version of the process-based BIOMASS simulation model to quantify the individual and combined effects of elevated air temperature (2° and 4°C above ambient) and CO<sub>2</sub> concentration (350 ppm above ambient) on the net primary production (NPP) of Scots pine forests growing in Denmark, Finland, Iceland, Norway, and Sweden. This work revealed that air temperature increases of 2° and 4°C led to mean NPP increases of 11 and 20 percent, respectively. However, when the air's CO<sub>2</sub> concentration was simultaneously increased from 350 to 700 ppm, the corresponding mean NPP increases rose to 41 and 55 percent. Last, when the air's CO<sub>2</sub> content was doubled at the prevailing ambient temperature, the mean value of the NPP rose by 27 percent. Consequently, as the air's CO<sub>2</sub> content continues to rise, Ponderosa pines of Denmark, Finland, Iceland, Norway, and Sweden should grow ever more productively; and if air temperature also rises, they will likely grow better still.

Given the above results, as the air's CO<sub>2</sub> content continues to rise, we can expect to see the root systems of Scots pines significantly enhanced, together with the mycorrhizal fungal networks that live in close association with them and help secure the nutrients the trees need to sustain large CO<sub>2</sub>-induced increases in biomass production. Concurrently, we can expect to see much smaller changes in total

evaporative water loss, which means that whole-tree water use efficiency should also be significantly enhanced.

## 7.1.2.10. Spruce

Several studies have recently documented the effects of elevated CO<sub>2</sub> on photosynthesis in various varieties of spruce (genus *Picea*). In the relatively short-term study of Tjoelker *et al.* (1998a), black spruce (*Picea mariana*) seedlings grown for three months at atmospheric CO<sub>2</sub> concentrations of 580 ppm exhibited photosynthetic rates that were about 28 percent greater than those displayed by control seedlings fumigated with air containing 370 ppm CO<sub>2</sub>. Similarly, Egli *et al.* (1998) reported that Norway spruce (*Picea abies*) seedlings grown at 570 ppm CO<sub>2</sub> displayed photosynthetic rates that were 35 percent greater than those exhibited by seedlings grown at 370 ppm. In two branch bag studies conducted on mature trees, it was demonstrated that twice-ambient levels of atmospheric CO<sub>2</sub> enhanced rates of photosynthesis in current-year needles by 50 percent in Norway spruce (Roberntz and Stockfors, 1998) and 100 percent in Sitka spruce (*Picea sitchensis*) (Barton and Jarvis, 1999). Finally, in the four-year open-top chamber study of Murray *et al.* (2000), the authors reported that Sitka spruce seedlings growing at 700 ppm CO<sub>2</sub> exhibited photosynthetic rates that were 19 and 33 percent greater than those observed in control trees growing in ambient air and receiving low and high amounts of nitrogen fertilization, respectively.

Because elevated CO<sub>2</sub> enhances photosynthetic rates in spruce species, this phenomenon should lead to increased biomass production in these important coniferous trees. In the short-term three-month study of Tjoelker *et al.* (1998b), for example, black spruce seedlings receiving an extra 210 ppm CO<sub>2</sub> displayed final dry weights that were about 20 percent greater than those of seedlings growing at ambient CO<sub>2</sub>. Similarly, after growing Sitka spruce for three years in open-top chambers, Centritto *et al.* (1999) reported that a doubling of the atmospheric CO<sub>2</sub> concentration enhanced sapling dry mass by 42 percent.

In summary, it is clear that as the CO<sub>2</sub> content of the air increases, spruce trees will likely display enhanced rates of photosynthesis and biomass production, regardless of soil nutrient status. Consequently, rates of carbon sequestration by this abundant coniferous forest species will likely be enhanced.

Additional information on this topic, including reviews of newer publications as they become available, can be found at <http://www.co2science.org/subject/t/treesspruce.php>.

## 7.1.2.11. Tropical

Several studies have recently documented the effects of elevated atmospheric CO<sub>2</sub> concentrations on photosynthesis in various tropical and sub-tropical trees. In the relatively short-term study of Lovelock *et al.* (1999a), for example, seedlings of the tropical tree *Copaifera aromatica* that were grown for two months at an atmospheric CO<sub>2</sub> concentration of 860 ppm exhibited photosynthetic rates that were consistently 50-100 percent greater than those displayed by control seedlings fumigated with air containing 390 ppm CO<sub>2</sub>. Similarly, Lovelock *et al.* (1999b) reported that a 10-month 390-ppm increase in the air's CO<sub>2</sub> content boosted rates of net photosynthesis in 30-m tall *Luehea seemannii* trees by 30 percent. Likewise, in the review paper of Schaffer *et al.* (1999), it was

noted that atmospheric CO<sub>2</sub> enrichment had previously been shown to enhance rates of net photosynthesis in a number of tropical and sub-tropical fruit trees, including avocado, banana, citrus, mango, and mangosteen. Even at the ecosystem level, Lin *et al.* (1998) found that a 1,700-m<sup>2</sup> synthetic rainforest mesocosm displayed a 79 percent enhancement in net ecosystem carbon exchange rate in response to a 72 percent increase in the air's CO<sub>2</sub> content.

Because elevated CO<sub>2</sub> enhances photosynthetic rates in tropical and sub-tropical trees, it should also lead to increased carbohydrate and biomass production in these species. At a tropical forest research site in Panama, twice-ambient CO<sub>2</sub> concentrations enhanced foliar sugar concentrations by up to 30 percent (Wurth *et al.*, 1998), while doubling the foliar concentrations of starch (Lovelock *et al.*, 1998) in a number of tree species. Also, in the study of Hoffmann *et al.* (2000), elevated CO<sub>2</sub> (700 ppm) enhanced dry weights of an "uncut" Brazilian savannah tree species (*Keilmeyera coriacea*) by about 50 percent, while it enhanced the dry weight of the same "cut" species by nearly 300 percent. Although not specifically quantified, Schaffer *et al.* (1997) noted that twice-ambient CO<sub>2</sub> exposure for one year obviously enhanced dry mass production in two mango ecotypes. Finally, in the six-month study of Sheu *et al.* (1999), a doubling of the atmospheric CO<sub>2</sub> concentration increased seedling dry weight in *Schima superba* by 14 and 49 percent when grown at ambient and elevated (5°C above ambient) air temperatures, respectively.

It is clear that as the air's CO<sub>2</sub> content rises, tropical and sub-tropical trees will likely display enhanced rates of photosynthesis and biomass production, even under conditions of herbivory and elevated air temperature. Consequently, greater carbon sequestration will also likely occur within earth's tropical and sub-tropical forests as ever more CO<sub>2</sub> accumulates in the atmosphere.

### 7.1.2.12. Wood Density

Numerous experiments have demonstrated that trees grown in air enriched with CO<sub>2</sub> nearly always sequester more biomass in their trunks and branches than do trees grown in ambient air. Several studies also have looked at the effects of elevated CO<sub>2</sub> on the density of that sequestered biomass.

Rogers *et al.* (1983) observed no difference in the wood density of loblolly pine (*Pinus taeda*) trees grown at 340 and 718 ppm CO<sub>2</sub> for 10 weeks; but they found a 33 percent CO<sub>2</sub>-induced increase in the wood density of sweetgum (*Liquidambar styraciflua*) trees that were grown at these concentrations for only eight weeks. Doyle (1987) and Telewski and Strain

(1987) studied the same two tree species over three growing seasons in air of 350 and 650 ppm CO<sub>2</sub>, finding no effect of atmospheric CO<sub>2</sub> enrichment on the stem density of sweetgum, but a mean increase of 9 percent in the stem density of loblolly pine.

Conroy *et al.* (1990) grew seedlings of two *Pinus radiata* families at 340 and 660 ppm CO<sub>2</sub> for 114 weeks, finding CO<sub>2</sub>-induced trunk density increases for the two families of 5.4 and 5.6 percent when soil phosphorus was less than adequate and increases of 5.6 and 1.2 percent when it was non-limiting. In a similar study, Hattenschwiler *et al.* (1996) grew six genotypes of clonally propagated four-year-old Norway spruce (*Picea abies*) for three years at CO<sub>2</sub> concentrations of 280, 420, and 560 ppm at three different rates of wet nitrogen deposition. On average, they found that wood density was 12 percent greater in the trees grown at the two higher CO<sub>2</sub> concentrations than it was in the trees grown at 280 ppm.

Norby *et al.* (1996) grew yellow poplar or “tulip” trees (*Liriodendron tulipifera*) at ambient and ambient plus 300 ppm CO<sub>2</sub> for three years, during which time the wood density of the trees increased by approximately 7 percent. Tognetti *et al.* (1998) studied two species of oak tree—one deciduous (*Quercus pubescens*) and one evergreen (*Quercus ilex*)—growing in the vicinity of CO<sub>2</sub> springs in central Italy that raised the CO<sub>2</sub> concentration of the surrounding air by approximately 385 ppm. This increase in the air’s CO<sub>2</sub> content increased the wood density of the deciduous oaks by 4.2 percent and that of the evergreen oaks by 6.4 percent.

Telewski *et al.* (1999) grew loblolly pine trees for four years at ambient and ambient plus 300 ppm CO<sub>2</sub>. In their study, wood density determined directly from mass and volume measurements was increased by 15 percent by the extra CO<sub>2</sub>; average ring density determined by X-ray densitometry was increased by 4.5 percent.

Beismann *et al.* (2002) grew different genotypes of spruce and beech (*Fagus sylvatica*) seedlings for four years in open-top chambers maintained at atmospheric CO<sub>2</sub> concentrations of 370 and 590 ppm in combination with low and high levels of wet nitrogen application on both rich calcareous and poor acidic soils to study the effects of these factors on seedling toughness (fracture characteristics) and rigidity (bending characteristics such as modulus of elasticity). They found that some genotypes of each species were sensitive to elevated CO<sub>2</sub>, while others were not. Similarly, some were responsive to elevated

nitrogen deposition, while others were not. Moreover, such responses were often dependent upon soil type. Averaged across all tested genotypes, however, atmospheric CO<sub>2</sub> enrichment increased wood toughness in spruce seedlings grown on acidic soils by 12 and 18 percent at low and high levels of nitrogen deposition, respectively. In addition, atmospheric CO<sub>2</sub> enrichment increased this same wood property in spruce seedlings grown on calcareous soils by about 17 and 14 percent with low and high levels of nitrogen deposition, respectively. By contrast, elevated CO<sub>2</sub> had no significant effects on the mechanical wood properties of beech seedlings, regardless of soil type.

Finally, Kilpelainen *et al.* (2003) erected 16 open-top chambers within a 15-year-old stand of Scots pines growing on a nutrient-poor sandy soil of low nitrogen content near the Mekrijärvi Research Station of the University of Joensuu, Finland. Over the next three years they maintained the trees within these chambers in a well-watered condition, while they enriched the air in half of the chambers to a mean daytime CO<sub>2</sub> concentration of approximately 580 ppm and maintained the air in half of each of the two CO<sub>2</sub> treatments at 2°C above ambient. In the ambient temperature treatment the 60 percent increase in the air’s CO<sub>2</sub> concentration increased latewood density by 27 percent and maximum wood density by 11 percent, while in the elevated-temperature treatment it increased latewood density by 25 percent and maximum wood density by 15 percent. These changes led to mean overall CO<sub>2</sub>-induced wood density increases of 2.8 percent in the ambient-temperature treatment and 5.6 percent in the elevated-temperature treatment.

In light of these several observations, it is clear that different species of trees respond differently to atmospheric CO<sub>2</sub> enrichment, and that they respond with still greater variety under different sets of environmental conditions. In general, however, atmospheric CO<sub>2</sub> enrichment tends to increase wood density in both seedlings and mature trees more often than not, thereby also increasing a number of strength properties of their branches and trunks.

Additional information on this topic, including reviews of newer publications as they become available, can be found at <http://www.co2science.org/subject/w/wooddensity.php>.

## 7.1.2.13. Forests

Forests contain perennial trees that remove CO<sub>2</sub> from the atmosphere during photosynthesis and store its carbon within their woody tissues for decades to periods sometimes in excess of a thousand years. Thus, it is important to understand how increases in the air's CO<sub>2</sub> content affect forest productivity and carbon sequestration, which has a great effect on the rate of rise of the air's CO<sub>2</sub> concentration. In this summary, we review several recent scientific publications pertaining to these subjects.

By examining various properties of tree rings, researchers can deduce how historical increases in the air's CO<sub>2</sub> concentration have already affected tree productivity and water use efficiency. Duquesnay *et al.* (1998), for example, analyzed the relative amounts of <sup>12</sup>C and <sup>13</sup>C present in yearly growth rings of beech trees raised in silviculture regimes in northeastern France, determining that their intrinsic water use efficiencies rose by approximately 33 percent during the past century, as the air's CO<sub>2</sub> concentration rose from approximately 280 to 360 ppm. In another case, Rathgeber *et al.* (2000) used tree-ring density data to create a historical productivity baseline for forest stands of *Pinus halepensis* in southeastern France, from which they determined that the net productivity of such forests would increase by 8 to 55 percent with a doubling of the air's CO<sub>2</sub> content. Finally, when running a forest growth model based on empirical observations reported in the literature, Lloyd (1999) determined that the rise in the atmospheric CO<sub>2</sub> concentration since the onset of the Industrial Revolution likely increased the net primary productivity of mature temperate deciduous forests by about 7 percent. In addition, he determined that a proportional increase in anthropogenic nitrogen deposition likely increased forest net primary productivity by 25 percent. And when he combined the two effects, the net primary productivity stimulation rose to 40 percent, which is more than the sum of the individual growth enhancements resulting from the increases in CO<sub>2</sub> and nitrogen.

The results of these studies demonstrate that historic increases in the air's CO<sub>2</sub> content have already conferred great benefits upon earth's forests. But will future increases in the air's CO<sub>2</sub> concentration continue to do so? Several research teams have embarked on long-term studies of various forest communities in an attempt to address this important question. What follows are some important

observations that have been made from their mostly ongoing CO<sub>2</sub>-enrichment studies.

In 1996, circular FACE plots (30-m diameter) receiving atmospheric CO<sub>2</sub> concentrations of 360 and 560 ppm were established in a 15-year-old loblolly pine (*Pinus taeda*) plantation in North Carolina, USA, to study the effects of elevated CO<sub>2</sub> on the growth and productivity of this particular forest community, which also had several hardwood species present in the understory beneath the primary coniferous canopy. Using this experimental set-up as a platform for several experiments, Hymus *et al.* (1999) reported that net photosynthetic rates of CO<sub>2</sub>-enriched loblolly pine trees were 65 percent greater than rates observed in control trees exposed to ambient air. These greater rates of carbon fixation contributed to the 24 percent greater growth rates observed in the CO<sub>2</sub>-enriched pine trees in the first year of this long-term study (Naidu and DeLucia 1999). In addition, DeLucia and Thomas (2000) reported that the elevated CO<sub>2</sub> increased rates of net photosynthesis by 50 to 160 percent in four subdominant hardwood species present in the forest understory. Moreover, for one species—sweetgum (*Liquidambar styraciflua*)—the extra CO<sub>2</sub> enhanced rates of net photosynthesis in sun and shade leaves by 166 and 68 percent, respectively, even when the trees were naturally subjected to summer seasonal stresses imposed by high temperature and low soil water availability. Consequently, after two years of atmospheric CO<sub>2</sub> enrichment, total ecosystem net primary productivity in the CO<sub>2</sub>-enriched plots was 25 percent greater than that measured in control plots fumigated with ambient air.

In a similar large-scale study, circular (25-m diameter) FACE plots receiving atmospheric CO<sub>2</sub> concentrations of 400 and 530 ppm were constructed within a 10-year-old sweetgum plantation in Tennessee, USA, to study the effects of elevated CO<sub>2</sub> on the growth and productivity of this forest community. After two years of treatment, Norby *et al.* (2001) reported that the modest 35 percent increase in the air's CO<sub>2</sub> content boosted tree biomass production by an average of 24 percent. In addition, Wullschlegel and Norby (2001) noted that CO<sub>2</sub>-enriched trees displayed rates of transpirational water loss that were approximately 10 percent lower than those exhibited by control trees grown in ambient air. Consequently, elevated CO<sub>2</sub> enhanced seasonal water use efficiencies of these mature sweetgum trees by 28 to 35 percent.

On a smaller scale, Pritchard *et al.* (2001) constructed idealized ecosystems (containing five different species) representative of regenerating longleaf pine (*Pinus palustris* Mill.) communities of the southeastern USA, fumigating them for 18 months with air containing 365 and 720 ppm CO<sub>2</sub> to study the effects of elevated CO<sub>2</sub> on this forest community. They reported that elevated CO<sub>2</sub> increased the above- and below-ground biomass of the dominant longleaf pine individuals by 20 and 62 percent, respectively. At the ecosystem level, elevated CO<sub>2</sub> stimulated total above-ground biomass production by an average of 35 percent. Similar results for regenerating temperate forest communities have been reported by Berntson and Bazzaz (1998), who documented a 31 percent increase in Transition Hardwood-White Pine-Hemlock forest mesocosm biomass in response to two years of fumigation with twice-ambient concentrations of atmospheric CO<sub>2</sub>.

It is clear that as the air's CO<sub>2</sub> concentration continues to rise, forests will likely respond by exhibiting significant increases in total primary productivity and biomass production. Consequently, forests will likely grow much more robustly and significantly expand their ranges, as has already been documented in many parts of the world, including gallery forest in Kansas, USA (Knight *et al.*, 1994) and the Budal and Sjødal valleys in Norway (Olsson *et al.*, 2000). Such CO<sub>2</sub>-induced increases in growth and range expansion should result in large increases in global carbon sequestration within forests.

### 7.1.3. Aquatic Plants

We have shown how atmospheric CO<sub>2</sub> enrichment typically enhances the growth and productivity of nearly all terrestrial plants. But what about *aquatic* plants? In this section we seek to answer that question.

#### 7.1.3.1. Freshwater Algae

How do freshwater algae respond to increases in the air's CO<sub>2</sub> content? The subject has not been thoroughly researched, but the results of the studies discussed below provide a glimpse of what the future may hold as the atmosphere's CO<sub>2</sub> concentration continues its upward course.

Working with cells of the freshwater alga *Chlorella pyrenoidosa*, Xia and Gao (2003) cultured them in Bristol's solution within controlled environment chambers maintained at low and high light levels (50 and 200 μmol/m<sup>2</sup>/s) during 12-hour light periods that were followed by 12-hour dark periods for a total of 13 days, while the solutions in which the cells grew were continuously aerated with air of either 350 or 700 ppm CO<sub>2</sub>. When the cells were harvested (in the exponential growth phase) at the conclusion of this period, the biomass (cell density) of the twice-ambient CO<sub>2</sub> treatment was found to be 10.9 percent and 8.3 percent greater than that of the ambient-air treatment in the low- and high-light regimes, respectively, although only the high-light result was statistically significant. The two scientists concluded from these observations that a "doubled atmospheric CO<sub>2</sub> concentration would affect the growth of *C. pyrenoidosa* when it grows under bright solar radiation, and such an effect would increase by a great extent when the cell density becomes high." Their data also suggest the same may well be true when the alga grows under *not-so-bright* conditions.

Working on a much larger scale "in the field" with six 1.5-m-diameter flexible plastic cylinders placed in the littoral zone of Lake Hampen in central Jutland, Denmark (three maintained at the ambient CO<sub>2</sub> concentration of the air and three enriched to 10 times the ambient CO<sub>2</sub> concentration), Andersen and Andersen (2006) measured the CO<sub>2</sub>-induced growth response of a mixture of several species of filamentous freshwater algae dominated by *Zygnema* species, but containing some *Mougeotia* and *Spirogyra*. After one full growing season (May to November), they determined that the biomass of the microalgal mixture in the CO<sub>2</sub>-enriched cylinders was increased by 220 percent in early July, by 90 percent in mid-August, and by a whopping 3,750 percent in mid-November.

In another study of the subject, Schippers *et al.* (2004a) say "it is usually thought that unlike terrestrial plants, phytoplankton will not show a significant response to an increase of atmospheric

CO<sub>2</sub>,” but they note, in this regard, that “most analyses have not examined the full dynamic interaction between phytoplankton production and assimilation, carbon-chemistry and the air-water flux of CO<sub>2</sub>,” and that “the effect of photosynthesis on pH and the dissociation of carbon (C) species have been neglected in most studies.”

In an attempt to rectify this situation, Schippers *et al.* developed “an integrated model of phytoplankton growth, air-water exchange and C chemistry to analyze the potential increase of phytoplankton productivity due to an atmospheric CO<sub>2</sub> elevation,” and as a test of their model, they let the freshwater alga *Chlamydomonas reinhardtii* grow in 300-ml bottles filled with 150 ml of a nutrient-rich medium at enclosed atmospheric CO<sub>2</sub> concentrations of 350 and 700 ppm that they maintained at two air-water exchange rates characterized by CO<sub>2</sub> exchange coefficients of 2.1 and 5.1 m day<sup>-1</sup>, as described by Shippers *et al.* (2004b), while periodically measuring the biovolume of the solutions by means of an electronic particle counter. The results of this effort, as they describe it, “confirm the theoretical prediction that if algal effects on C chemistry are strong, increased phytoplankton productivity because of atmospheric CO<sub>2</sub> elevation should become proportional to the increased atmospheric CO<sub>2</sub>,” which suggests that algal productivity “would double at the predicted increase of atmospheric CO<sub>2</sub> to 700 ppm.” Although they note that “strong algal effects (resulting in high pH levels) at which this occurs are rare under natural conditions,” they still predict that effects on algal production in freshwater systems could be such that a “doubling of atmospheric CO<sub>2</sub> may result in an increase of the productivity of more than 50%.”

In the last of the few papers we have reviewed in this area, Logothetis *et al.* (2004) note that “the function and structure of the photosynthetic apparatus of many algal species resembles that of higher plants (Plumley and Smidt, 1984; Brown, 1988; Plumley *et al.*, 1993),” and that “unicellular green algae demonstrate responses to increased CO<sub>2</sub> similar to those of higher plants in terms of biomass increases (Muller *et al.*, 1993).” However, they also note that “little is known about the changes to their photosynthetic apparatus during exposure to high CO<sub>2</sub>,” which deficiency they began to correct via a new experiment, wherein batches of the unicellular green alga *Scenedesmus obliquus* (wild type strain D3) were grown autotrophically in liquid culture medium for several days in a temperature-controlled

water bath of 30°C at low (55 μmol m<sup>-2</sup> s<sup>-1</sup>) and high (235 μmol m<sup>-2</sup> s<sup>-1</sup>) light intensity while they were continuously aerated with air of either 300 or 100,000 ppm CO<sub>2</sub>. This protocol revealed that exposure to the latter high CO<sub>2</sub> concentration produces, in their words, a “reorganization of the photosynthetic apparatus” that “leads to enhanced photosynthetic rates, which ... leads to an immense increase of biomass.” After five days under low light conditions, for example, the CO<sub>2</sub>-induced increase in biomass was approximately 300 percent, while under high light conditions it was approximately 600 percent.

Based on these few observations, it is not possible to draw any sweeping conclusions about the subject. However, they do indicate there may be a real potential for the ongoing rise in the air’s CO<sub>2</sub> content to significantly stimulate the productivity of this freshwater contingent of earth’s plants.

Additional information on this topic, including reviews of newer publications as they become available, can be found at <http://www.co2science.org/subject/a/aquaticplants.php>.

### 7.1.3.2. Freshwater Macrophytes

In this section we discuss the findings of papers that investigate the influence of CO<sub>2</sub> concentrations as it applies to submersed, floating, and emergent freshwater macrophytes, beginning with studies of aquatic plants that live their lives totally submersed in freshwater environments.

For several multi-week periods, Idso (1997) grew specimens of corkscrew vallisneria (*Vallisneria spiralis*) in several 10- and 29-gallon glass tanks (containing 10-cm bottom-layers of common aquarium gravel) that were filled with tap water maintained within 0.5°C of either 18.2°C or 24.5°C, while the semi-sealed air spaces above these “Poor Man’s Biospheres,” as he christened them, were maintained at a number of different CO<sub>2</sub> concentrations. With the harvesting of plants at the end of the study, this protocol revealed that the CO<sub>2</sub>-induced growth enhancement of the plants was *linear* (in contrast to the gradually declining CO<sub>2</sub>-induced growth enhancements typically exhibited by most terrestrial plants as the air’s CO<sub>2</sub> content climbs ever higher), and that the linear relationship extended to the highest atmospheric CO<sub>2</sub> concentration studied: 2,100 ppm. In addition, he found that the CO<sub>2</sub>-induced growth increase experienced by the plants in the higher of the two water temperature treatments (a 128 percent increase in going from an atmospheric CO<sub>2</sub> concentration of 365 ppm to one of 2,100 ppm) was 3.5 times greater than that of the plants in the lower water temperature treatment. Although this response may seem rather dramatic, it is not unique; Idso reports that Titus *et al.* (1990), who studied the closely related *Vallisneria spiralis*, “observed that the biomass of their experimental plants also rose linearly with the CO<sub>2</sub> content of the air above the water within which they grew, and that [it] did so

from the value of the [then] current global mean (365 ppm) to a concentration fully ten times larger.”

In another study of a closely allied species, Yan *et al.* (2006) collected turions of *Vallisneria spiralis* from Liangzi Lake, Hubei Province, China, and planted them in tanks containing 15-cm-deep layers of fertile lake sediments, topped with 40 cm of lake water, that were placed in two glasshouses—one maintained at the ambient atmospheric CO<sub>2</sub> concentration of 390 ppm and the other maintained at an elevated concentration of 1,000 ppm—where the plants grew for a period of 120 days, after which they were harvested and the dry weights of their various organs determined. As they describe it, this work indicated that the “total biomass accumulation of plants grown in the elevated CO<sub>2</sub> was 2.3 times that of plants grown in ambient CO<sub>2</sub>, with biomass of leaves, roots and rhizomes increasing by 106%, 183% and 67%, respectively.” Most spectacularly of all, they report that “turion biomass increased 4.5-fold,” because “the mean turion numbers per ramet and mean biomass per turion in elevated CO<sub>2</sub> were 1.7-4.3 and 1.9-3.4 times those in ambient CO<sub>2</sub>.”

In Denmark, in a study of small slow-growing evergreen perennials called *isoetids* that live submersed along the shores of numerous freshwater lakes, Andersen *et al.* (2006) grew specimens of *Littorella uniflora* in sediment cores removed from Lake Hampen in 75-liter tanks with 10-cm overburdens of filtered lake water for a period of 53 days, while measuring various plant, water, and sediment properties, after which they destructively harvested the plants and measured their biomass. Throughout this period, half of the tanks had ambient air bubbled through their waters, while the other half were similarly exposed to a mixture of ambient air and pure CO<sub>2</sub> that produced a 10-fold increase in the air’s CO<sub>2</sub> concentration. This ultra-CO<sub>2</sub>-enrichment led to a 30 percent increase in plant biomass, as well as “higher O<sub>2</sub> release to the sediment which is important for the cycling and retention of nutrients in sediments of oligotrophic softwater lakes.” And when the ultra-CO<sub>2</sub>-enrichment was maintained for an entire growing season (May-November), Andersen and Andersen (2006) report that the 10-fold increase in aquatic CO<sub>2</sub> concentration enhanced the biomass production of *Littorella uniflora* by a much larger 78 percent.

In a study of an “in-between” type of plant that has submersed roots and rhizomes that are anchored in water-body sediments, but which has floating leaves on the surface of the water and emergent

flowers that protrude above the water surface, Idso *et al.* (1990) grew water lilies (*Nymphaea marliac*) for two consecutive years in sunken metal stock tanks located out-of-doors at Phoenix, Arizona (USA) and enclosed within clear-plastic-wall open-top chambers through which air of either 350 or 650 ppm CO<sub>2</sub> was continuously circulated. This work revealed that in addition to the leaves of the plants being larger in the CO<sub>2</sub>-enriched treatment, there were 75 percent more of them than there were in the ambient-air tanks at the conclusion of the initial five-month-long growing season. Each of the plants in the high-CO<sub>2</sub> tanks also produced twice as many flowers as the plants growing in ambient air; and the flowers that blossomed in the CO<sub>2</sub>-enriched air were more substantial than those that bloomed in the air of ambient CO<sub>2</sub> concentration: they had more petals, the petals were longer, and they had a greater percent dry matter content, such that each flower consequently weighed about 50 percent more than each flower in the ambient-air treatment. In addition, the stems that supported the flowers were slightly longer in the CO<sub>2</sub>-enriched tanks, and the percent dry matter contents of both the flower and leaf stems were greater, so that the total dry matter in the flower and leaf stems in the CO<sub>2</sub>-enriched tanks exceeded that of the flower and leaf stems in the ambient-air tanks by approximately 60 percent.

Just above the surface of the soil that covered the bottoms of the tanks, there were also noticeable differences. Plants in the CO<sub>2</sub>-enriched tanks had more and bigger basal rosette leaves, which were attached to longer stems of greater percent dry matter content, which led to the total biomass of these portions of the plants being 2.9 times greater than the total biomass of the corresponding portions of the plants in the ambient-air tanks. In addition, plants in the CO<sub>2</sub>-enriched tanks had more than twice as many unopened basal rosette leaves.

The greatest differences of all, however, were hidden within the soil that covered the bottoms of the stock tanks. When half of the plants were harvested at the conclusion of the first growing season, for example, the number of new rhizomes produced over that period was discovered to be 2.4 times greater in the CO<sub>2</sub>-enriched tanks than it was in the ambient-air tanks; the number of major roots produced there was found to be 3.2 times greater. As with all other plant parts, the percent dry matter contents of the new roots and rhizomes were also greater in the CO<sub>2</sub>-enriched tanks. Overall, therefore, the total dry matter production within the submerged soils of the water lily ecosystems was 4.3 times greater in the CO<sub>2</sub>-

enriched tanks than it was in the ambient-air tanks; the total dry matter production of all plant parts—those in the submerged soil, those in the free water, and those in the air above—was 3.7 times greater in the high-CO<sub>2</sub> enclosures.

Over the second growing season, the growth enhancement in the high-CO<sub>2</sub> tanks was somewhat less; but the plants in those tanks were so far ahead of the plants in the ambient-air tanks that in their first five months of growth, they produced what it took the plants in the ambient-air tanks fully 21 months to produce.

Moving on to plants that are exclusively floating freshwater macrophytes, Idso (1997) grew many batches of the common water fern (*Azolla pinnata*) over a wide range of atmospheric CO<sub>2</sub> concentrations at two different water temperatures (18.2°C and 24.5°C) in Poor Man's Biospheres for periods of several weeks. This work revealed that a 900-ppm increase in the CO<sub>2</sub> concentration of the air above the tanks led to only a 19 percent increase in the biomass production of the plants floating in the cooler water, but that it led to a 66 percent biomass increase in the plants floating in the warmer water.

In an earlier study of *Azolla pinnata*, Idso *et al.* (1989) conducted three separate two- to three-month experiments wherein they grew batches of the floating fern out-of-doors in adequately fertilized water contained in sunken metal stock tanks located within clear-plastic-wall open-top chambers that were continuously maintained at atmospheric CO<sub>2</sub> concentrations of either 340 or 640 ppm, during which time the plants were briefly removed from the water and weighed at weekly intervals, while their photosynthetic rates were measured at hourly intervals from dawn to dusk on selected cloudless days. As a result of this protocol, they found the photosynthetic and growth rates of the plants growing in ambient air “first decreased, then stagnated, and finally became negative when mean air temperature rose above 30°C.” In the high CO<sub>2</sub> treatment, on the other hand, they found that “the debilitating effects of high temperatures were reduced: in one case to a much less severe negative growth rate, in another case to merely a short period of zero growth rate, and in a third case to no discernible ill effects whatsoever—in spite of the fact that the ambient treatment plants in this instance all died.”

Last, in a study of an emergent freshwater macrophyte, Ojala *et al.* (2002) grew water horsetail (*Equisetum fluviatile*) plants at ambient and double-ambient atmospheric CO<sub>2</sub> concentrations and ambient

and ambient + 3°C air temperatures for three years, although the plants were subjected to the double-ambient CO<sub>2</sub> condition for only approximately five months of each year. This work revealed that the increase in air temperature boosted maximum shoot biomass by 60 percent, but the elevated CO<sub>2</sub> had no effect on this aspect of plant growth. However, elevated CO<sub>2</sub> and temperature—both singly and in combination—positively affected *root* growth, which was enhanced by 10, 15, and 25 percent by elevated air temperature, CO<sub>2</sub>, and the two factors together, respectively.

In light of the several experimental findings discussed above, we conclude that the ongoing rise in the air's CO<sub>2</sub> content will likely have significant positive impacts on most freshwater macrophytes, including submersed, floating, and emergent species.

### 7.1.3.3. Marine Macroalgae

How do marine macroalgae respond to increases in the air's CO<sub>2</sub> content? The results of the studies discussed below provide a glimpse of what the future may hold in this regard, as the atmosphere's CO<sub>2</sub> concentration continues its upward climb.

Gao *et al.* (1993) grew cultures of the red macroalgae *Gracilaria* sp. and *G. chilensis* in vessels enriched with nitrogen and phosphorus that were continuously aerated with normal air containing 350 ppm CO<sub>2</sub>, air enriched with an extra 650 ppm CO<sub>2</sub>, and air enriched with an extra 1,250 ppm CO<sub>2</sub> for a period of 19 days. Compared to the control treatments, the relative growth enhancements in the + 650-ppm and +1250-ppm CO<sub>2</sub> treatments were 20 percent and 60 percent, respectively, for *G. chilensis*, and 130 percent and 190 percent, respectively, for the *Gracilaria* sp.

With respect to these findings, the researchers comment that “in their natural habitats, photosynthesis and growth of *Gracilaria* species are likely to be CO<sub>2</sub>-limited, especially when the population density is high and water movement is slow.” Hence, as the air's CO<sub>2</sub> content continues to rise, these marine macroalgae should grow ever better in the years ahead. Such should also be the case with many other macroalgae, for Gao *et al.* note that “photosynthesis by most macroalgae is probably limited by inorganic carbon sources in natural seawater,” citing the studies of Surif and Raven (1989), Maberly (1990), Gao *et al.* (1991), and Levavasseur *et al.* (1991) as evidence for this statement.

In a subsequent study, Kubler *et al.* (1999) grew *Lomentaria articulata*, a red seaweed common to the Northeast Atlantic intertidal zone, for three weeks in hydroponic cultures subjected to various atmospheric CO<sub>2</sub> and O<sub>2</sub> concentrations. In doing so, they found that oxygen concentrations ranging from 10 to 200 percent of ambient had no significant effect on either the seaweed's daily net carbon gain or its total wet biomass production rate. By contrast, CO<sub>2</sub> concentrations ranging from 67 to 500 percent of ambient had highly significant effects on these parameters. At twice the ambient CO<sub>2</sub> concentration, for example, daily net carbon gain and total wet

biomass production rates were 52 and 314 percent greater than they were at ambient CO<sub>2</sub>.

More recently, Zou (2005) collected specimens of the brown seaweed *Hizikia fusiforme* from intertidal rocks along the coast of Nanao Island, Shantou, China, and maintained them in glass aquariums that contained filtered seawater enriched with 60 μM NaNO<sub>3</sub> and 6.0 μM NaH<sub>2</sub>PO<sub>4</sub>, while continuously aerating the aquariums with air of either 360 or 700 ppm CO<sub>2</sub> and periodically measuring seaweed growth and nitrogen assimilation rates, as well as nitrate reductase activities. By these means they determined that the slightly less than a doubling of the air's CO<sub>2</sub> concentration increased the seaweed's mean relative growth rate by about 50 percent, its mean rate of nitrate uptake during the study's 12-hour light periods by some 200 percent, and its nitrate reductase activity by approximately 20 percent over a wide range of substrate nitrate concentrations.
